ACKNOWLEDGMENTS

This update of Chapter 1 is based on the foundation developed in previous editions by Dr Ken Jubb and, more recently, Dr Nigel Palmer. It is an honor to follow in their footsteps. I am grateful to the many pathologists who have contributed illustrations to this chapter, in particular Dr Rob Fairley. Significant contributions have also come from the transparency collections of pathology departments at Ontario Veterinary College, Texas A&M University, Massey University, North Carolina State University, Ohio State University, University of California-Davis, and Western College of Veterinary Medicine.

Diseases of bones

GENERAL CONSIDERATIONS

Bone is a highly specialized connective tissue, its properties depending largely on the unique nature of its extracellular matrix. In addition to providing mechanical support and protecting key organ systems from traumatic injury, bone is intimately involved in the homeostasis of calcium, an essential cation in a wide range of bodily functions. In spite of their apparent inertia, *bones are dynamic organs, undergoing constant remodeling throughout life.* Even in mature individuals, bone tissue is continually undergoing localized resorption and replacement in response to the demands of mineral homeostasis and alterations in mechanical forces. The dynamic nature of bones is well illustrated by their impressive powers of repair following injury.

Because of the difficulties associated with processing mineralized tissue, the study of bones, both by researchers and diagnosticians, has lagged behind that of most other organ systems. The skeleton is seldom examined in detail during routine necropsy and it is highly likely that many disorders go undiagnosed. Even in cases where a bone disease is suspected, many veterinary pathologists do not feel confident in their approach to making a diagnosis. *Familiarity with the gross and microscopic anatomy of bones, factors regulating bone formation and resorption, and an understanding of the responses of bone to injury are key to an appreciation of the pathogenesis and pathology of bone diseases.* The initial sections of this chapter will therefore focus on these aspects and outline an approach to examining the skeleton at necropsy.

STRUCTURE AND FUNCTION OF BONE TISSUE

Cellular elements

Bone tissue consists of four cell types: *osteoblasts, osteocytes, lining cells, and osteoclasts.* The first three are derived from primitive

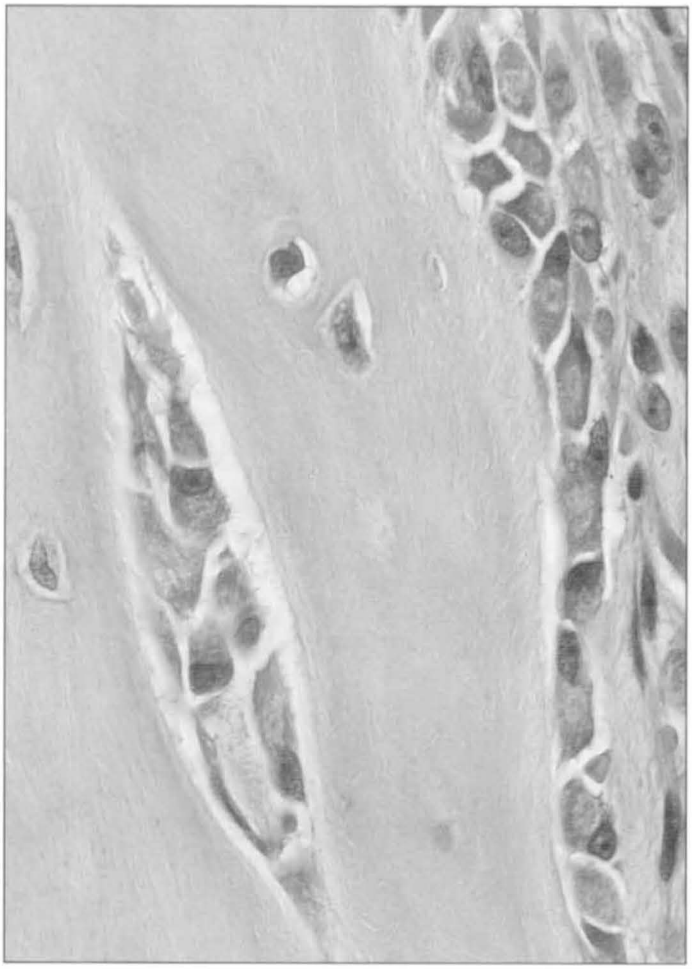

Figure 1.1 Active osteoblasts at a site of rapid bone formation in a newborn kitten. Note the eccentric nuclei, basophilic cytoplasm and prominent Golgi zone in many of the cells. Some osteoblasts have surrounded themselves with osteoid to become osteocytes.

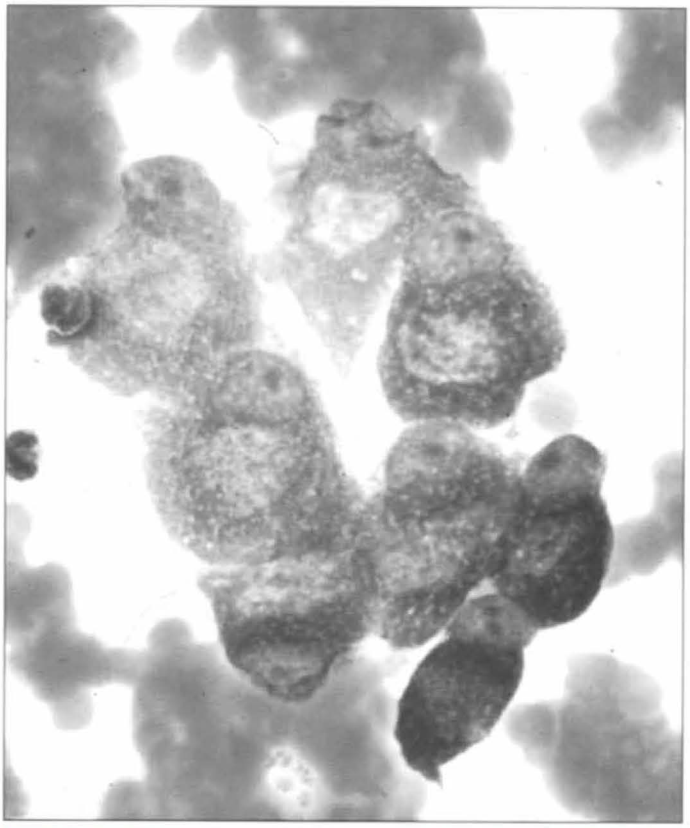

Figure 1.2 Active osteoblasts in a cytological preparation showing the characteristic eccentric nucleus, basophilic cytoplasm and prominent Golgi zone.

osteoprogenitor cells of mesenchymal origin, which are present in bone as well as other tissues, and which can be induced to differentiate into osteoblasts under the influence of appropriate paracrine and autocrine stimuli. Osteoclasts are derived from hematopoietic stem cells, probably of the monocyte series.

Osteoblasts *are responsible for manufacturing osteoid*, the organic component of bone matrix. Active osteoblasts, which line surfaces where bone formation is occurring, have abundant rough endoplasmic reticulum and a prominent Golgi apparatus, reflecting their role in protein synthesis. Histologically they appear as plump, cuboidal cells with basophilic cytoplasm, their nuclei sometimes being polarized away from the adjacent bone surface (Fig. 1.1). The typical morphologic features of osteoblasts are often more easily appreciated in cytologic preparations (Fig. 1.2). Not only do osteoblasts produce the osteoid, *they play a role in initiating its mineralization*, although the mechanism is not fully understood. The membranes of osteoblasts are rich in alkaline phosphatase, which appears to be involved in mineralization of both osteoid and cartilage. The high level of alkaline phosphatase activity measured normally in the serum of rapidly growing young animals presumably reflects the intense osteoblastic activity that is occurring in the developing skeleton. There is mounting evidence that the osteoblast is the central cell through which bone resorption and formation are mediated. In addition to osteoid, they produce an array of *regulatory factors* that are deposited in bone matrix and which play a critical role in bone remodeling.

Inactive osteoblasts, or **bone-lining cells**, are flattened cells with few organelles that cover endosteal bone surfaces that are undergoing neither formation nor resorption. Although barely visible in histological sections, these are the most abundant cells on the endosteal surface of the adult skeleton and link with each other to *form a functional barrier* between the extracellular fluid compartment of bone tissue and that of surrounding tissues. Bone-lining cells are believed to be involved in calcium homeostasis by regulating the exchange of calcium and other ions, such as sodium and magnesium, between bone fluid and extracellular fluid, under the influence of parathyroid hormone. It is likely that bone-lining cells can produce osteoid and contribute to bone deposition should the demand arise at a site of previous inactivity. Endosteal osteoprogenitor cells may be residents of this population of bone-lining cells.

During active bone formation, about 10–20% of osteoblasts at regular intervals along a bone-forming surface surround themselves with osteoid and become **osteocytes** (see Fig. 1.1). *These are the most abundant cells of bone tissue, residing in small spaces (lacunae) within the mineralized matrix.* Newly formed osteocytes retain some morphological and functional characteristics of osteoblasts, but as they mature and become embedded deeper in the mineralized matrix, the amount of rough endoplasmic reticulum in their cytoplasm is reduced considerably and they develop features more typical of phagocytic cells. Osteocytes maintain contact with adjacent osteocytes, and with bone-lining cells or osteoblasts on the surface, by a network of branching cytoplasmic processes extending through *canaliculi*. In routinely stained histological sections, the canaliculi are not visible and only the nuclei of osteocytes are usually apparent.

Osteocytes are thought to be capable of producing and resorbing bone in their immediate vicinity, thereby decreasing or increasing the size of their lacunae. This process is known as *osteocytic osteolysis*. The perilacunar bone matrix is less heavily mineralized and more labile than that in other areas. The action of osteocytes on this perilacunar bone is believed to be important in regulating the concentration of calcium and other minerals in the bone fluid compartment. Because of the large surface area of mineralized bone exposed to either osteocytes or their canaliculi, significant quantities of calcium can be mobilized from this source very rapidly in response to the demands of calcium homeostasis. Although osteocytes can enlarge their lacunae by resorbing perilacunar bone matrix, this process of osteocytic osteolysis does not play a significant role in structural modifications of bones, or in the development of bone lesions associated with disease processes.

Osteocytes probably survive for several years in the mature skeleton but eventually die, leaving empty lacunae. The gradual loss of osteocytes is presumably a normal phenomenon, compensated by the construction of new bone as part of the remodeling process that occurs throughout life. In disease states in which bone necrosis is a feature, there is no immediate loss in structural integrity of the dead bone tissue, but efforts to remove the remaining mineralized matrix and replace it with new bone suggest that its function is impaired.

Osteoclasts *are primarily responsible for resorption of bone tissue*. They are probably related to monocytes and macrophages, which are capable of resorbing bone in vitro, but are sufficiently different histochemically to suggest that they may possess a distinct stem cell. Osteoclasts are rich in acid phosphatase and a range of other acid hydrolases, packaged in primary lysosomes. The acid phosphatase isoenzyme present in osteoclasts is tartrate-resistant, unlike the tartrate-sensitive acid phosphatase found in monocytes and macrophages. Osteoclasts are easily recognizable histologically as large, multinucleated cells with eosinophilic cytoplasm, typically situated on bone surfaces and often within shallow pits called **Howship's lacunae**. The presence of Howship's lacunae on a bone surface is convincing evidence of previous resorption at that site, even if no osteoclasts are present at the time of observation. Although not always apparent histologically, osteoclasts involved in active bone resorption have a highly specialized "ruffled" or brush border contiguous with the bone surface (Fig. 1.3). A clear zone adjacent to the brush border is free of organelles but contains actin-like filaments, which may assist in anchoring the cell to the bone matrix. This attachment of active osteoclasts to the bone surface is an essential requirement for resorption to occur, as is the activity of a specific intracellular, membrane-bound tyrosine kinase. Deletion of the gene coding for this enzyme in mice has been shown to induce osteopetrosis, a disease characterized by defective osteoclastic activity.

During **osteoclastic bone resorption**, an acid environment is created in the narrow space between the cell and the bone surface. Hydrogen and bicarbonate ions are generated from carbon dioxide and water by the action of carbonic anhydrase II on the brush border membrane of osteoclasts. An ATP-mediated proton pump, also located on the brush border membrane, actively transfers hydrogen ions into the extracellular space. The acidity of the local environment not only induces demineralization of the bone, it enhances the activity of the acid hydrolases released from osteoclasts when primary lysosomes fuse with the cell membrane of the brush border. Fragments of degraded matrix are endocytosed by osteoclasts and further digested within secondary lysosomes.

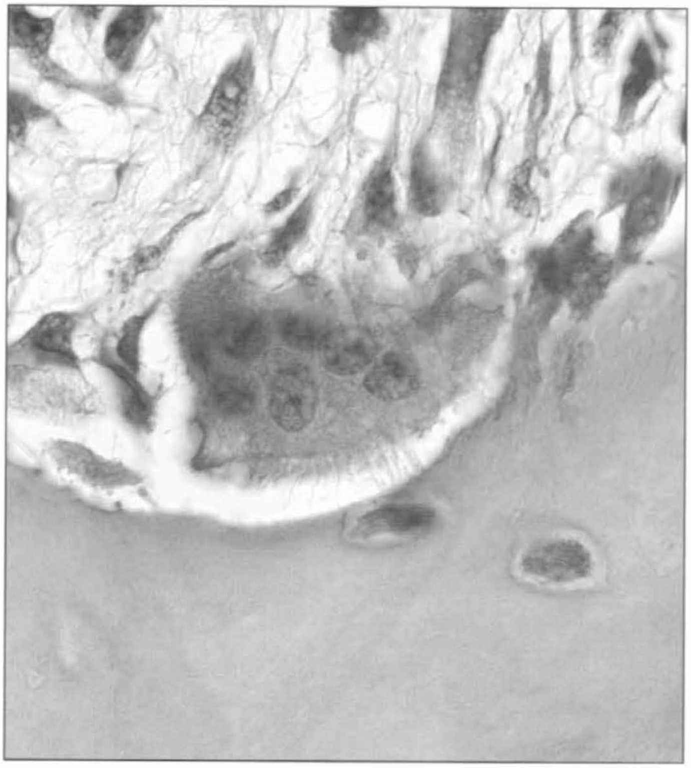

Figure 1.3 Multinucleated osteoclast in a shallow pit (Howship's lacuna) on a bone surface undergoing resorption. Note the ruffled border of the osteoclast adjacent to the bone.

The potential rate of removal of bone by osteoclasts is much greater than the rate of formation by osteoblasts. An individual osteoclast can erode approximately 400 μm^3 of bone, and travel 100 μm across a bone surface, per hour. As a result, localized or generalized removal of bone during the normal physiological processes of modeling and remodeling, or in disease states, can occur very rapidly.

Once osteoclasts have completed their required phase of resorption, they most likely undergo apoptosis and disappear from resorption sites. This is characterized by condensation of nuclear chromatin, loss of the ruffled border and detachment from the bone surface. Drugs that inhibit bone resorption have been shown to induce osteoclast apoptosis both in vitro and in vivo. Importantly, parathyroid hormone promotes the survival of osteoclasts and in cases of either nutritional or renal hyperparathyroidism, surviving osteoclasts are found in medullary spaces mixed with fibroblastic elements. The abnormal persistence of osteoclasts in these sites is an important aid to the diagnosis of these conditions.

Bone matrix

Bone matrix consists of an *organic component, called* **osteoid**, *and an inorganic component comprised predominantly of hydroxyapatite crystals*. The main constituent of osteoid (approximately 90%) is **type I collagen**, which is also the predominant form of collagen in tendons, ligaments, dentine, and the ocular sclera. Each collagen molecule consists of three polypeptide chains assembled into a triple helix, which is a highly stable configuration, resistant to proteolytic degradation, and which forms the basic unit of all collagenous structures. The strength of bone and other collagenous structures is due in part to the manner in which individual collagen molecules are aggregated into fibrils, with each fibril overlapping its neighbor by about one quarter of its length. This creates a characteristic banding pattern, clearly evident on transmission electron microscopy. The tensile strength of collagenous structures is further enhanced by intermolecular cross-links, which form by the oxidative deamination of either lysyl or hydroxylysyl residues under the influence of the copper-dependent enzyme lysyl oxidase. The number of these cross-links in bone collagen is greater than that of the collagen types found in soft tissues. Interference with the formation of cross-links, as occurs in copper deficiency or certain toxicity diseases (see below), may significantly alter the mechanical properties of bone and other connective tissues.

Several *noncollagenous proteins* are also produced by osteoblasts and form part of the organic matrix of bone. The most abundant of these is **osteonectin**, a phosphoprotein that interacts with both type I collagen and hydroxyapatite, and has been shown to facilitate the mineralization of type I collagen in vitro. Osteonectin concentration is highest in mature bone, especially in areas with the highest degree of mineralization. **Osteocalcin**, also referred to as *bone Gla protein* because of its γ-carboxyglutamic acid (Gla) residues, is also abundant in bone, accounting for up to 10% of total noncollagenous proteins. Its synthesis by osteoblasts is vitamin K-dependent and is stimulated by 1,25 dihydroxyvitamin D. Osteocalcin is deposited in osteoid shortly before mineralization and binds strongly to calcium ions and to hydroxyapatite, suggesting that it is important in the mineralization process. There is also evidence to suggest that it may be involved in the recruitment of osteoclasts to sites of bone resorption or remodeling. Interestingly, depletion of osteocalcin concentration to less than 1% of normal in rats fed warfarin is not accompanied by a reduction in the mechanical strength of bone. Osteocalcin is also found in plasma, where it serves as a marker for osteoblastic activity. A second Gla-containing protein, *matrix Gla protein*, occurs in bone as well as several other tissues. Its function is not known but it appears early in skeletal development when osteocalcin levels are still low, suggesting a possible role in bone development.

The **proteoglycans** of bone matrix are considerably smaller and less abundant than those found in cartilage matrix, possessing a relatively small protein core and only one or two glycosaminoglycan (chondroitin sulfate) side-chains. The bone proteoglycans are concentrated near the mineralization front where they are believed to play a *key role in the organization and mineralization of the matrix*. During this process, the protein core is degraded, leaving the chondroitin sulfate side-chains, which persist in the mineralized matrix of bone.

Several other noncollagenous proteins have been detected in bone matrix, including *osteopontin*, a sialoprotein that binds strongly to hydroxyapatite, and many other glycoproteins and phosphoproteins whose functions are unknown.

Bone matrix also contains a *variety of growth factors* that are capable of inducing mitogenic responses in a range of cell types, including bone cells. These factors, which probably play an important role in bone development, modeling and remodeling, especially at the local level, include: bone morphogenetic proteins, fibroblast growth factors, platelet-derived growth factors, insulin-like growth factors, and transforming growth factors β.

The **inorganic (mineral) component** of bone matrix is known to consist largely of **hydroxyapatite** [$Ca_{10}(PO_4)_6(OH)_2$], but its structure and properties are poorly understood. In addition to calcium and phosphate, bone mineral contains considerable quantities of *carbonate, magnesium, sodium and zinc*, not all of which are available for exchange. *Fluoride* is also present in small amounts in bone matrix. Ultrastructurally, hydroxyapatite is present in bone matrix either as thin, needle-like crystals oriented in the same direction as collagen fibrils, or as an amorphous, granular phase, depending on the type of bone.

Matrix mineralization

The mineralization of skeletal tissues is a highly complex process, and is only partly understood. In organ systems throughout the body, extracellular tissue fluids in equilibrium with plasma are supersaturated with respect to hydroxyapatite. Many also contain type I collagen similar to that in bone, but mineralization does not normally occur. This is most likely due to the presence of potent inhibitors, which must be enzymatically degraded before mineralization can be initiated. In bone, the selective and localized degradation of such inhibitors, and the synthesis by osteoblasts of unique molecules that promote mineralization, could account for the orderly manner in which mineral deposition occurs in this tissue. However, the presence of substrates that promote nucleation at humoral solute concentrations is also required.

There is no doubt that **matrix vesicles**, *tiny extracellular organelles originating as cytoplasmic blebs from osteoblasts, chondrocytes and odontoblasts*, play an important role in initiating the mineralization process, particularly in cartilage undergoing endochondral ossification. These vesicles are rich in calcium-binding phospholipids and proteins, alkaline phosphatase, pyrophosphatases, phospholipase A_2 and in metalloproteinases that degrade proteoglycans, potential inhibitors of mineralization. Although the mechanism is still uncertain, the initial nucleation of hydroxyapatite crystals occurs on the inner surface of matrix vesicle membranes, at least in mineralizing cartilage matrix. Phospholipids in vesicles are believed to sequester calcium, while pyrophosphatases and metalloproteinases inactivate local inhibitors and alkaline phosphatase generates phosphates, allowing mineralization to proceed.

Although mineral deposition in some tissues such as growth plate cartilage appears to be mediated almost exclusively by matrix vesicles, this is not the case for bone matrix. Unlike cartilage, where mineralization of collagen fibrils does not occur, hydroxyapatite crystals are deposited in the type I collagen fibrils of bone. Evidence suggests however that collagen fibrils alone are not capable of initiating primary nucleation. The adsorption to collagen of bone-specific noncollagenous proteins such as osteonectin and osteocalcin, both of which are strong binders of Ca^{2+} ions, may create appropriate sites for nucleation. Once initiated, the mineral spreads in an orderly manner throughout collagen fibers until the entire aqueous space of the fiber is filled with hydroxyapatite crystals. The mineralization of individual fibers occurs rapidly, as evidenced by the sharp division between highly and sparsely mineralized matrix at the junction between mineralized bone and osteoid seams.

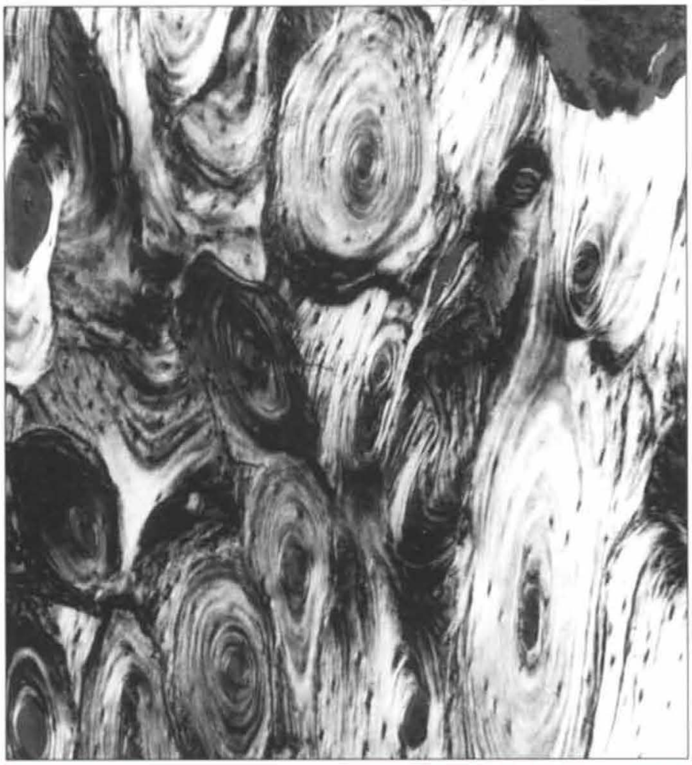

Figure 1.4 Transverse (slightly oblique) section of cortical bone viewed under polarized light to show the **osteons or Haversian systems**, which consist of concentric lamellae of bone surrounding a central vascular canal.

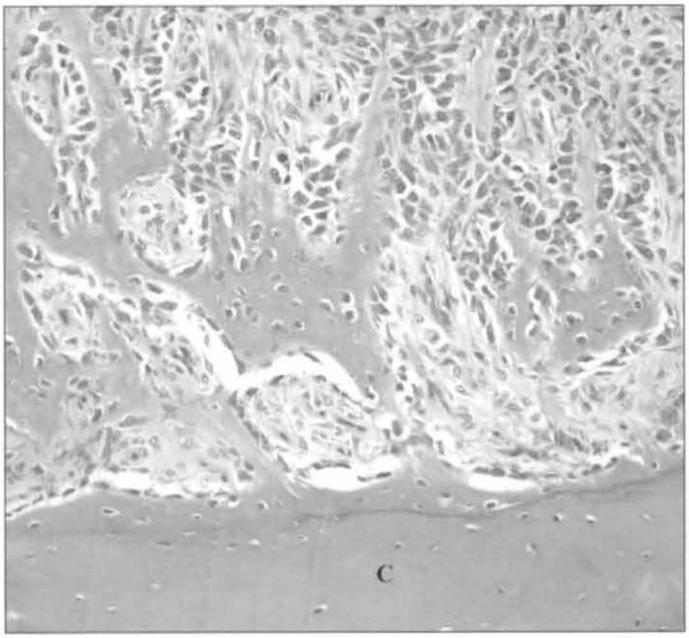

Figure 1.5 Trabeculae of **woven bone** emerging from the cortex (C) beneath an elevated periosteum. The osteocytes in the woven bone are more numerous than in the mature lamellar bone of the cortex and are irregularly distributed. The matrix of the woven bone is slightly more basophilic than that of the mature bone.

Osteoid does not become mineralized for 5–10 days after deposition. As a result, *a thin layer of unmineralized osteoid*, the **osteoid seam**, covers the surfaces where bone is being formed. Although not always apparent histologically in decalcified tissue sections, the osteoid seam is usually more eosinophilic than previously mineralized bone tissue and, in lamellar bone, separated from it by *a basophilic line*, the **mineralization front**. The osteoid seam may be 5–15 μm in depth, depending on its rate of formation. Once mineralization of osteoid begins, it occurs very rapidly, with over 60% of the matrix becoming mineralized almost immediately. However, the remaining deposition of mineral is a slow cumulative process that can take weeks to complete.

Structural organization of bone tissue

Although the cellular elements of bone tissue, and the basic composition of the matrix, are relatively constant, there is variation in the organization of these components both at the macroscopic and microscopic level. The adult skeleton consists predominantly of mature **lamellar bone**, where the collagen fibers of the bone matrix are oriented in parallel layers. This pattern is clearly apparent in histological sections viewed under polarized light (Fig. 1.4). Osteocytes are present in small slit-like lacunae between layers in a regular pattern, their distribution reflecting the orderly manner in which osteoblasts manufacture lamellar bone. In dense cortical bone, the lamellae are organized into **osteons** or **Haversian systems**, consisting of concentric lamellae surrounding a central vascular canal (Fig. 1.4). *Osteons run longitudinally through the cortex and are cemented together by interstitial lamellae.* The trabecular or spongy bone of medullary cavities consists of variable numbers of lamellae arranged parallel to the surface rather than organized into osteons.

The alternating pattern of birefringent and nonbirefringent layers in lamellar bone has traditionally been interpreted as reflecting a 90° switch in orientation of collagen fibers between successive layers, creating a structure with physical strength similar to plywood. This model has remained unquestioned since the early 20th century, but has been challenged by recent studies using scanning electron microscopy. An alternative model proposes that lamellar bone consists of alternating layers of collagen-rich (dense) and collagen-poor (loose) lamellae, only the former showing birefringence.

A variant of lamellar bone is often seen on the weight-bearing aspects of long bones of rapidly growing animals, especially young ruminants. In these areas, the outer cortex is often arranged in laminar arrays rather than conventional Haversian systems, and is known as **laminar bone**.

In the developing fetus, and at sites of rapid bone formation during postnatal life, the *collagen fibers in bone matrix are arranged in a haphazard, interwoven fashion*. This immature form of bone tissue is referred to as **woven bone**, or coarse-bundle bone. Its matrix is more basophilic than that of lamellar bone and the osteocytes are larger, more numerous, and are irregularly arranged (Fig. 1.5). During skeletal maturation and remodeling, woven bone is resorbed and replaced with lamellar bone, which has greater strength, but it is seen in adults at sites where bone is produced rapidly in response to injury, inflammation or neoplasia. Fracture calluses invariably contain this form of bone tissue, as do bone-forming tumors.

A third type of bone, **chondroid bone**, arises directly from fibrocartilaginous origins and is found in ossifying tendon sheaths, of bone derived from neural crest origins and probably from some mixed tumors.

Formation of cranial bones

The pathology of the cranial bones often differs from bones elsewhere in the body, and some of the cranial bones may be spared in disorders that affect other bones. This is probably due to the complex origins of the cranial bones. The base of the cranium develops from a hyaline cartilage model that mineralizes and subsequently undergoes endochondral ossification. The remainder of the cranial bones and also the facial bones arise from mesenchyme directly by the process of intramembranous bone formation. Experimental studies using chimeric chick embryos and transgenic mice indicate that neural crest cells populate the sutures of membranous cranial bones, contribute to tooth morphogenesis and the formation of odontoblasts, dentine and cementum of teeth, and in the formation of the mandible and its cartilaginous articulation with the temporal bones. Chondroid bone that develops from neural crest cells populates the cranial bone sutures, and also forms as an intermediate step in the formation of intramembranous skull bones. Sutures remain as active sites of intramembranous bone production, and are probably the site of origin for the distinctive tumor that arises in the skull, the multilobular tumor of bone.

The embryology and development of the vertebral column is also complex, and in most vertebrae there are eight separate ossification centers. However, the atlas and axis differ in their structure and development.

Regulation of bone formation and resorption

The regulation of bone cell function is accomplished by the action of a variety of systemic hormones and the local action of cytokines, which not only influence the recruitment and action of differentiated osteoblasts and osteoclasts, but also may stimulate the proliferation of their precursors. A list of systemic and local factors involved in bone remodeling is presented in Table 1.1.

Systemic hormones known to have either direct or indirect effects on the skeleton include: parathyroid hormone, 1,25-dihydroxyvitamin D$_3$, calcitonin, glucocorticoids, growth hormone, insulin, sex steroids, and thyroid hormones. **Parathyroid hormone** (PTH) is a potent activator of osteoclastic bone resorption, but its action appears to be mediated through osteoblasts or bone-lining cells as PTH receptors have been identified on osteoblasts but not osteoclasts. Furthermore, in vitro studies have demonstrated that the activation of osteoclasts by PTH depends on the presence of osteoblasts. The TNF-family molecule RANK-L (receptor activator of NF-kappaB ligand) has recently been identified as an essential signal in osteoclast development, activation, and survival. RANK-L is highly expressed in areas of bone remodeling and at sites of pathological bone loss in a variety of disease states in man and animals.

Osteoclasts are poorly able to resorb unmineralized bone matrix and since a thin layer of osteoid covers all bone surfaces, except those undergoing resorption, this layer must be removed before resorption can be initiated. Osteoblasts also may be involved in this process through activation of a latent form of collagenase, the synthesis and secretion of which are enhanced by PTH. In addition to its effect on bone resorption, PTH has been shown experimentally both to inhibit and stimulate bone formation, depending on the duration of administration and the dose rate. High doses cause increased bone resorption leading to fibrous osteodystrophy. In contrast, low and intermittent doses of PTH that are too small to affect serum calcium concentration have been shown to promote bone formation and increase bone mineral density. This anabolic effect of PTH is mediated through inhibition of apoptosis of osteoblasts and osteocytes, thereby increasing their lifespan.

Table 1.1 Factors controlling bone remodeling

Systemic factors	Local factors
Polypeptide hormones - Parathyroid hormone - Calcitonin - Insulin - Growth hormone **Steroid hormones** - Vitamin D (1,25-dihydroxyvitamin D$_3$ - Sex hormones - Corticosteroids **Thyroid hormones**	**Cytokines** - Interleukins (IL-1, IL-6, IL-11) - Insulin-like growth factors (IGF-I, IGF-II) - Transforming growth factors (TGF-β) - Bone morphogenetic proteins - Fibroblast growth factors - Platelet-derived growth factor - Tumor necrosis factors - Interferons - Colony stimulating factors (M-CSF, GM-CSF) **Prostaglandins** - Prostaglandin E2 **Nitric oxide**

Like PTH, **1,25-dihydroxyvitamin D$_3$** (1,25(OH)$_2$D$_3$), *the active form of vitamin D$_3$, is a potent stimulator of osteoclastic bone resorption.* It promotes the differentiation and fusion of osteoclast progenitors and activates mature osteoclasts, probably by a mechanism similar to, but independent of, PTH. Receptors for 1,25(OH)$_2$D$_3$ do not occur on osteoclasts but are present on osteoblasts, supporting the involvement of osteoblasts in mediating osteoclastic resorption triggered by 1,25(OH)$_2$D$_3$. The effect of 1,25(OH)$_2$D$_3$ on bone formation is complex, but it appears to be required for normal bone growth and mineralization. This effect on mineralization is partly related to maintaining adequate serum concentrations of calcium and phosphorus, but evidence for a direct effect of 1,25(OH)$_2$D$_3$ on mineralization has been provided by experiments in mice and rats. The synthesis of osteocalcin by osteoblasts is stimulated by 1,25(OH)$_2$D$_3$, but there is confusion over the exact role of this peptide hormone and other metabolites of vitamin D$_3$ on bone formation.

Calcitonin *has a direct, but transient, inhibitory effect on osteoclastic bone resorption* but does not appear to influence bone formation. Following exposure to calcitonin, active osteoclasts rapidly lose their ruffled border and become physically separated from the underlying bone surface. There is also an inhibitory effect on osteoclast formation through reduced proliferation of progenitor cells and reduced differentiation of committed precursors. Calcitonin is capable of inhibiting PTH-induced bone resorption in vitro, but the mechanism and significance of this action is unclear.

Insulin does not regulate bone resorption but *plays an important role in the synthesis of bone matrix, and in cartilage formation.* As such, it has a major influence on normal skeletal growth. Rather than influence bone cell replication, insulin stimulates bone matrix synthesis by differentiated osteoblasts. **Growth hormone** promotes longitudinal growth of bones in immature individuals and appositional bone growth in adults, but its action is indirect, being mediated through insulin-like growth factors produced by the liver.

Glucocorticoids *have a significant catabolic effect on the skeleton* through actions on both osteoblasts and osteoclasts. There is direct inhibition of osteoblastic activity, thereby reducing bone formation, and an indirect enhancement of osteoclastic resorption. The latter is probably due to inhibition of enteric calcium absorption and impaired renal tubular calcium reabsorption, leading to reduced serum ionized calcium concentration and secondary hyperparathyroidism. Reduction in bone mass is a recognized sequel to long-term corticosteroid therapy both in human and animal patients.

Estrogens and **androgens** appear to be *important regulators of skeletal growth and maturation.* Androgen receptors are present on osteoblasts, but at low densities. During puberty, androgens stimulate bone growth, while in male adults they are involved in the maintenance of the skeleton. Androgens do not affect osteoclasts directly, but may inhibit bone resorption indirectly by inhibiting the recruitment of osteoclast precursors from bone marrow. A significant effect of estrogens appears to be to inhibit bone resorption. Immediately after menopause, a decline in circulating estrogen levels in some women is accompanied by a rapid acceleration in bone loss, leading to osteoporosis. Treatment of postmenopausal women with estrogen has been shown to significantly reduce the risk of osteoporosis-related fractures. Estrogen may inhibit bone resorption by reducing the synthesis of cytokines such as interleukin-6, although the exact mechanism is unknown.

Thyroid hormones are important for normal skeletal development, primarily through *stimulation of cartilage growth,* but they also stimulate bone resorption. In human patients, accelerated bone resorption in hyperthyroidism may result in hypercalcemia and increased risk of osteoporosis. Hypothyroidism during fetal development has been linked to congenital abnormalities of the skeleton in animals. Reduced longitudinal bone growth, delayed ossification and impaired bone resorption were reported in lambs following fetal thyroidectomy, while delayed ossification of carpal bones in newborn foals has been described in association with hyperplastic goiter.

In addition to the range of systemic hormones capable of influencing bone formation and resorption, several locally produced **growth regulatory factors** or **cytokines** with paracrine, autocrine, or juxtacrine functions have been identified. In fact, these factors are likely to be more important than the systemic hormones in initiating physiologic bone resorption and remodeling, which occurs in discrete localities throughout the skeleton. Many of these growth factors become stored in the matrix and their release in active form during future episodes of bone resorption may stimulate the differentiation and proliferation of osteoblast precursors. They can be grouped into distinct families based on their action and target cell, but there is considerable overlap and redundancy in their activities.

The **insulin-like growth factors** (IGF-I and IGF-II) are growth hormone-dependent polypeptides produced by several tissues, including bone. *They are known to have powerful systemic and local effects on bone formation and maintenance of bone mass.* IGF-I, which is more potent than IGF-II, stimulates the proliferation of osteoblast precursors and enhances matrix synthesis by differentiated osteoblasts. It also inhibits the degradation of bone collagen, most likely by inhibiting the expression of interstitial collagenase by osteoblasts. The synthesis of IGF-I is stimulated by PTH and other agents that stimulate cAMP in bone cells, but is inhibited by glucocorticoids. The reduced bone mass that occurs in association with glucocorticoid excess may be due in part to this inhibition of IGF-I.

Transforming growth factor-β (TGF-β), another family of polypeptide hormones produced both in bone and other tissues, *has powerful effects on both osteoclasts and osteoblasts, and probably plays a key role in bone remodeling.* During bone resorption, TGF-βs are released from the bone matrix in active form. They inhibit the proliferation and differentiation of osteoclast precursors, as well as the activity of mature osteoclasts. TGF-βs also stimulate the replication of osteoblast progenitors, increase collagen synthesis by differentiated osteoblasts and induce osteoblast chemotaxis in vitro.

Bone morphogenetic proteins (BMPs) are a *large subgroup of signaling molecules* within the TGF-β superfamily and have been the subject of intense research in recent years. Approximately 30 different BMPs with overlapping expression patterns have been identified. BMP-specific antagonists, such as noggin and chordin, have also been identified. BMPs appear early in embryogenesis and are involved in the induction of bone and cartilage development during organogenesis. They stimulate osteoblast differentiation and have a unique property of inducing heterotopic bone formation in vivo. This has led to considerable interest in the possible therapeutic use of BMPs in disease conditions where enhanced bone formation is desirable.

Acidic and basic **fibroblast growth factors** (FGFs) also have been shown to *stimulate bone formation* but, unlike TGF-βs, they do not influence bone resorption. FGFs probably generate additional osteoblast precursors, leading to increased numbers of differentiated osteoblasts, and are effective in stimulating new bone formation to restore bone mass. Abnormalities in FGF receptors have been identified in human patients with certain inherited skeletal disorders, including achondroplasia. **Platelet-derived growth factor** (PDGF) is a *potent stimulator of new bone formation, but also promotes bone resorption.*

Estrogen depletion induced by ovariectomy in a rat model markedly increases the synthesis of **interleukin-6** (IL-6) and **interleukin-11** (IL-11) by osteoblasts or their precursors in the bone marrow stroma. *These cytokines appear to play a crucial role in the recruitment, proliferation, and differentiation of osteoclast progenitors that eventually lead to reduced bone mass in estrogen deficiency.* Further support is derived from studies in mice following deletion of the IL-6 gene. Unlike normal controls, mice lacking the IL-6 gene do not show any reduction in bone mass after ovariectomy. **Interleukin-1** (IL-1) and **tumor necrosis factor-α** (TNF-α) are related cytokines that act synergistically on bone and also have been implicated in the pathogenesis of postmenopausal osteoporosis. Both are potent stimulators of osteoclastic activity in vitro and in vivo and may be involved in mediating focal bone resorption in certain inflammatory disorders. Unlike other cytokines, **γ-interferon** does not stimulate bone resorption. In fact, it selectively inhibits the resorption stimulated by IL-1 and TNF, probably through inhibition of prostaglandin synthesis. **Osteoprotegerin** (OPG), a newly described receptor-like protein, is a member of the TNF receptor family, and acts as a decoy receptor for RANK-L. Its major role appears to be in regulating bone remodeling through a negative effect on the maturation and activation of osteoclasts.

Several **colony-stimulating factors** (CSFs) influence bone resorption by regulating the proliferation and differentiation of osteoclast precursors. Their importance is highlighted by studies in mice with the *op/op* variant of osteopetrosis, where there is impaired production of macrophage colony-stimulating factor (M-CSF or CSF-1). A decrease in osteoclast formation, leading to reduced bone resorption and osteopetrosis, can be reversed transiently by the administration of M-CSF. Granulocyte macrophage colony-stimulating factor (GM-CSF) can also increase osteoclast differentiation from their precursors, thereby promoting bone resorption. Osteoblasts are capable of secreting GM-CSF following exposure to bacterial endotoxin or PTH.

Prostaglandins (PGs), in particular those of the E series, are another group of *important mediators of local bone resorption.* They are characterized by restricted, local activity before being rapidly degraded, making studies of their in vivo action extremely difficult. Consequently, their precise role has not been determined. PGE_2 appears to directly stimulate osteoclastic activity and may be a mediator of bone resorption regulated by osteoblasts. Local production of PGE_2 in response to inflammation, mechanical trauma, or neoplasia is likely to contribute to the bone resorption that is often associated with such conditions. PGE_2 has also been linked to the bone resorption and hypercalcemia associated with certain malignancies.

Nitric oxide, generated by the nitric oxide synthase group of enzymes, may be an important mediator of bone cell function. In vitro studies have revealed a biphasic effect on bone resorption. At low concentrations, nitric oxide potentiates IL-1-induced osteoclastic bone resorption, suggesting that small amounts of nitric oxide may be required for normal osteoclast activity. In contrast, high concentrations of nitric oxide strongly inhibit bone resorption both in organ cultures and in cultures of isolated osteoclasts. This inhibitory effect appears to be due to apoptosis of osteoclast progenitors, induced by the action of nitric oxide derived from osteoblasts. The effect of nitric oxide on osteoblast function is less clear, although estrogen has been shown to stimulate nitric oxide synthase activity in both endothelial cells and osteoblasts, suggesting a possible role of nitric oxide in mediating the protective effects of estrogen on bone. At high concentrations, nitric oxide inhibits osteoblast growth and differentiation. This provides a possible explanation for the reduced bone formation and osteoporosis that occurs in association with certain inflammatory conditions. The role of nitric oxide in vivo has yet to be established, but there is increasing evidence to support its role as an important regulator of bone turnover.

Remodeling of bone tissue

Throughout postnatal life, old or defective bone is constantly being replaced with new bone tissue by a process of **remodeling**. This occurs at a local level and involves the coordinated activities of osteoclasts and osteoblasts in so-called **bone remodeling units**, presumably mediated by a complex interaction between systemic hormones and locally acting cytokines. The remodeling sequence starts with activation of osteoblasts (probably bone-lining cells) by external signals such as hormones, cytokines, or growth factors to induce accelerated formation of osteoclasts from their precursors. The osteoclasts attach to the bone surface, seal it off from the extracellular space, and resorb bone matrix and mineral. Then follows a reversal phase during which resorption ceases, the osteoclasts detach from the bone and disappear, probably by apoptosis. Osteoblasts are attracted by an unknown mechanism to the resorption site where they deposit new bone.

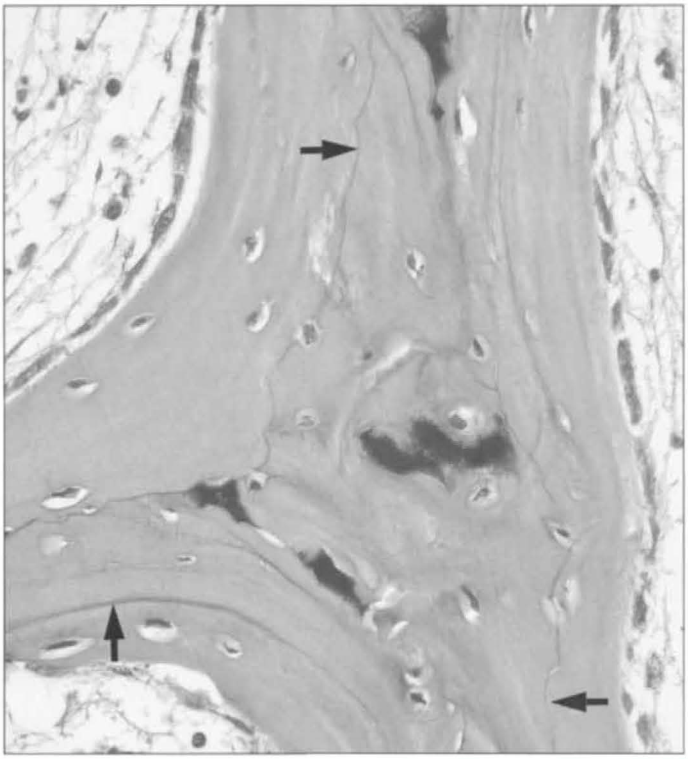

Figure 1.6 Cementing lines in a segment of trabecular bone. The smoothly contoured lines (vertical arrow) are referred to as **resting lines** and indicate sites at which bone formation had ceased for a period then recommenced. The scalloped lines (horizontal arrows) are **reversal lines** and reflect previous resorption, followed by deposition of new bone.

In the cortex, activated osteoclasts form a "cutting cone" which bores longitudinally through the dense, primary bone, creating a *resorption canal.* As the canal advances, it becomes lined by osteoblasts, which fill the space with concentric layers of new lamellar bone, creating a *secondary osteon or Haversian system.* This process provides a mechanism for on-going internal replacement of cortical bone without altering its gross form or function. Remodeling of trabecular bone follows a similar sequence, but from the trabecular surface, without the formation of resorption canals.

In histological sections, the separate units of secondary bone that form during remodeling can be distinguished from each other, and from adjacent primary bone, by the presence of deeply basophilic **cementing lines** (Fig. 1.6). These lines are created by the deposition of a thin layer of highly mineralized, collagen-free matrix at sites where bone resorption or formation ceases. Two types of cementing lines are recognized. Those with a scalloped appearance are termed **reversal lines**, and indicate a site where previous bone resorption had occurred, then new bone deposited in its place. Smoothly contoured cementing lines, or **resting lines**, mark sites where bone formation ceased for a period, then re-commenced. The number and pattern of cementing lines may provide useful information on the recent history of an area of bone, in particular regarding the rate of turnover.

Markers of bone remodeling

Although not used routinely in veterinary medicine, various **markers of bone remodeling** or turnover can be measured in serum or urine and may add support to a clinical diagnosis, or be of value in research. *Serum alkaline phosphatase activity is a well-recognized indicator of osteoblastic activity*, increased levels occurring in diseases characterized by increased bone formation such as hyperparathyroidism. Its diagnostic value is limited however by the fact that high levels are also detected normally in rapidly growing young animals. Furthermore, other isoforms of alkaline phosphatase are commonly used as indicators of cholestatic liver disease in several species and hyperadrenocorticism in dogs. Another potentially useful indicator of osteoblastic activity is *serum osteocalcin*. Approximately 10–25% of the osteocalcin synthesized by osteoblasts escapes into the circulation and serum concentrations are proportional to the rate of osteoid synthesis.

Bone resorption, associated with increased osteoclastic activity, is reflected by increased serum activity of *tartrate-resistant acid phosphatase*, an enzyme released by osteoclasts during the degradation of bone matrix. Increased urinary concentration of *hydroxyproline* has long been considered a marker of bone resorption, but this amino acid is present in all types of collagen, not just the type I collagen of bone, and cannot therefore be considered specific. Recent interest has focused on measurement of urinary concentrations of the *pyridinium cross-links* that bind the nontriple helical portions of one collagen molecule to another. Of these molecules, hydroxylysyl pyridinoline is the most abundant, but is less specific for type I collagen than deoxypyridinoline. Both can be detected in urine as either free or peptide-bound forms using commercially available kits.

In dogs, horses, rats and humans, considerable diurnal variations in the serum and urinary concentrations of bone markers have been demonstrated. This may reflect circadian rhythms in the rates of bone formation and resorption. There has been increasing interest in such markers of bone resorption in human medicine as indicators of post-menopausal bone loss or monitoring the effectiveness of antiresorptive therapy, but their application in animals is still largely confined to research.

Ectopic mineralization and ossification

Extraskeletal deposition of either amorphous calcium phosphate or hydroxyapatite crystals, referred to as **ectopic** or **heterotopic mineralization** (calcification), occurs in a range of disease conditions, and must be differentiated from **ectopic ossification**, where the mineral is deposited in the form of bone tissue.

Three main forms of ectopic mineralization are recognized in animals: metastatic, dystrophic, and idiopathic. **Metastatic mineralization** is a frequent complication of disease conditions associated with hypercalcemia and/or hyperphosphatemia, such as vitamin D toxicity, hypercalcemia of malignancy, primary hyperparathyroidism and uremia. In dogs, direct precipitation of mineral occurs when the *calcium-phosphate solubility product*, expressed in mg/dL, persistently exceeds 60. The mineral deposited in metastatic mineralization typically occurs in the outer medullary region of the kidney, the fundus of the stomach, and the lungs, all of which are involved in acid secretion and possess a local alkaline environment favoring mineral precipitation. Other favored sites include the media of large arteries and the elastic tissue of the endocardium, but the reason for such predilection is not clear.

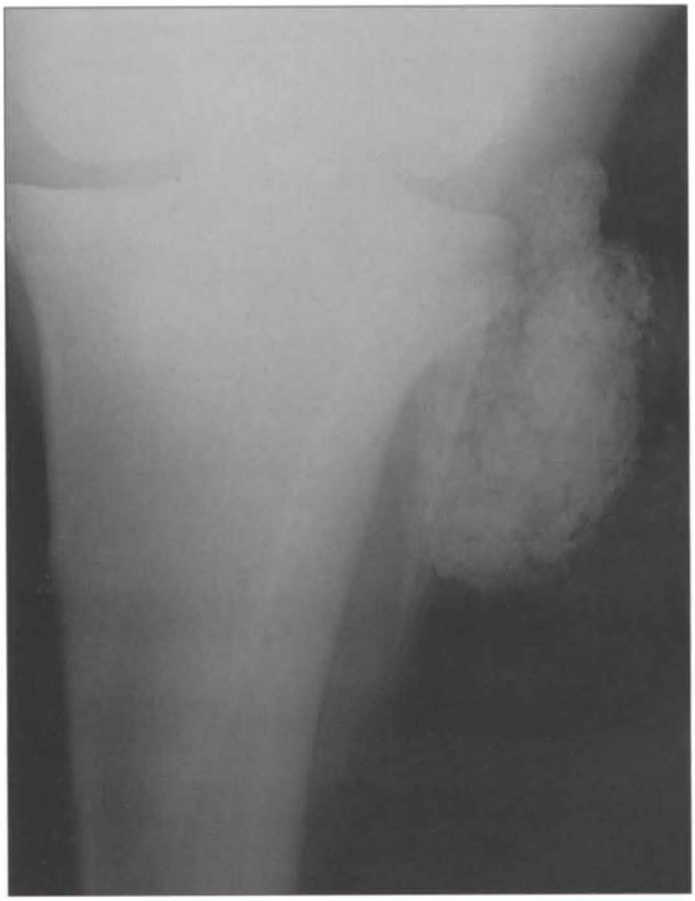

Figure 1.7 Tumoral calcinosis in a horse. A large, discrete mass lateral to the femoro-tibial joint contains multiple radiodense deposits.

Dystrophic mineralization occurs in association with *damaged tissue* rather than an elevated calcium-phosphate solubility product, probably due to the release or establishment of cellular components with nucleation properties following injury. Examples include mineral deposition in the caseous lesions of bovine tuberculosis and caprine paratuberculosis, and the mineralization of muscle fibers in animals with nutritional myodegeneration.

Idiopathic forms of ectopic mineralization occur in a variety of unrelated disease syndromes, including **calcinosis cutis**, which is characterized by widespread mineralization of dermal elastic fibers in association with hyperadrenocorticism, and **tumoral calcinosis** (*calcinosis circumscripta*), where tumor-like nodules of ectopic mineralization develop in soft tissues, often close to joints. Tumoral calcinosis in horses usually occurs in animals about 2–4 years of age, and 90% of lesions develop on the lateral aspect of the stifle (Fig. 1.7). The lesions may be single or multiple and are sometimes attached to the joint capsule, but not to the overlying skin. They usually appear as hard, well-circumscribed, nonpainful, subcutaneous swellings ranging in size from about 3–12 cm in diameter. Individual lesions consist of a tough, outer, fibrous capsule with collagenous trabeculae dividing the interior into numerous variable-sized locules consisting of finely granular, chalky white accumulations of calcium salts, surrounded by a rim of granulomatous inflammation cells. The lesions usually do not cause lameness and do not recur after surgical removal. Tumoral calcinosis in humans is also characterized by deposition of mineral in locular masses adjacent to major joints, particularly the shoulder and hip. Autosomal recessive inheritance is suggested to account for approximately one third of human cases, and hyperphosphatemia is often present, but the pathogenesis is unknown.

In dogs, the manifestations of calcinosis circumscripta are variable, and show breed preferences. In German Shepherds, the lesions are generally solitary, occurring most often in the skin near pressure points, but multiple lesions occur in some dogs, often attached to tendons, joint capsules, or the periosteum. Involvement of the vertebral processes of C-4 and C-5 was reported in three 5–6-month-old Great Dane puppies from the same litter, suggesting the possibility of a familial etiology. The lesions are usually nonpainful and nonprogressive, but may cause clinical signs if they interfere with the function of adjacent structures. For example, spinal cord compression caused by paravertebral calcinosis circumscripta occurred in two young dogs of different breeds. Although the pathogenesis is not known, repetitive trauma has been suggested as a predisposing factor, at least in some cases with skin involvement. Trauma is less likely to be responsible for lesions associated with vertebrae or involving the tongue, as has been reported.

A syndrome characterized by calcium hydroxyapatite deposition in the spinal canal of young Great Dane puppies has been reported to cause paraplegia and incoordination. Mineral deposition may also be present in joints and soft tissues of affected pups. In one report, the condition occurred in two litters of related Great Danes and was considered familial.

Ectopic ossification refers to the *formation of nonneoplastic trabecular bone in extraosseous sites*, presumably following the induction of pluripotential stem cells by appropriate growth factors. In most cases, ectopic bone is detected as an incidental finding at necropsy without an obvious predisposing cause. Typical sites include the pulmonary connective tissue of dogs and cattle, and the cervical and lumbosacral dura mater of aged dogs (ossifying pachymeningitis). Ectopic ossification also occurs in the supporting connective tissue of certain tumors in dogs, particularly mammary carcinomas, where it is very common, and to a lesser extent in thyroid and salivary carcinomas.

Specific disease entities associated with widespread ossification of soft tissues have been described both in human patients and animals and may involve overexpression or dysregulation of bone morphogenetic proteins. The temptation with such diseases in animals is to classify them according to the human syndrome that they most closely resemble. Such comparisons are usually subjective and may not be appropriate in all cases. A syndrome resembling human **fibrodysplasia ossificans progressiva** has been described in several cats and occasionally in the dog, although some of these cases more closely resemble myositis ossificans. In cats, the disease is characterized by *progressive, symmetrical, hyperplasia and ossification of connective tissue in the subcutis and epimysium of the neck, dorsum and limbs.* Affected cats have ranged in age from 5 months to 6 years. A feature of the disease in humans, and in some reported cases in animals, is the formation of bone in soft tissue sites by the process of endochondral ossification. In the 5-month-old cat referred to above, there was massive thickening of joint capsules and synovial membranes of several limb joints with disorganized hyaline cartilage (Fig. 1.8A, B). There was bilateral involvement of carpal and stifle joints in addition to several metatarsophalangeal and interphalangeal joints. Many foci of endochondral ossification were scattered throughout the hyperplastic

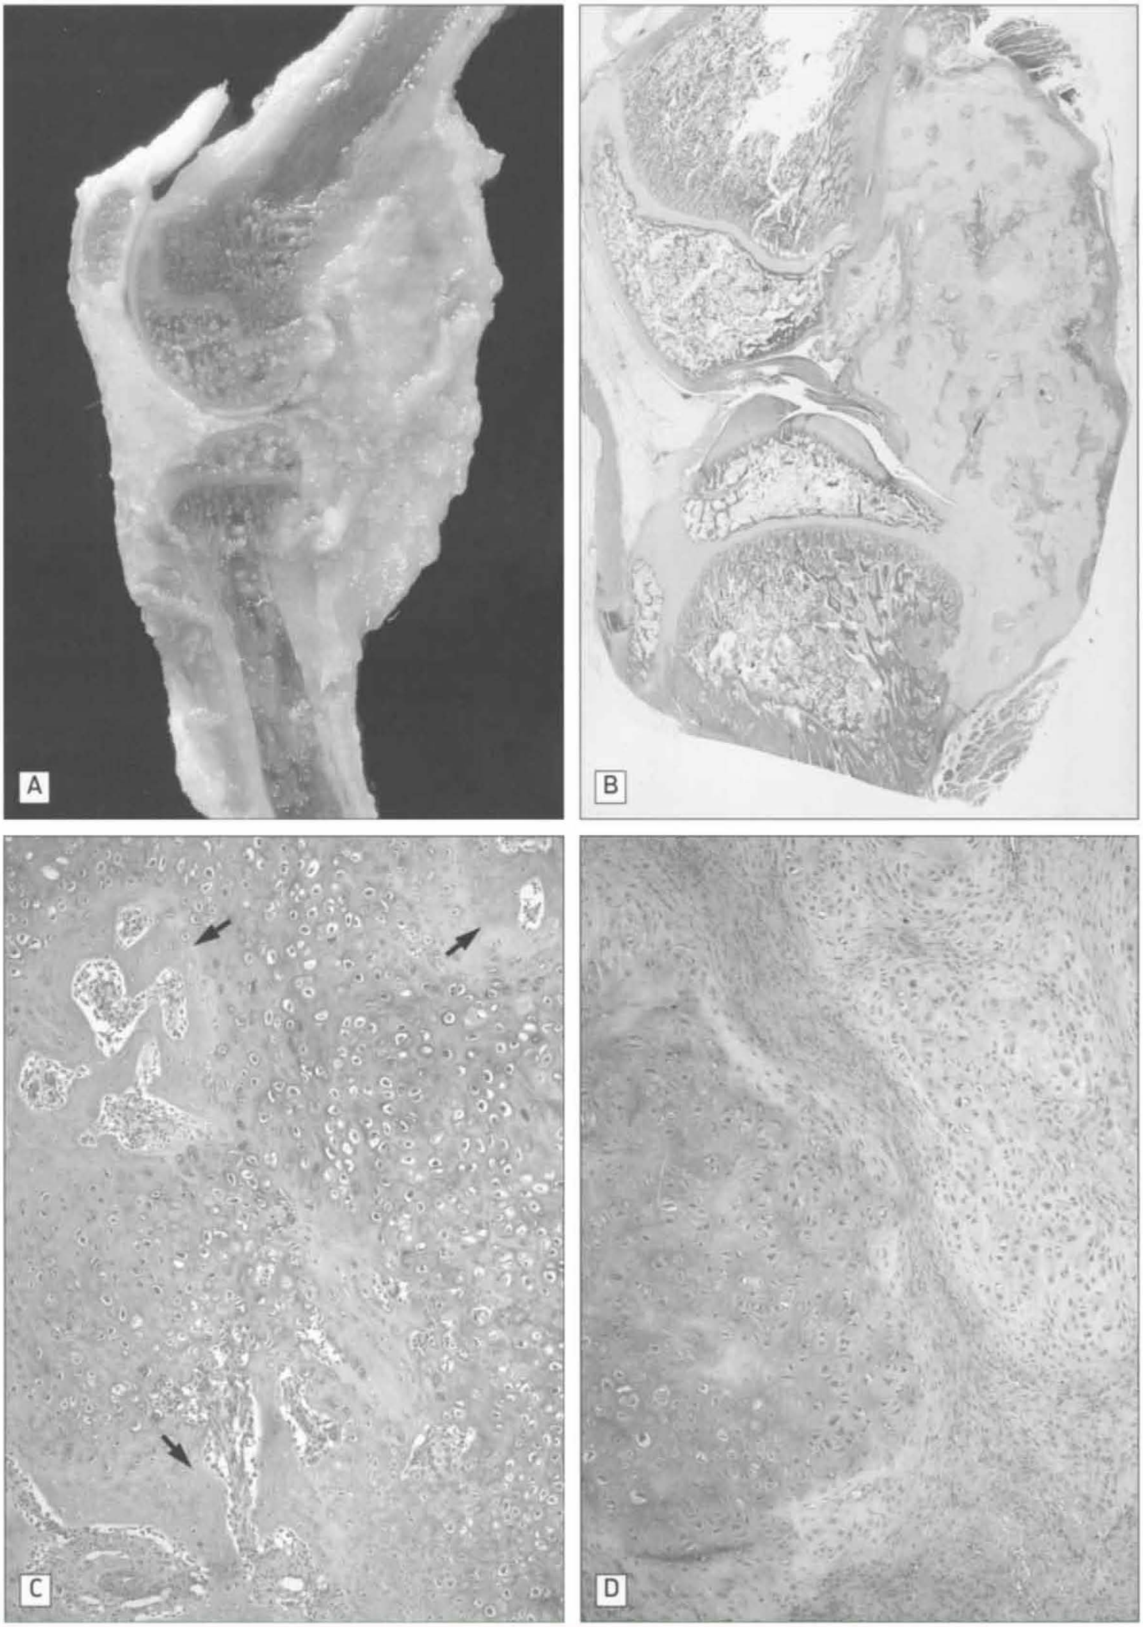

Figure 1.8 Fibrodysplasia ossificans progressiva in a 5-month-old kitten. **A.** Left stifle joint showing massive thickening of the joint capsule on the caudal aspect of the joint with tissue resembling cartilage. Similar lesions involved the right stifle, and several other limb joints. **B.** Subgross preparation of the same lesion, showing a cartilaginous mass bridging the stifle joint and attaching to the cortex of the adjacent femur and tibia in the region of the capsular insertions. **C.** Microscopically, the lesion consists of disorganized hyaline cartilage containing many plump chondrocytes and undergoing multifocal endochondral ossification (arrows). **D.** Biopsy of an early lesion from the same kitten, showing proliferating nodules of disorganized hyaline cartilage with features suggestive of chondrosarcoma.

cartilage, which, in some areas, had microscopic features suggestive of chondrosarcoma (Fig. 1.8C, D). The disease in man is associated with overexpression of at least one of the BMPs and is inherited as an autosomal dominant trait. Although there is no evidence of a genetic etiology in cats, there have been too few reported cases for this to be established.

Myositis ossificans has also been reported in cats and in a dog, but differs from fibrodysplasia ossificans in being *localized and asymmetric*. The lesions characteristically possess a peripheral zone of orderly maturation from fibrous tissue to mineralized osteoid, which is gradually replaced by lamellar bone. The prognosis following surgical removal is very good. Trauma is considered the initiating factor in most human cases of myositis ossificans, and the same probably applies to animals. Ossification of a hematoma may be the mechanism in some cases.

Generalized forms of myositis ossificans have been reported in cats and pigs but may have been more appropriately classified as fibrodysplasia ossificans. The disease in pigs was familial, occurring at 2–6 months of age in 34 of 115 offspring of an affected boar, and was characterized by widespread ossification of soft tissues, especially around vertebrae. The boar had developed similar lesions at 9 months of age.

Ectopic bone may form in lesions that have been mineralized for an extended period, possibly due to metaplasia of cells involved in the initial process of mineralization. This may account for the disseminated foci of metaplastic bone that form occasionally in the skin of dogs with hyperadrenocorticism and calcinosis cutis. Alternatively, the cutaneous osseous metaplasia in such cases may be due to local production of specific growth factors, including TGF-β, FGFs, and BMPs, by inflammatory cells in the dermis. TGF-β has been found in large quantities in inflammatory disorders of the skin of human patients with osteoma cutis, a condition similar to that described in dogs, and has been associated with the differentiation of fibroblastic cells into osteoblasts.

Where ectopic bone forms in close association with or becomes attached to a bone, differentiation of the lesion from a fracture callus or a parosteal osteosarcoma may prove difficult. Depending on its stage of maturation, a fracture callus is likely to contain remnants of cartilage or chondro-osseous bone, while *ectopic bone is composed exclusively of trabecular bone*. In parosteal osteosarcoma, the spaces between trabeculae will be populated with mesenchymal cells showing features of malignancy, rather than a single layer of osteoblasts lined up along the surface of bone trabeculae.

BONES AS ORGANS

Development and anatomy

There are two distinct processes by which bone formation occurs in the developing fetus. *Flat bones of the skull develop by* **intramembranous ossification**. Mesenchymal progenitor cells migrate from the neural crest to form condensations at specific, highly vascular, sites in the head region and some other flat bones, where they differentiate directly into osteoblasts and produce anastomosing trabeculae of woven bone. These centers of ossification expand by on-going osteoblastic differentiation of mesenchymal cells at the periphery and apposition of new bone on the surface of trabeculae, to form a plate. A fibrous layer, *the periosteum*, separates the developing membrane bone from adjacent tissues and controls its shape. Individual bones of the developing skull are separated by connective tissue **sutures** until growth ceases, at which time a bony union forms. With maturity, the woven bone is remodeled and replaced by lamellar bone. Intramembranous bone formation also occurs at the periosteal surfaces of all bones during growth.

Most bones of the skeleton, including those of the limbs, vertebral column, pelvis, and base of the skull, develop by **endochondral ossification**. In this process, condensations of primitive mesenchymal cells differentiate into chondrocytes and produce crude cartilage models of the adult bone destined to form at that site. An avascular fibrous layer, the perichondrium, surrounds each cartilage model. As expansion of the model continues by interstitial growth, chondrocytes near the center become hypertrophic, and the matrix undergoes mineralization. Meanwhile, the perichondrium becomes invaded with capillaries, converting it into a periosteum, and a narrow cuff of bone forms by intramembranous ossification around the mid-shaft region of the developing bone. Capillaries and osteoclasts then invade the hypertrophic cartilage from the periosteum and establish a vascular network. Preosteoblasts also enter with the invading capillaries and differentiate into osteoblasts, which deposit osteoid on remnants of the mineralized cartilage, creating a **primary ossification center**. This process of endochondral ossification continues as the chondrocytes at either end of the developing bone continue to proliferate and the model expands in length and width. Once the bone reaches a certain stage of development, **secondary ossification centers** appear at one or both ends (depending on the bone), and expand by endochondral ossification to form the **epiphyses** of long bones. As the epiphyses expand, they remain separated from the primary ossification center, now occupying the **diaphysis** and **metaphysis** of the developing bone, by the **physis** or **growth plate**. Limited growth in size of the epiphysis continues by endochondral ossification beneath

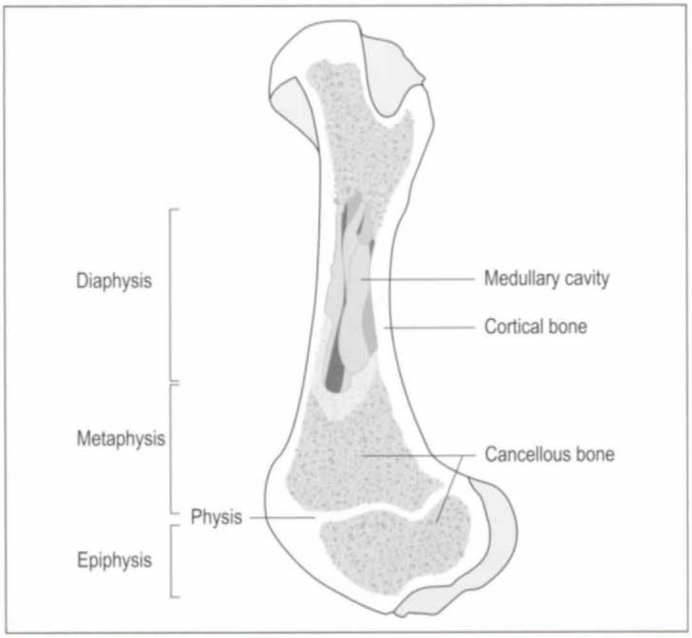

Figure 1.9 Drawing of the femur from a newborn calf, illustrating the **gross anatomy and terminology** of the different regions.

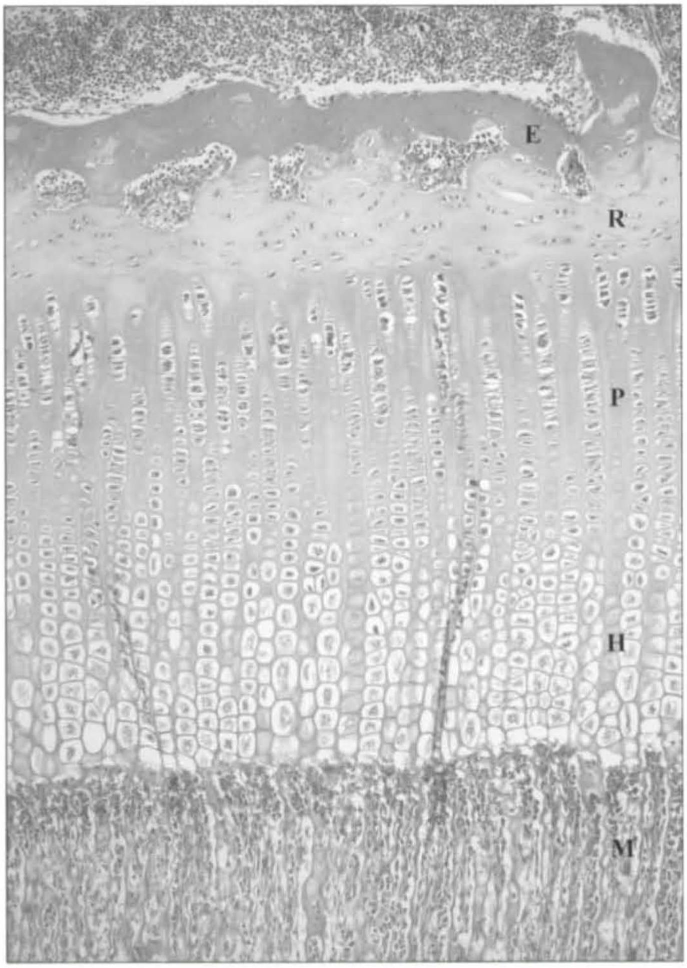

Figure 1.10 Physis or growth plate of a young animal showing the reserve (R), proliferative (P), and hypertrophic (H) zones. The reserve zone is anchored to trabecular bone of the epiphysis (E). Also note the abrupt transition from the hypertrophic zone of the physis to the metaphysis (M).

the articular cartilage at the articular–epiphyseal cartilage complex. The epiphyseal side of the growth plate soon becomes capped by a layer of trabecular bone, preventing further growth from that side, but proliferation of chondrocytes in the growth plate and endochondral ossification on the metaphyseal side continues until maturity. The gross anatomy and terminology of a developing long bone, in this case the femur of a newborn calf, is illustrated in Figure 1.9.

During active bone growth, *the hyaline cartilage of the growth plate is organized into three easily recognizable zones* (Fig. 1.10). A **reserve**, or **resting zone**, with irregularly dispersed chondrocytes and pale-staining matrix, is anchored to the trabecular bone of the epiphysis. The chondrocytes in this zone have the lowest concentration of intracellular ionized calcium, but the matrix has the highest concentration of type-II collagen. In the **proliferative zone**, the chondrocytes are tightly packed into longitudinal columns, the cell at the top being the progenitor cell for longitudinal growth of each column. The chondrocytes in this zone are actively dividing, accumulating glycogen, and synthesizing matrix proteoglycans. The columns of chondrocytes are separated by deeply basophilic cartilage matrix rich in aggregated proteoglycans, which inhibit mineralization in spite of the presence of matrix vesicles. Within columns, only thin matrix septa separate individual chondrocytes. The chondrocytes of the **hypertrophic zone** become enlarged, but remain metabolically active and are responsible for preparing the matrix for mineralization. They rely on anaerobic glycolysis for energy production because of the distance from epiphyseal blood vessels, which terminate at the top of the proliferative zone, and the inability of oxygen to diffuse from the metaphysis through the mineralized matrix of the lower hypertrophic zone. The energy is used primarily in the accumulation, storage, then release of calcium as part of the mineralization process. The lower region of the hypertrophic zone is commonly referred to as the *zone of degeneration*, as the chondrocytes appear to have separated from the pericellular matrix and become degenerate in sections prepared for histology and electron microscopy by routine methods. Following the development of more sophisticated techniques for preparing sections of cartilage for transmission electron microscopy, this concept has been challenged. Rather than being degenerate, these chondrocytes appear to be highly differentiated cells capable of synthesizing type-X collagen, chondrocalcin and other macromolecules that, together with matrix vesicles, are likely to be involved in initiating matrix mineralization. Mineralization of the cartilage matrix occurs in the deepest layer of the hypertrophic zone and is an essential event in the process of endochondral ossification. This mineralized layer is not evident in histological sections prepared after demineralization. The transition from growth plate to metaphysis is abrupt, and is designated by the last intact layer of chondrocytes.

Around the perimeter of the growth plate there is a wedge-shaped groove of cells, termed the **ossification groove of Ranvier**. The cells in this groove proliferate and are responsible for increasing the diameter of the physis during growth. A dense layer of fibrous tissue, the **perichondrial ring of LaCroix**, surrounds the groove of Ranvier and is continuous with the fibrous layer of the periosteum. As such, it provides strong mechanical support at the bone–cartilage junction of the growth plate, an area that is prone to injury in fast-growing young animals.

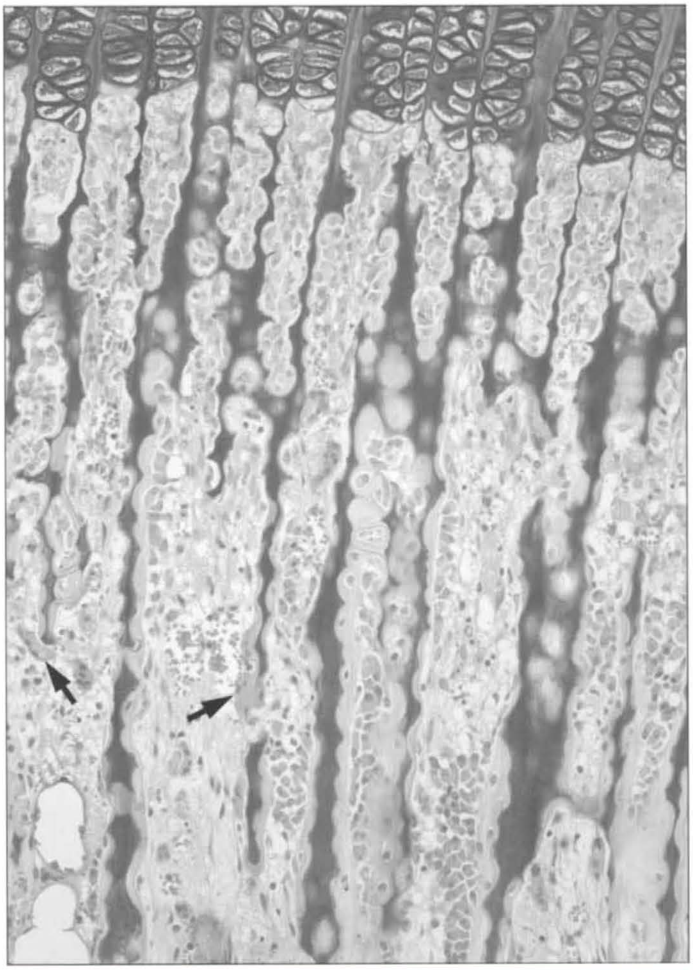

Figure 1.11 Primary spongiosa in a rapidly growing young animal. Basophilic spicules of calcified cartilage matrix extending into the metaphysis at right angles to the growth plate, form a lattice on which osteoblasts are lining up and depositing osteoid. Osteoclasts (arrows) are resorbing some trabeculae from the medullary end.

From the metaphyseal side of the growth plate, osteoclasts attack the mineralized cartilage matrix and rapidly remove the delicate transverse septa between individual chondrocytes within columns, allowing vascular invasion. The thicker longitudinal septa of mineralized cartilage matrix between columns of chondrocytes are not resorbed at this stage. Instead, they provide a framework on which newly differentiated osteoblasts line up and deposit a layer of woven bone (Fig. 1.11). *This lattice of trabeculae, with a basophilic core of mineralized cartilage covered by a thin, eosinophilic layer of bone is termed the* **primary spongiosa.** Trabeculae of the primary spongiosa extend at right angles to the direction of the growth plate, but deeper in the metaphysis, the trabeculae are remodeled by the coordinated action of osteoclasts and osteoblasts and are realigned in directions most suited to withstanding the mechanical forces acting on the bone. During this process, the cartilage cores and woven bone of the primary spongiosa are largely removed and replaced by thicker trabeculae of lamellar bone, which form the **secondary spongiosa.** While growth in length of a bone is continuing from the growth plate, osteoclastic resorption of trabeculae occurs at the metaphyseal–diaphyseal junction in order to *create the medullary cavity.*

The thickness of a growth plate is relatively constant across the width of the bone and is proportional to its rate of growth. So too is the distance to which trabeculae of the primary spongiosa extend into the metaphysis before they are remodeled. As growth slows, the different layers within the growth plate become narrow, and a transverse layer of trabecular bone forms on the metaphyseal side. The cartilage of the growth plate is then replaced with a bony scar, which is gradually remodeled into trabecular bone, blurring the margin between the epiphysis and metaphysis. The timing of growth plate closure varies both between and within bones and is controlled to a large degree by androgens and estrogens, but it is likely that nutritional factors can also play a role. In the radius, the distal growth plate remains open longer, and contributes significantly more to the length of the bone, than the proximal growth plate. In the humerus, femur, and tibia, the opposite is true. *The fastest-growing growth plates are the ones that are most likely to suffer damage due to trauma or nutritional imbalances*, and are therefore worthwhile sites to examine at necropsy, and to sample for histopathology.

The growth in width of the diaphysis in young animals occurs by intramembranous ossification beneath the **periosteum**, *which covers the surface of bones except at their articular ends and at insertion points of muscles and tendons.* The periosteum has a tough outer fibrous layer and a more cellular inner layer, *the cambium*, which contributes preosteoblasts for new bone formation (Fig. 1.12). Where muscle fibers and tendons insert onto bones, dense collagen fibers termed **Sharpey's fibers** become embedded in the bone matrix. The periosteum has a rich supply of nerve endings and blood vessels. *The inner bone surface is lined by a thin layer of osteogenic cells called the* **endosteum.**

Regulation of physeal growth

Many of the systemic hormones and local growth factors that regulate the formation and resorption of bone tissue also influence growth plate function. Their effect may be on a particular zone of the growth plate, and may vary with the age of the animal. **Growth hormone** and its mediators, the **insulin-like growth factors** (IGF-I and IGF-II), act throughout all zones of the growth plate, but **IGF** receptors are most abundant in the proliferative zone, implying a strong influence on cellular proliferation and hence longitudinal growth. **Thyroid hormones** are essential for cartilage growth and the maturation of chondrocytes, and appear to act synergistically with IGF-I. Deficiency of thyroid hormones leads to growth retardation and cretinism. **PTH** acts primarily on the proliferative and upper hypertrophic zones of the growth plate, and has a direct mitogenic effect on chondrocytes, as well as stimulating proteoglycan synthesis. It enhances the mitogenic effect of local growth factors. **Calcitonin** has been shown to accelerate chondrocyte maturation and matrix mineralization. The primary influence of **glucocorticoids** on the growth plate is to inhibit chondrocyte differentiation and proliferation. In young animals, excessive glucocorticoids from either endogenous or exogenous sources result in growth retardation. At physiological concentrations, **androgens** are anabolic factors, stimulating proteoglycan synthesis by chondrocytes in young animals, but they also stimulate mineralization in the growth plate. High doses of androgens actually depress growth and accelerate growth plate closure. **Estrogens**, in general, exhibit an inhibitory effect on longitudinal bone growth, excessive levels leading to premature closure of growth plates.

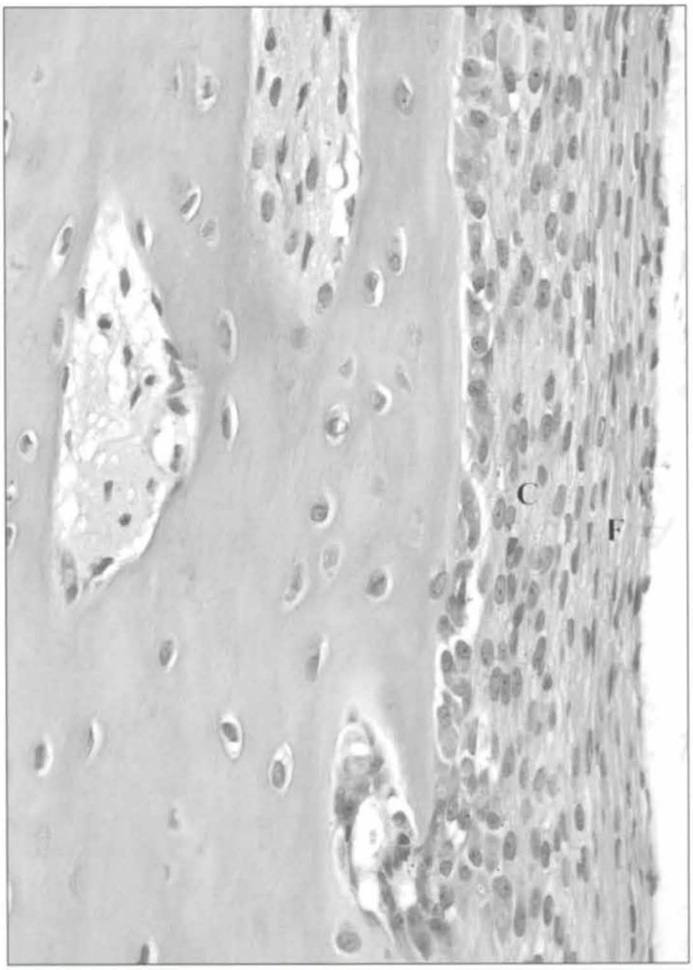

Figure 1.12 Periosteum in an actively growing young animal. Note the outer fibrous layer (F) and the cambium layer (C) containing primitive mesenchymal cells. A single layer of active osteoblasts lines the bone surface.

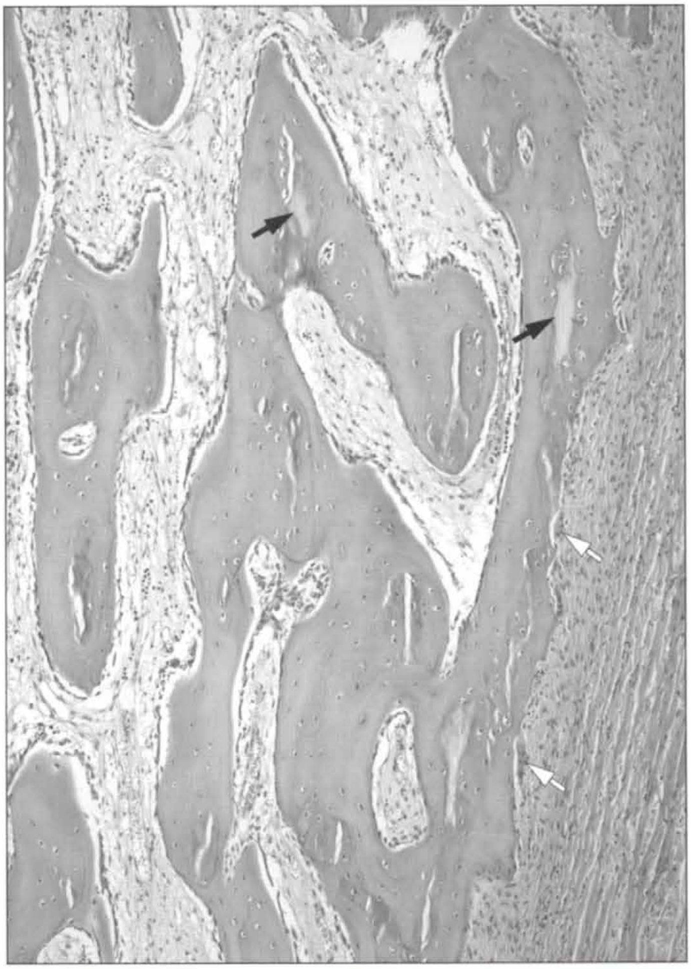

Figure 1.13 Architectural modeling in the metaphysis of a long bone during growth in length. In order to maintain the flare in the metaphyseal region, osteoclasts (white arrows) resorb bone at the periosteal surface, while osteoblasts actively deposit bone along trabeculae of the primary and secondary spongiosa. Trabecular bone of endochondral origin is thus converted into dense cortical bone. The spicules of mineralized cartilage (black arrows) derived from the growth plate persist until the cortex is remodeled.

Replication of chondrocytes is stimulated by several local growth factors, including **TGF-β**, **FGF**, and **epidermal growth factor** (EGF). TGF-β, in addition to its role as a regulator of bone formation, is also involved in the formation of cartilage, and has been shown to be a potent inhibitor of interleukin-1, which induces degradation of growth plate chondrocytes. **Prostaglandins** are present at low levels in the growth plate and although they have been shown to inhibit alkaline phosphatase activity and collagen synthesis while stimulating proteoglycan synthesis, their overall effect on growth plate function in unclear.

Modeling

In order to establish the unique shape of a long bone, extensive architectural **modeling** *occurs throughout the growth phase.* As the bone increases in size, the diameter of the diaphysis increases by deposition of new bone beneath the periosteum and resorption from the endosteal surface. However, growth in length is more complex and involves the coordinated actions of osteoclasts and osteoblasts operating on different bone surfaces. The diameter of most long bones is greatest at the level of the growth plate, then tapers through the metaphyseal region to its narrowest region in the diaphysis. This basic funnel shape is maintained during growth in length by continual osteoclastic resorption beneath the periosteum around the circumference of the metaphysis, thereby reducing its diameter. Meanwhile, osteoblasts rapidly deposit new bone within tunnels between the peripheral trabeculae of the primary and secondary spongiosa, converting it into dense cortical bone (Fig. 1.13). During this process, spicules of mineralized cartilage originating from the growth plate become incorporated into the cortex and will remain there until they are removed by remodeling.

The peripheral metaphysis of a growing long bone is therefore an area of intense osteoclastic and osteoblastic activity. The cortex is relatively porous, consisting of trabecular bone undergoing compaction, and there is extensive peritrabecular fibrosis. This must be borne in mind when examining histological sections from such areas in young animals with suspected metabolic bone diseases, particularly fibrous osteodystrophy.

The normal curvature present in some bones is produced during growth by a modeling process referred to as **osseous drift**, whereby the shaft of a bone moves on its long axis. This is accomplished by successive waves of osteoblastic and osteoclastic activity beneath appropriate periosteal and endosteal surfaces of the diaphyseal cortex,

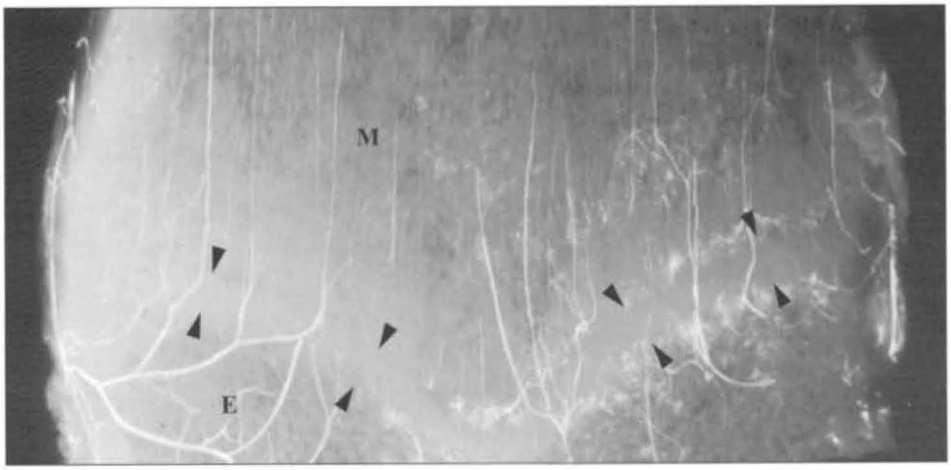

Figure 1.14 Transphyseal blood vessels. Cabinet radioangiogram of a 2 mm thick slice of decalcified distal 3rd metacarpal bone from a 13-day-old foal. The physis is between the arrowheads. The arterial blood supply to this area had been injected with radio-opaque dye immediately after death. Numerous transphyseal arteries can be seen crossing from the epiphysis (E) to the metaphysis (M). (Courtesy of EC Firth.)

presumably under the influence of both genetic and mechanical forces, leading to the formation of laminar bone deposits. The same process is involved in efforts to correct shape abnormalities in long bones resulting from malunited fractures, or other acquired defects altering the mechanical forces acting on a bone.

Bones respond to increased usage during the growth phase by an increase in bone mass, particularly in the density and thickness of the cortex. In adults, increased mechanical usage does not increase bone mass, but can decrease remodeling and conserve the amount of bone already present.

Blood supply

The blood supply to bones is derived from arteries entering the medullary cavity through foramina in the cortices of the diaphysis, metaphysis, and epiphysis, as well as periosteal arteries. In young growing animals, **nutrient arteries** supply the diaphyseal marrow and most of the central area of the metaphysis, while **metaphyseal arteries** supply the peripheral regions. Terminal branches from these vessels pass vertically towards the metaphyseal surface of the growth plate, where they end in fenestrated capillary loops immediately below the last intact transverse septum of the mineralized cartilage matrix. At this point they turn back sharply into wide-bore venules characterized by low flow rate. Some terminal branches of the nutrient and metaphyseal arterial systems anastomose with each other but they do not penetrate the growth plate.

Epiphyseal arteries supply the epiphyses or secondary centers of ossification and small branches pass through narrow cartilage canals in the reserve zone of the growth plate to terminate at the start of the proliferative zone. This is the only source of oxygen and nutrients to the growth plate as no blood vessels terminate in the hypertrophic zone. Further branches of the epiphyseal artery pass to the undersurface of the overlying articular cartilage, where they form vascular loops similar to those on the metaphyseal side of growth plates, and participate in endochondral ossification.

Transphyseal blood vessels have been identified in newborn animals of several species (Fig. 1.14), but their function remains obscure. Most evidence suggests that the direction of arterial flow in these vessels is from the epiphysis to the metaphysis, but that venous flow occurs in the opposite direction. Transphyseal blood vessels do not provide nutrients to the growth plate but may enhance the blood supply to the metaphysis during the rapid growth phase in very young animals. At sites where transphyseal vessels enter the metaphysis, they are surrounded by cartilage projections, which might be expected to strengthen the union between the epiphysis and metaphysis at a time when the growth plate is highly susceptible to shear forces. These vessels may also be involved in certain diseases of bones, such as osteomyelitis, where they provide a possible route for spread of infection across the growth plate. The periphery of the growth plate is supplied by perichondrial arteries to the perichondrial ring of LaCroix, and by metaphyseal arteries.

The blood supply to the bone cortex in young animals is predominantly derived from the endosteal surface by way of nutrient arteries, and the flow of blood within the cortex is centrifugal. Arterial blood enters Haversian systems of the cortex through capillaries communicating with medullary sinusoids, but venous drainage occurs through the periosteal surface. With age, the cortex becomes increasingly dependent on **periosteal arteries** for its blood supply.

POSTMORTEM EXAMINATION OF THE SKELETON

Of all organ systems, the skeleton is perhaps the most neglected during postmortem examination, even by experienced pathologists. Most organs are examined as part of the routine necropsy technique, but examination of the skeleton is more often confined to those occasions where the clinical history clearly indicates a skeletal problem. As a result, many skeletal disorders are likely to be missed. Furthermore, lack of familiarity with the normal appearance of skeletal structures commonly leads to misinterpretation in cases where a skeletal disease is suspected and a detailed examination of the skeleton is performed.

Gross examination

Complete examination of the skeleton is both impractical and unnecessary. A standard procedure for examining the skeleton should include an assessment of the shape, flexibility and breaking strength of readily accessible bones, such as ribs, cranium and key limb bones during routine necropsy. *No skeletal examination is complete without sectioning one or two representative long bones longitudinally* to reveal the growth plates, the thickness of the cortex, and the amount and density of trabecular bone in metaphyseal and epiphyseal regions. When the clinical history suggests the possibility of a skeletal disorder, a more detailed assessment is required. Antemortem radiographs are a valuable component of the gross examination in such cases and may highlight areas requiring special attention. The pathologist should insist on viewing them before commencing the necropsy. Radiographs of lesions identified during necropsy, either in the form of whole bones or sawn slabs, can also provide valuable information on the extent and severity of bone lysis or demineralization, but is an insensitive indicator of diffuse bone loss, as occurs in osteoporosis.

The manifestations of generalized skeletal diseases are likely to be most severe in certain bones. Even within bones, some regions may be affected more severely than others. For example, lesions associated with metabolic bone diseases, such as rickets and fibrous osteodystrophy, will be most marked at sites of rapid bone formation. The growth plates of the distal radius, proximal humerus, distal femur, and proximal tibia should therefore be targeted for gross and histological examination. Costochondral junctions of the largest ribs are also useful sites to examine in such cases. In osteoporosis, the depletion of trabecular bone is more rapid than that of cortical bone, presumably due to the greater surface area available for resorption in trabecular bone tissue.

Histological techniques and stains

Bone specimens for histological processing should be sawn at approximately 5 mm thickness and immersed in neutral buffered formalin. Other than in a few specialist laboratories equipped to prepare undemineralized bone sections, the specimens must then be demineralized prior to sectioning. In most laboratories, this involves the use of *commercial decalcifying agents*, usually consisting of strong acid solutions, which induce decalcification within 24–48 h. In the interests of section quality, the specimen should not be left in the decalcifying fluid any longer than necessary. It is important that bone slabs are no thicker than 5 mm, in order to minimize the time they spend in the fluid. The endpoint for decalcification can be judged by probing the tissue with a needle or by radiography. The decalcified tissue should be immersed in flowing tap water for 2–4 h to remove the acid, which would otherwise interfere with staining procedures. Although strong decalcifying solutions will allow the rapid preparation of sections for diagnostic purposes, they will also cause more tissue damage and may therefore impair interpretation. *Slower decalcification* in a chelating solution such as ethylene-diamine tetra-acetic acid (EDTA), will take approximately 7 days, but enables the preparation of higher-quality histological sections.

The *preparation of undecalcified sections* requires the use of plastic embedding media, such as methyl methacrylate, and a heavy-duty sledge microtome. Several useful staining methods for undemineralized bone sections are available, including hematoxylin and eosin, Von Kossa, and Villanueva's bone stain.

Hematoxylin and eosin is also a good general-purpose stain for routine histological examination of demineralized bone sections, allowing clear differentiation of bone and cartilage matrices, and providing adequate cellular detail. However, it does not reliably allow assessment of the thickness of osteoid seams, which is of diagnostic significance in diseases such as rickets or osteomalacia. These seams generally appear pale orange/pink, in contrast to the slightly more basophilic bone that was previously mineralized, but the distinction is often too subtle or variable to allow confident interpretation. The Masson's trichrome method is another useful general-purpose stain for bone sections, but has similar limitations with regard to identifying osteoid seams. Staining methods that allow identification of unmineralized osteoid in demineralized sections have been published (see Ralis and Ralis, 1975 and Tripp and MacKay, 1972 in bibliography) and, although not used routinely, can be easily performed in laboratories that are unable to cut undemineralized sections.

Preparation artifacts in histological sections

Because of the difficulty in preparing histological sections from bones, artifactual changes are often present and could be misinterpreted as lesions. During the process of sawing bones prior to demineralization, multiple small, irregular-sized fragments of *bone "sawdust"* and soft-tissue debris often become embedded in spaces between bone trabeculae (Fig. 1.15). Such fragments are commonly misinterpreted as necrotic bone. Rinsing the cut surface of the bone under running water, and gently brushing it before fixation, can minimize this artifact. Since the fragments will be most abundant near sawn surfaces, further trimming of the face to be sectioned, after demineralization, will further reduce them. In a section where "sawdust" is a problem, slicing deeper into the paraffin block is likely to yield cleaner sections for examination.

The heat generated by a band saw, or power drill in the case of bone biopsies, may create coagulative changes, resembling early ischemic necrosis, along the edges of the specimen. Overexposure to strong acid solutions during decalcification inhibits the staining of nucleic acids by hematoxylin, and of collagen by eosin, resulting in poor cellular detail and difficulties in interpretation.

Another common histological artifact is the presence of empty clefts between bone surfaces and the soft tissues of the marrow cavity. This reflects the much greater shrinkage of the soft tissues, when compared to bone, during

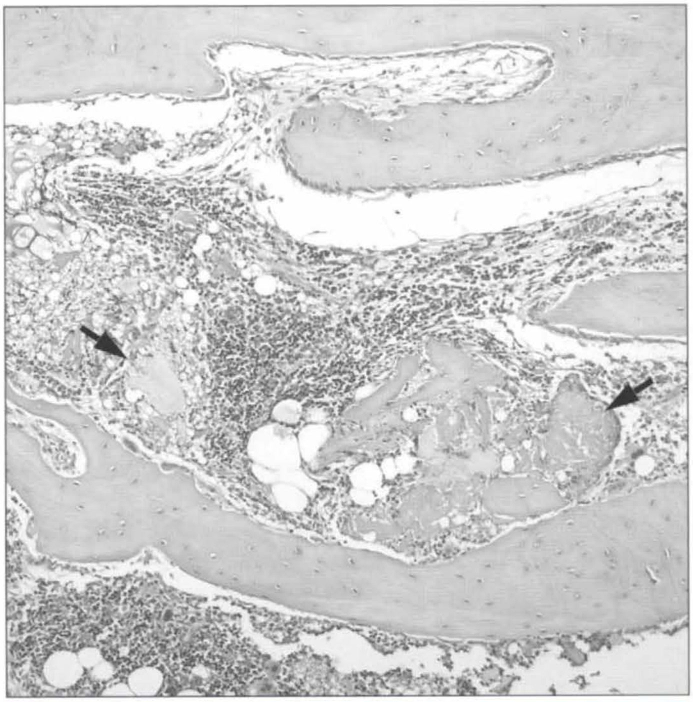

Figure 1.15 The multiple small fragments of bone and cartilage (arrows) embedded in the marrow spaces between trabeculae are **artifacts of sawing** ("sawdust") and should not be misinterpreted as lesions. Such artifacts are commonly present if sections are prepared too close to a sawn surface.

fixation in formalin. Consequently, osteoblasts or osteoclasts lining the bone surface may become separated from their site of activity. However, where bone resorption has been occurring, the surface of the bone will have a characteristic scalloped appearance. Also, bone does not adhere to microscope slides as well as soft tissues of the marrow spaces and may become dislodged, leaving large spaces lined by osteoblasts. These could be misinterpreted as vascular spaces.

Other laboratory techniques

The use of technetium labeling to identify areas of metabolically active bone, detected by scintigraphy, has dramatically improved the ability to detect bone abnormalities in the live animal. This technique greatly assists in locating multifocal lesions, such as the spread of metastatic disease within the skeleton, and although widely used in human medicine, has a relatively limited use for this purpose in animals.

A variety of other techniques may be used in the study of bones, but most are confined to the research laboratory. **Bone ash** measurements have historically been performed in animals with suspected metabolic bone diseases, but are of limited value for routine diagnosis because of the variability between individual bones and the lack of reliable reference ranges for animals of different age groups. More sophisticated and accurate methods for determining **bone density**, such as dual energy X-ray absorptiometry (DEXA scanning), have been developed for assessing bone mineral density in human patients, but are not readily available to most veterinary pathologists.

Microradiography of thick sections provides an indication of the pattern and degree of mineralization within the bone. Sections of bone, 60–100 μm thick, are placed in close contact with X-ray film and exposed. This creates an image of the bone section, which can be examined microscopically in association with histological sections prepared from the same slab.

The periodic administration to growing animals of **fluorescent markers**, which are deposited at sites of active mineralization, allows objective measurement of the rate of bone formation in physiological and disease states. The most commonly used marker is the antibiotic **tetracycline**, which fluoresces bright yellow when examined in undemineralized sections under UV light. Since the marker is only deposited at sites of active mineralization, a thin fluorescent line results from each dose. The distance is measured between lines representing sequential periods of exposure to the marker, and the rate of bone formation estimated.

RESPONSE TO MECHANICAL FORCES AND INJURY

The cells of bone tissue are capable of the same basic cellular responses as most other tissues, including *atrophy, hypertrophy, hyperplasia, metaplasia, neoplasia, degeneration, and necrosis*. Bones have an excellent capacity for repair or modification in response to a wide range of injurious stimuli or changes in mechanical demand. Depending on the stimulus, the response may be localized or generalized but, in general, the magnitude of skeletal response is greater in young growing animals than in adults. If the response is generalized, it is likely to be most prominent at sites of rapid bone growth or modeling.

Mechanical forces

Bone adapts or remodels in response to the mechanical demands placed upon it. According to **Wolff's law**, *it is deposited at sites where it is required and resorbed where it is not*. For example, trabeculae in the epiphyseal and metaphyseal regions of long bones are aligned in directions which best reflect the compressive forces associated with weight bearing, and the tension associated with muscle insertions. In young individuals, increased mechanical stress on the skeleton increases the density of metaphyseal trabecular bone and the thickness of cortices. Increased mechanical usage in adults does not lead to an increase in bone mass, but reduces remodeling activity and conserves the amount of bone already present. Decreased activity accelerates bone loss by removing the inhibition of remodeling, and reduces formation, leading to a net reduction in bone mass.

Reduced mechanical stress on bones due to partial or complete immobilization, as occurs during fracture repair, leads to increased resorption, resulting in decreased bone strength and stiffness. If an implant, such as a metal plate, remains attached to a bone after a fracture has repaired, it will share the mechanical load with the bone. The bone will then atrophy in proportion to the decreased load and its strength will be greatly reduced. For this reason, *rigid implants should be removed soon after a fracture has healed*. Such implants may also trigger the development of an osteosarcoma at the site (see below), providing further reason for their removal.

Prolonged weightlessness associated with space travel has also been shown to result in decreased bone mass in weight-bearing bones. In contrast, increased mechanical stress associated with strenuous exercise has been associated with increased bone density.

Growth plate damage

In young growing animals, the growth plate is the weakest structure in the ends of long bones and is prone to traumatic injury resulting from shearing forces, compressive forces, or, in the case of traction epiphyses (e.g., lesser trochanter of the femur), excessive tension. In general, *the fastest growing growth plates are the most susceptible to injury*, the distal radial physis being the most commonly affected. Undulations in the growth plates of some bones increase their resistance to separation in response to shearing forces.

The consequences of growth plate injury depend on several factors, including the nature of the lesion, its location, the age of the animal and the status of the blood supply. Growth plates subjected primarily to traction consist at least partly of fibrocartilage, which imparts increased resistance to tensile forces. Such growth plates are sometimes referred to as **apophyses**.

Complete separation through the growth plate, referred to as **epiphyseolysis** (or "slipped epiphysis"), is a relatively common sequel to severe trauma or horizontal shear forces acting in the region of the bone–growth plate interface. The separation almost invariably occurs through the hypertrophic zone, where the cell volume is greatest and the matrix, which provides strength to the physis, is relatively sparse. Providing the epiphyseal vasculature has not been disrupted, the prognosis for this type of fracture is very good as the proliferative zone of the growth plate, and its blood supply, are likely to remain intact. However, epiphyseolysis of the capital femoral epiphysis, which may be associated with birth trauma in calves and occurs with some frequency in growing foals and puppies, may result in avascular necrosis of the femoral head. This reflects the greater risk of vascular damage as the nutrient vessels to the proximal femoral epiphysis travel along the neck of the femur and traverse the rim of the growth plate. The vessels supplying most other long bone epiphyses enter the bone at some distance from the growth plate and are protected by the periosteum or the fibrous layer of the joint capsule. A syndrome characterized by physeal dysplasia and slipped capital femoral epiphysis has been described recently in cats (4.5–24 months of age), most of which were male and obese. The Siamese breed was over-represented. In affected cats, the physeal cartilage was abnormally thick and chondrocytes were in disorganized clusters surrounded by abundant matrix. A similar syndrome is recognized in adolescent, overweight boys. Epiphyseolysis of the femoral head also occurs in pigs and deer as a manifestation of osteochondrosis, where there is likely to be an underlying weakness in the growth plate. Slipped capital femoral epiphysis must be distinguished from Legg–Calvé–Perthes disease and fractures through the femoral neck.

The *most common type of physeal fracture* reported in dogs, cats, horses, and humans, is characterized by extension of the fracture along the growth plate for a variable distance, then out through the metaphysis, leaving a triangular fragment of metaphyseal bone still attached to the growth plate. As with complete epiphyseolysis, the prognosis for further growth is very good. In contrast, fractures that cross the growth plate, with displacement of the fragments, will lead to the formation of a bony bridge between the metaphysis and epiphysis, precluding further growth in length at that site.

It is relatively common for epiphyseal separations, similar to those described above, to be induced during postmortem examination of young animals when limb joints are disarticulated forcefully. Such "fractures" are not accompanied by hemorrhage and are therefore easily distinguished from antemortem epiphyseolysis.

Growth plates of major limb bones, particularly the distal radius and ulna, are also susceptible to crushing injuries caused by compressive forces transmitted through the epiphysis. Such injuries, if severe enough, damage the epiphyseal blood supply as well as chondrocytes in the proliferating zone, leading to cessation of growth. *When the lesion is confined to one side of the growth plate, as it often is, continued growth on the other side leads to* **angular limb deformity**.

In dogs, *premature closure of the distal ulnar growth plate* is a common cause of limb deformity. Shearing forces acting on this growth plate result in crushing injury rather than epiphyseolysis, because of its conical shape, and are therefore more likely to result in retarded growth. If the growth plate of the adjacent radius escapes injury, the required synchrony between the two bones during development will be disturbed. Shortening of the limb will be accompanied by cranial bowing of the radius, valgus deformity, and outward rotation of the carpal and metacarpal bones.

Angular limb deformities ("bent leg") have been associated with a range of disease syndromes in several species, and are not always due to growth plate lesions. These will be discussed separately in a later section of this chapter.

Detachment of the ischial tuberosity from the pelvis is a well-recognized entity in young breeding sows, resulting in acute lameness. The separation, which may be bilateral, usually occurs between 8 and 14 months of age, prior to the closure of the apophyseal growth plate between the tuber ischiadicum and the rest of the ischium. The tuber ischiadicum serves as the origin for the semitendinosus and semimembranosus muscles, and as an attachment for the sacrotuberous ligament. As such, it is subject to considerable traction force and any weakness in the growth plate, as may occur in osteochondrosis, predisposes it to fracture.

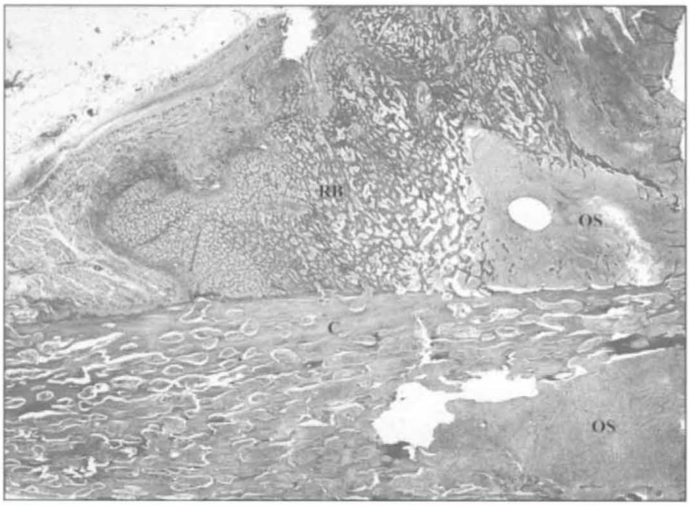

Figure 1.16 Reactive bone (RB) forming a so-called **"Codman's triangle"** beneath an elevated periosteum in a dog with osteosarcoma. The cortex (C) is porous due to tumor invasion. Sheets of tumor cells (OS) fill the medullary cavity and are replacing the sub-periosteal new bone in some areas.

Periosteal damage

Periosteal damage due to trauma stimulates rapid formation of new or **reactive bone** following activation and proliferation of osteoblast progenitors in the cambium layer. Trabeculae of woven bone extend from the underlying bone surface at acute angles, and can be readily distinguished histologically from the mature lamellar bone of the cortex (see Fig. 1.5). Separation of the periosteum from the bone surface by hemorrhage, inflammatory exudate, or neoplasia, or following surgical intervention, is also followed by *sub-periosteal new bone formation.* A pyramid-shaped region of new bone, referred to as **Codman's triangle**, may form beneath the periosteum in association with osteosarcoma (Fig. 1.16), but can also occur in association with other bone lesions, such as osteomyelitis. The mechanism of periosteal new bone formation is not clear, but it often precedes actual involvement of the periosteum by an underlying osteosarcoma or inflammatory process, suggesting that it may involve either local circulatory disturbances or the release of growth factors in response to bone resorption.

Localized outgrowths of new bone beneath the periosteum are referred to as **exostoses**. Depending on their size, and the inciting cause, they may either persist or gradually be removed by remodeling.

Fracture repair

Bone fractures are very common in animals and occur either when a bone is subjected to a mechanical force beyond that to which it is designed to withstand, or when there is an *underlying disease process that has reduced its normal breaking strength.* The latter is referred to as a **pathological fracture** and unless the predisposing disorder is corrected then the repair process is unlikely to be successful. The possibility of a localized bone disease (e.g., neoplasia or osteomyelitis) or a generalized disorder (e.g., fibrous osteodystrophy or osteoporosis) should always be considered if bone fracture has occurred without evidence of trauma.

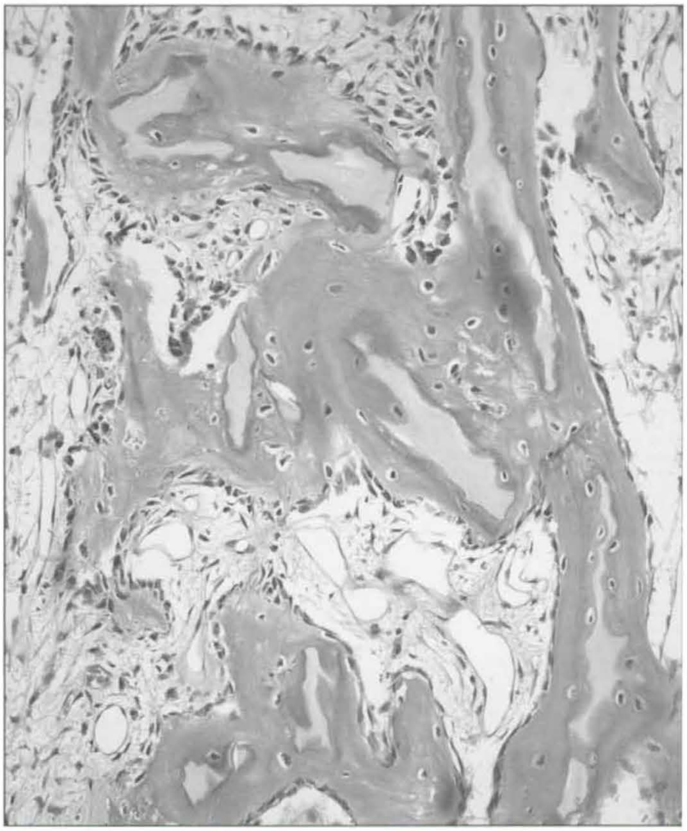

Figure 1.17 Trabecular microfractures in a calf with **osteogenesis imperfecta**. Note the abnormal alignment of cartilage cores in adjacent trabeculae that have been incorporated in a microcallus.

Types of fractures

Fractures are classified as **simple,** if there is a clean break separating the bone into two parts, or **comminuted**, if several fragments of bone exist at the fracture site. When one segment of bone is driven into another the fracture is referred to as an **impacted** fracture, and when there is a break in the overlying skin, usually due to penetration by a sharp fragment of bone, the fracture is referred to as **compound**. If there has been minimal separation between the fractured bone ends, and the periosteum remains intact, the lesion is classified as a **greenstick** fracture. An **avulsion** fracture occurs when there is excessive trauma at sites of ligamentous or tendinous insertions and a fragment of bone is torn away.

Microscopic fractures of individual trabeculae, or localized segments of cortical bone, also occur and are referred to as **microfractures**. Trabecular microfractures can sometimes be detected in histological sections by the abnormal alignment of their cartilage cores, which are normally situated at right angles to the growth plate, and parallel to the cartilage cores of adjacent trabeculae (Fig. 1.17). Such microfractures must however be differentiated from artifactual alterations in trabecular alignment that may occur when a bone is being sawn during processing. Once trabeculae have lost their cartilage core through remodeling this does not apply, and since the direction of remodeled trabeculae is less predictable, detection of microfractures is more difficult. *Multiple microfractures involving several adjacent trabeculae without gross displacement of the bone ends are referred to as* **infractions.** These are sometimes seen

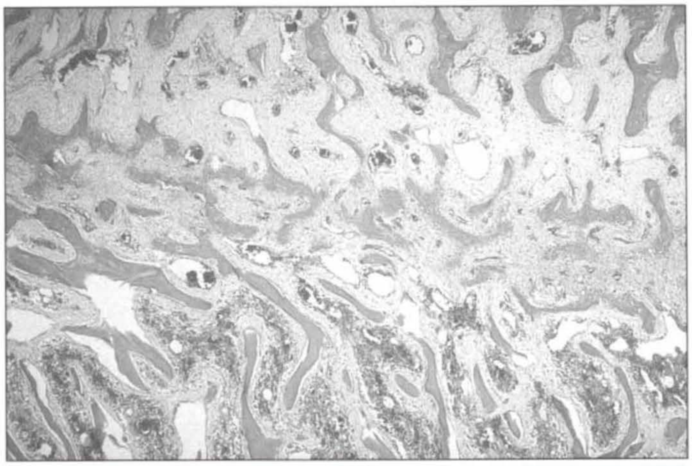

Figure 1.18 Infraction line in the metaphysis of a young pig with fibrous osteodystrophy. The abnormal alignment of trabeculae across the center of the field represents a band of healed trabecular microfractures.

in association with weight bearing on bones weakened by an underlying disease process, such as fibrous osteodystrophy (Fig. 1.18). Repeated bone trauma associated with strenuous exercise may lead to a **stress** fracture in the cortex of a limb bone. This represents the accumulation of several cortical microfractures, rather than a single traumatic event, and is typically seen in the dorsal or dorsomedial cortex of metacarpal III in young racehorses when they first enter training (see below).

Process of fracture repair

Unlike most other tissues, bone is capable of repair by regeneration rather than scar formation and successful repair of a fracture can return the bone both to its original shape and strength. The process of fracture repair follows a consistent pattern, but can be modified by methods of stabilization and by interfering factors, such as infection or the presence of an underlying bone disease.

The initial event in uncomplicated fracture repair is the *formation of a hematoma* between the bone ends. With disruption of the blood supply, *ischemic necrosis of bone* and other tissues in the vicinity of the fracture is inevitable. An *acute inflammatory response* is triggered by mediators released from the hematoma and from necrotic tissues. Inhibition of this inflammatory phase by anti-inflammatory drugs has been shown to interfere with the natural process of fracture repair. Although neutrophils and macrophages are the first cells to arrive at the fracture site, mesenchymal cells from the medullary cavity, endosteum, and cambium layer of the periosteum rapidly proliferate in and around the hematoma, forming a **callus** consisting initially of loose connective tissue. Subperiosteal new bone formation commences on the bone surface adjacent to the bone ends while primitive mesenchymal cells in the fracture gap differentiate into chondroblasts and replace the loose connective tissue with chondroid matrix. Meanwhile, osteoclasts appear and start to remove the dead bone. Osteoblasts producing new bone have been identified ultrastructurally in the medullary callus as early as 24 hours after fracture. Evidence suggests that at least some of these osteoblasts may be derived from transformed endothelial cells from capillaries and small venules in the vicinity of the fracture.

The early callus, consisting predominantly of hyaline cartilage, forms very rapidly and serves to anchor the fractured bone ends, allowing limited function while the repair process continues. As revascularization of the fracture site occurs, endochondral ossification within the callus leads to progressive replacement of the cartilage by trabeculae of woven bone. The *development of a bony callus* further stabilizes the fracture and allows a return to normal function, although the repair process continues. The *final phase* may take several months, or even years, and *involves the replacement of woven bone in the callus with mature lamellar bone*, and modeling of the callus to eventually restore the bone to its original shape. Once this process is completed, the strength of the bone will also be returned to its previous state. Modeling of the callus is more rapid in young animals than in adults and is more likely to result in complete resolution. In adults, residual changes such as persistence of medullary trabeculae and thickening of the periosteal bone surface are likely to persist at the fracture site.

The size of a fracture callus is proportional to the amount of movement between the fractured bone ends. Where there is considerable movement, callus formation will be exuberant, and may create diagnostic problems for the pathologist, especially in cases where the clinical history is incomplete and radiographs of the lesion are not available. In the early stages of callus formation the abundance of pleomorphic spindle cells, sometimes exhibiting primitive osteoid formation, can easily be misinterpreted as an osteosarcoma in biopsy specimens (Fig. 1.19). As the callus matures, a more organized pattern develops, with osteoblasts lining up along trabeculae of woven bone and the cells between trabeculae appearing less primitive. It must be remembered that an underlying osteosarcoma could have predisposed the bone to fracture and the two processes may in fact be present.

In fractures in which the separated ends have been perfectly aligned, and rigidly immobilized by metal plates or other methods of fixation, callus formation is minimal, or even nonexistent. The repair process in this situation is more protracted as it relies on the process of internal remodeling, whereby resorption canals form across the fracture line in the apposed cortices and new osteons are created. This is referred to as **primary cortical healing**.

There seems little doubt that local and systemic regulators of bone growth influence fracture repair, but their precise role has yet to be determined. Platelet-derived growth factor, transforming growth factor-β, fibroblast growth factor and bone morphogenetic proteins are released from the hematoma and necrotic bone soon after a bone fractures. These factors are important in regulating normal bone formation and resorption (see above) and are believed to play an important role in the modulation and coordination of callus formation during fracture repair. The possible therapeutic use of such growth factors in enhancing fracture repair is an exciting area of current research.

Complications of fracture repair

The repair process does not always proceed smoothly. In comminuted fractures, *fragments of necrotic bone that are too large for removal by osteoclastic resorption may persist at the site and interfere with the healing process*. Such bone fragments are referred to as **sequestrae**. The repair of compound fractures may be delayed by the development of bacterial osteomyelitis following contamination of the fracture site through the open skin wound. Failure to control the

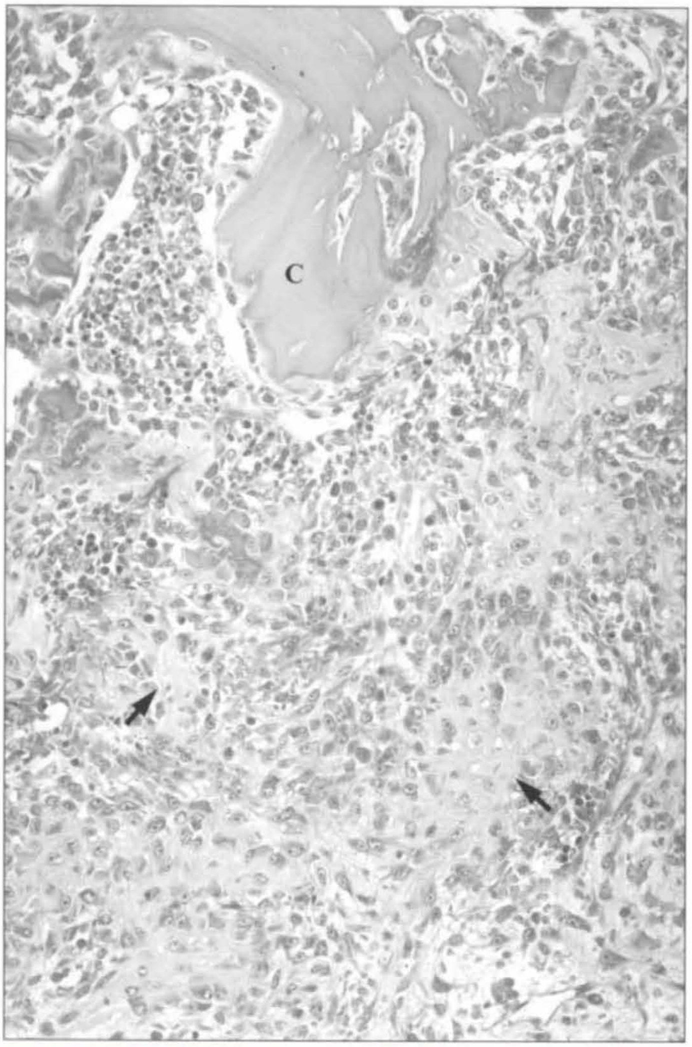

Figure 1.19 Repairing fracture at 1 week Disorganized condensations of plump mesenchymal cells are producing osteoid (arrows) in a manner similar to that which occurs in some osteosarcomas. A fragment of pre-existing cortical bone (C) is still present and serves as an attachment site for some of the newly formed bone spicules.

infection in the early stages will interfere with new bone formation and the resorption of dead bone. If the infection becomes chronic, new bone may form at the margin of healthy and diseased tissue in an attempt to wall off the infected area. The result may be the development of a large callus containing pockets of infection or fistulae surrounded by granulation tissue and trabecular bone. Any large fragments of bone engulfed by the inflammatory process are likely to persist as sequestrae, causing irritation, delayed healing, or nonhealing.

Excessive movement between bone ends during the repair process may inhibit the formation of a bony callus by continually disrupting attempts at revascularization. This favors the formation of cartilage and fibrous tissue and may lead to the development of a false joint or **pseudoarthrosis** at the fracture site. A pseudoarthrosis may also develop if soft tissues separate the fractured bone ends or if persistent infection inhibits callus formation.

Generalized skeletal disorders or deficiencies of nutrients crucial to bone formation will inevitably delay or prevent fracture repair, and must be corrected if normal healing is to proceed. Certain drugs, for example corticosteroids, can also interfere with bone healing.

Stress-related lesions in horses

A spectrum of stress-related lesions, including **bucked shins** and **incomplete cortical fractures**, *commonly affect the dorsal cortex of the third metacarpal bone in young sport horses*, particularly Thoroughbreds or Quarter Horses, undergoing intensive training for their first season of racing. Estimations of prevalence for bucked shins vary from 30–90% of all young horses in training. *Incomplete cortical fractures (so-called saucer fractures)* usually occur several months after the initial signs of bucked shins. Both lesions affect the left third metacarpal bone more often than the right, but they may be bilateral.

Bucked shins is characterized by the formation of smoothly contoured foci of periosteal new bone on the dorsal aspect of the metacarpal bone, accompanied by pain and swelling. For many years, bucked shins was considered to be the result of fatigue injuries leading to microfractures in the dorsal cortex of the metacarpal bone, with subsequent callus formation. This seems unlikely, as the extent of new bone formation is in excess of what would be expected as a response to such microfractures with negligible bone displacement and instability. Recent studies have suggested an alternative hypothesis. According to this hypothesis, repeated high-strain fatigue during training or racing decreases bone stiffness. This *then induces the formation of reactive bone on the periosteal surface in an effort to increase the inertial properties of the bone and increase its resistance to bending*, as would be predicted by Wolff's law.

Incomplete cortical fractures (stress or saucer fractures) seldom occur in horses that have not previously had bucked shins, suggesting that the conditions are related, but only about 12% of horses with bucked shins eventually develop such fractures. They usually occur 6–12 months after the onset of bucked shins and involve the periosteal new bone that forms on the dorsal or dorsolateral aspect of the third metacarpal. Until this bone is remodeled and strengthened, it is susceptible to fatigue injury during the high-strain cyclic loading associated with training or racing. Failure of the bone may be in the form of many small saucer-shaped stress fractures, extending part way into the cortex before returning to the surface.

Stress-related lesions are often found incidentally in the **distal condyles** of the third **metacarpal** and **metatarsal** bones of Thoroughbred racehorses. Linear defects in the articular cartilage adjacent to the sagittal ridge are closely related to increased density of the subchondral bone and to intense focal remodeling of the bone immediately adjacent to the articular defects. These changes are presumably a response to increased strain associated with training and may predispose to condylar fractures.

SKELETAL DYSPLASIAS

A variety of genetic abnormalities primarily affecting bone formation or remodeling have been reported in humans and domestic animals. These are collectively known as skeletal dysplasias and are *usually associated with short stature, abnormally shaped bones, and/or increased bone fragility*. Not surprisingly, human skeletal dysplasias have been subjected to much greater scientific scrutiny than those in animals, leading to the development of detailed and sometimes confusing systems of classification, based on their radiographic appearance, the bones involved, age of onset, or pathogenesis. A comprehensive international classification system for skeletal dysplasias, proposed in 1991, includes well over 100 entities. Advances in molecular biology will inevitably lead to the development of a more precise classification system based on the actual genetic defect. Already, the mutations underlying several human skeletal dysplasias have been identified and it is now apparent that some disorders previously thought to be separate entities, are merely examples of variable expression of the same genetic defect. Skeletal dysplasias of animals are seldom investigated in as much detail as their human counterparts and classification is often imprecise, but it is clear that a similar range of conditions exist, creating opportunities for the development of potentially useful animal models. Studies in animals, particularly laboratory mice, are already proving valuable in helping to identify the molecular basis of inherited disorders of the skeleton and other body systems. Such studies may also generate new information on the role of specific proteins in bone function and physiology.

The diversity of skeletal dysplasias reflects the complexity of the processes involved in bone formation and remodeling, and the large number of genes required for normal development. In some dysplasias the entire skeleton is involved, while in others the defect is confined to individual bones or regions within bones. The terminology generally reflects either the distribution of lesions or the nature of the defect. Some examples of commonly used terms are listed in Table 1.2.

Most skeletal dysplasias in animals are usually either lethal or semi-lethal, but the gene frequency of some disorders in some breeds, has reached surprisingly high levels. This most likely reflects either inbreeding, or excessive use of a sire carrying a defective gene. The latter has clearly been responsible for the very high prevalence reached by certain genetic diseases in cattle, where artificial breeding is widely practiced.

Table 1.2 Terminology of some congenital abnormalities in skeletal development

Term	Nature of the defect
Generalized	
• Achondroplasia	— absence of cartilage development
• Chondrodysplasia	— Disordered cartilage development
• Osteogenesis imperfecta	— Genetic defect in type-I collagen formation characterized by osteopenia and excessive bone fragility
• Osteopetrosis	— Persistence of primary and/or secondary spongiosa due to defect in osteoclastic bone resorption
• Skeletal dysplasia	— Disordered skeletal development
Head	
• Brachycephalic	— Shortening of the head
• Brachygnathia	— Abnormally short jaw (inferior or superior)
• Campylognathia	— Harelip
• Palatoschisis	— Cleft palate
• Prognathia	— Abnormal projection of the jaw
Spine	
• Kyphosis	— Abnormal dorsal curvature of the spinal column
• Lordosis	— Abnormal ventral curvature of the spinal column
• Scoliosis	— Lateral deviation in the spinal column
Limbs	
• Amelia	— Absence of one or more limbs
• Hemimelia	— Absence of the distal part of a limb
• Micromelia	— Presence of abnormally small limbs
• Notomelia	— Accessory limb attached to the back
• Peromelia	— Congenital deformity of the limbs
• Phocomelia	— Absence of the proximal portion of one or more limbs
Digits	
• Adactyly	— Absence of a digit
• Dactylomegaly	— Abnormally large digits
• Ectrodactyly	— Partial or complete absence of a digit
• Polydactyly	— Presence of supernumerary digits
• Polypodia	— Presence of supernumerary feet
• Syndactyly	— Fusion of digits

Not all skeletal abnormalities are caused by genetic defects. Exposure of developing fetuses to certain toxic principles, mineral deficiencies, or infectious agents at appropriate stages of gestation can create skeletal lesions virtually indistinguishable from those with a genetic etiology. For the veterinary pathologist, it is as important to accurately determine the cause of the problem as it is to characterize the lesions. Otherwise valuable stud animals may be slaughtered unnecessarily or teratogenic agents may go undetected. In this section, discussion will focus on those skeletal dysplasias of domestic animals that are known, or strongly believed, to be genetic in origin. Acquired skeletal abnormalities will be discussed in a later section.

Generalized skeletal dysplasias

Several important generalized disorders of bones are recognized in animals, all of them having analogous human counterparts. The underlying defect may lie in the formation of cartilage, thus affecting all bones that form by endochondral ossification. Such disorders are referred to as **chondrodysplasias** and affected individuals, no matter what the species, usually *show various degrees of dwarfism.* The term **achondroplasia** is often used in place of chondrodysplasia to describe diseases characterized by *disproportionate dwarfism,* especially in human medicine, and although it is less accurate, the term is entrenched in the literature. Alternatively, the defect may involve the synthesis of a specific component of bone matrix, e.g., type I collagen, as occurs in **osteogenesis imperfecta**. A defect in bone remodeling is the mechanism involved in another group of skeletal dysplasias, the **osteopetroses**. Only those disorders reported in domestic animals are included in this section but from time to time, the veterinary pathologist will be confronted with bone deformities that do not resemble any of the syndromes currently recognized in animals. In such cases, reference to the substantial human literature on skeletal dysplasias may be useful.

Chondrodysplasias

The *dwarfism of the chondrodysplasias is disproportionate,* in contrast to the proportionate or primordial dwarfism associated with somatotropin deficiency. Primordial dwarfism is usually inherited as a recessive trait and is well recognized in horses and dogs, where it forms the basis of several distinct breeds, e.g., Miniature Poodle. The chondrodystrophic dog breeds, e.g., Dachshund, Pekingese, and Basset Hound, are actually variant forms of disproportionate dwarfs. These forms of chondrodysplasia are inherited as polygenic traits associated with defects in hormone receptors, matrix components, or chondrocyte regulatory factors, and differ from the less "desirable" chondrodysplasias discussed below, which are believed to be caused by single gene defects.

Cartilage grows by both interstitial proliferation and surface apposition. Longitudinal growth of the cartilage model in the fetus, and at growth plates in young animals, relies primarily on interstitial proliferation of chondrocytes, while transverse growth occurs by interstitial growth and apposition. In some chondrodysplasias, appositional growth is normal but interstitial growth of cartilage is defective, resulting in premature closure of growth plates and reduced length of long bones. The intersphenoid, spheno-occipital, and interoccipital synchondroses at the base of the skull also develop by interstitial proliferation of chondrocytes and close prematurely in such disorders. In some chondrodysplastic calves, bony ridges project into the cranial cavity, possibly due to early fusion of the spheno-occipital synchondrosis and altered growth in this region of the skull. Although there is hypoplasia of basocranial bones and impaired development of the ethmoids and turbinates, the mandible, which enlarges by appositional growth, develops normally, leading to prognathia inferior. As the brain continues to grow, the cranium becomes domed and hydrocephalus may develop. The spinal column is shorter than normal due to reduced length of individual vertebrae, as are the ribs, but costochondral junctions may be enlarged since the cartilage expands by appositional growth.

The underlying molecular defects in most chondrodysplasias of animals have yet to be determined but their identification will eventually provide a more precise system of classification than is currently possible. In human achondroplasia, the most common form of heritable disproportionate dwarfism in people, the cartilage lacks a receptor for a growth factor as a result of a mutation in the gene encoding fibroblast growth factor receptor 3 (FGFR3). Such discoveries provide clues for investigating the mechanisms of chondrodysplasias in animals and may lead to the development of valuable animal models for assessing treatment options in human patients.

Chondrodysplasias of cattle

Several phenotypic forms of inherited chondrodysplasia occur in different breeds of cattle, and are broadly classified on the basis of their morphological characteristics into *"bulldog," Telemark, "snorter" (brachycephalic), and long-headed (dolichocephalic) types.* Because of the range of syndromes, it is likely that more than one gene locus is involved, or at least that there are different modifying alleles influencing the expression of a major gene.

The most severe form of bovine chondrodysplasia is the lethal **bulldog type**, which occurs in the Dexter and Holstein breeds, and possibly in Charolais and Jersey. Dexter cattle are considered short-legged derivatives of the Kerry breed, originating from Ireland, and are gaining in popularity in many countries because of the desirability of small, easily managed cattle for "lifestyle" farms. Some short-legged Dexters are heterozygous for an *incompletely dominant gene* which, when homozygous, gives rise to a bulldog calf. Bulldog calves may be carried to full term but are usually aborted before the seventh month of gestation and may not be detected by the owner. In all cases, they possess severe, relatively consistent, skeletal abnormalities. As well as being *much smaller than normal for the stage of pregnancy, they have extremely short limbs, which are usually rotated, a domed head with retruded muzzle and protruding mandible, and a large ventral abdominal hernia* (Fig. 1.20A). The tongue is of normal size so protrudes markedly, and the hard palate is absent. The shortened limb bones consist of mushroom-shaped, cartilaginous epiphyses separated by a short, central segment of diaphyseal bone. Histologically, the long bones lack distinct growth plates. Instead, the physeal cartilage consists of densely packed chondrocytes showing no orderly arrangement into columns (Fig. 1.20B), and a fibrillar intercellular matrix surrounding large, vascular, cartilage canals. Due to defective endochondral ossification at growth plates there is little growth in the length of long bones and no distinct primary or secondary spongiosa (Fig. 1.20B). In contrast, intramembranous ossification beneath the periosteum appears to proceed normally and contributes disproportionately to the bone volume (Fig. 1.20C). Holstein bulldog calves are similar to those of the Dexter breed, *but in Holsteins, the defect is characterized by autosomal recessive inheritance* rather than as an incomplete dominant. The defective gene coding for chondrodysplasia in Dexter cattle has recently been identified, and a test for carriers is now commercially available.

The **Telemark lethal** form of bovine chondrodysplasia is inherited as an *autosomal recessive trait* and, as such, the heterozygous parents are phenotypically normal. Affected calves are born alive but cannot stand, and die of suffocation shortly after birth. The head and facial abnormalities are similar to those of bulldog calves, and the limbs, although not quite as short as in bulldog calves, are much shorter than normal and rotated to varying degrees. A similar

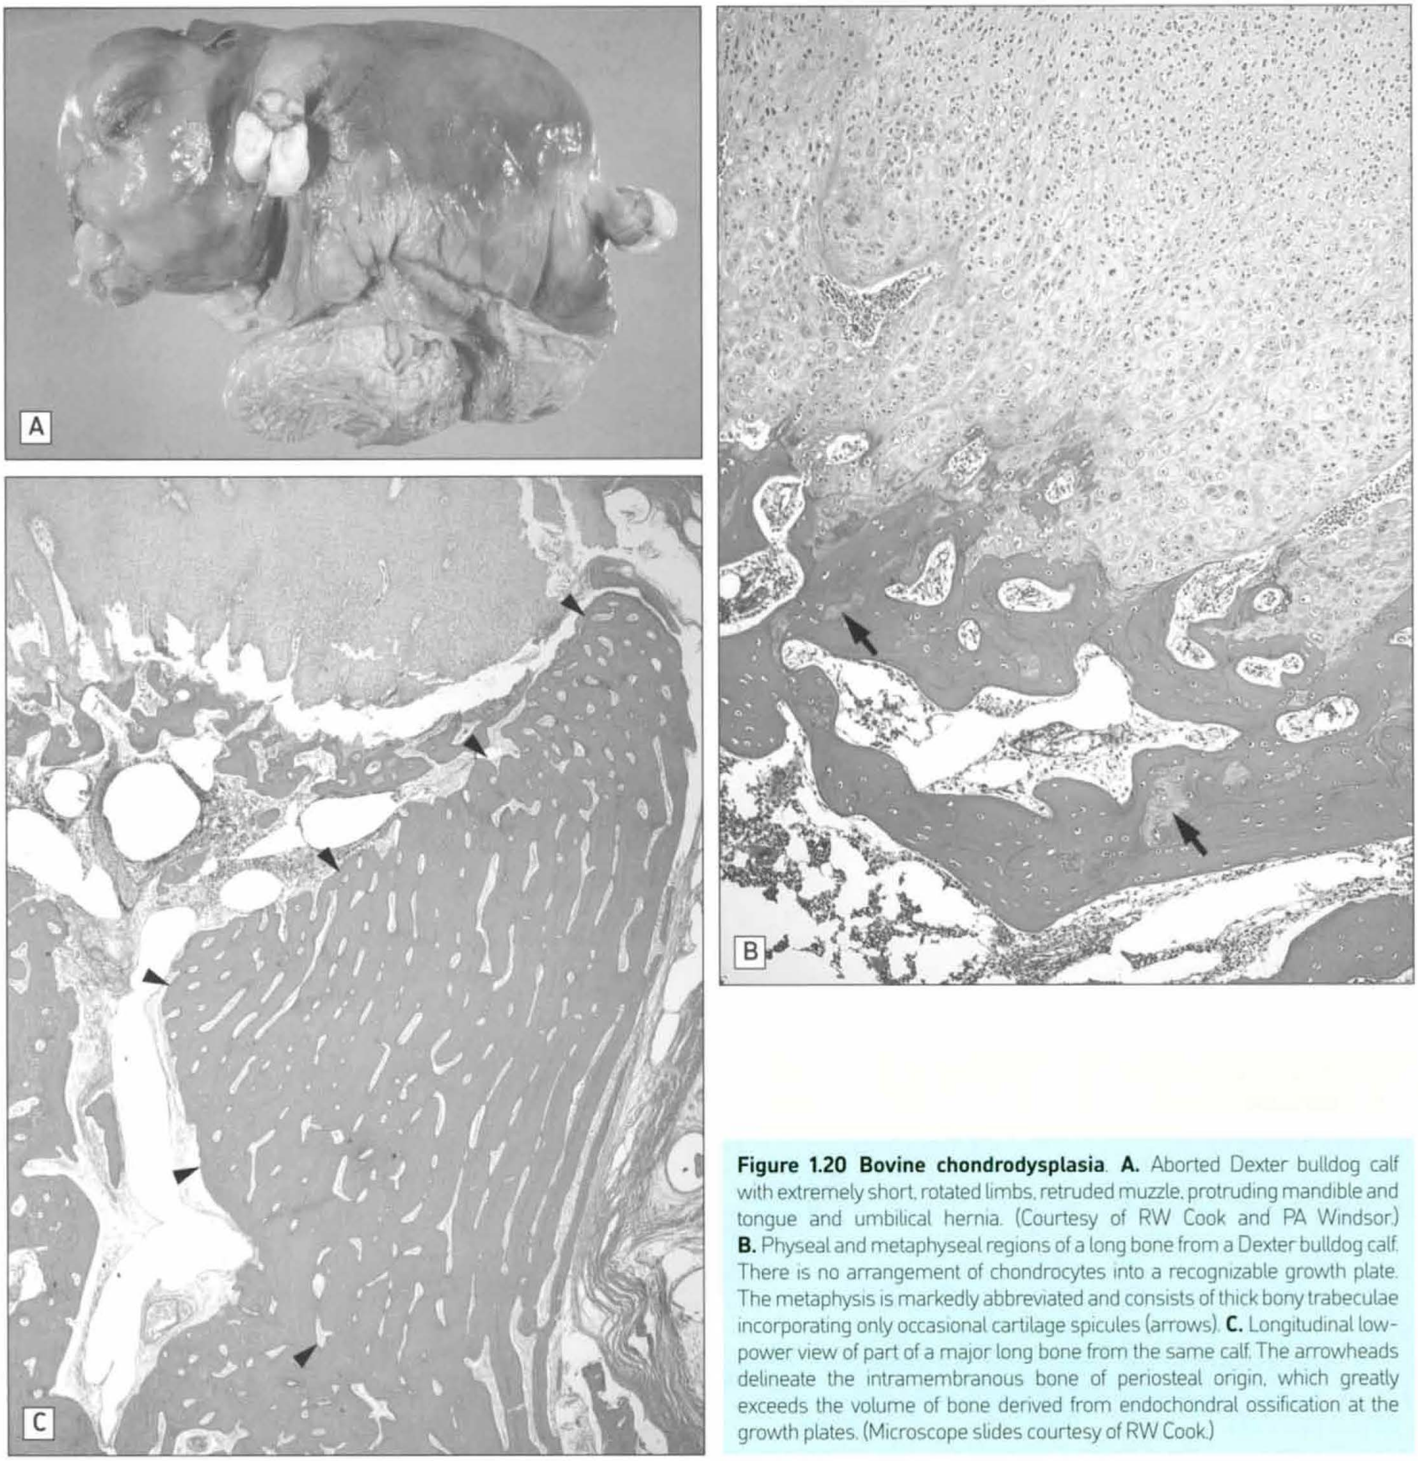

Figure 1.20 Bovine chondrodysplasia. A. Aborted Dexter bulldog calf with extremely short, rotated limbs, retruded muzzle, protruding mandible and tongue and umbilical hernia. (Courtesy of RW Cook and PA Windsor.) **B.** Physeal and metaphyseal regions of a long bone from a Dexter bulldog calf. There is no arrangement of chondrocytes into a recognizable growth plate. The metaphysis is markedly abbreviated and consists of thick bony trabeculae incorporating only occasional cartilage spicules (arrows). **C.** Longitudinal low-power view of part of a major long bone from the same calf. The arrowheads delineate the intramembranous bone of periosteal origin, which greatly exceeds the volume of bone derived from endochondral ossification at the growth plates. (Microscope slides courtesy of RW Cook.)

disorder, characterized by autosomal recessive inheritance, occurs in Jersey cattle, but shows much greater phenotypic variability. The lesions in Jerseys may include a short, broad head, deformed mandible, cleft palate, and short, spiraled limbs, but many calves have mild lesions and are viable.

Brachycephalic ("snorter") type dwarfism was common in the Hereford breed in North America and New Zealand during the late 1940s and early 1950s, but also occurred in other beef breeds, especially the Angus. Although inherited as an *autosomal recessive trait*, the defect appears to be partially expressed in heterozygotes, which are slightly smaller and more compact than normal. Selection for this phenotype most likely facilitated the spread of the chondrodysplasia gene in these traditional beef breeds and accounted for the high gene frequency. With a change in emphasis towards a larger frame score in beef cattle, and the introduction of programs to eliminate the defective gene, *snorter dwarfism is now rare.*

Snorter dwarfism is a much milder form of chondrodysplasia than the bulldog and Telemark types, but *affected calves have a short, broad head with bulging forehead, retruded upper jaw and a slightly protruding mandible* (Fig. 1.21). The eyes are prominent and laterally displaced. The vertebral column is shortened and the ventral borders of individual vertebrae are flattened, a useful diagnostic feature

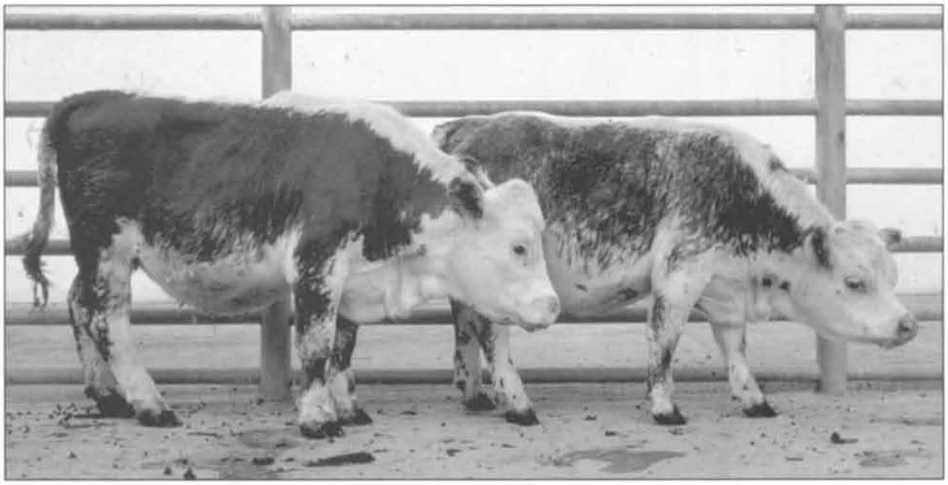

Figure 1.21 Bovine chondrodysplasia. Two brachycephalic ("snorter") dwarf Hereford calves with characteristic short stature, domed forehead, retruded upper jaw and distended abdomen. (Courtesy of RD Jolly.)

visible radiographically in young calves. Chronic ruminal tympany is a feature of snorter dwarfs, possibly as a result of reduced intra-abdominal space and impaired eructation. There is premature closure of basocranial synchondroses leading to compression of the cerebellum and shortening of the brain stem. The distal limb bones are proportionately shorter than proximal bones, the metacarpi showing the greatest degree of shortening. Interestingly, the width of long bones from brachycephalic dwarfs is comparable to, or greater than, that of normal calves. *The ratio of total metacarpal length to diaphyseal diameter is therefore a useful diagnostic indicator of this form of dwarfism.* In snorter dwarfs the ratio is usually 4.0 or less, but in normal animals it is greater than 4.5. Histological changes in the growth plates of snorter dwarfs are relatively mild and are not of diagnostic value. The microscopic organization of growth plates into their different zones is normal, but the columns of palisading chondrocytes are shorter, less hypertrophied and more irregular.

Long-headed or **dolichocephalic** dwarfs are slightly larger than snorter dwarfs, but the main difference is that *the head is proportionately much longer and tapers to a narrow muzzle.* Affected animals may have crooked limbs, slow growth rate and are unthrifty. Another form of chondrodysplasia, considered to be *rhizomelic* in type, occurs in Japanese Brown cattle. Lesions are confined to the long bones of the limbs and are associated with degenerative changes in growth plates and disordered endochondral ossification.

Proportionate dwarfism has been reported in an estimated 21 of 63 (33%) progeny from a clinically normal purebred Charolais bull. The miniature calves were derived both from Charolais cows and crossbred cows of diverse breeding, over several years. Affected calves weighed from 5–16 kg at birth and were born 2 weeks or more premature, with a high proportion dead at birth. Other than their small size, there were no anatomical differences between the miniature and normal calves sired by the bull. The condition was considered to be inherited as an *autosomal dominant trait*, probably resulting from a new mutation in the bull's primordial germ cells. This would explain the fact that the bull was clinically normal, and that less than 50% of its progeny were affected.

Chondrodysplasias of sheep

The most common, and potentially important, form of hereditary chondrodysplasia in sheep is **spider lamb syndrome**, *a semi-lethal condition of Suffolk and Hampshire sheep.* Spider lambs were first recognized in North America in the late 1970s and the defect has since been introduced to Australia and New Zealand with imported Suffolk genetic material. The trait is characterized by *autosomal recessive inheritance with complete penetrance*, but with variation in expressivity between individuals. The prevalence of spider lamb syndrome in North America has reached a much higher level than would normally be expected for a semi-lethal genetic disorder, possibly due to selection for long-legged animals heterozygous for the "spider" gene.

Lambs with spider syndrome may be aborted or stillborn, but most are born alive showing skeletal deformities of variable severity. Some appear clinically normal at birth but develop typical signs of the disease within their first month of life, including *disproportionately long limbs and neck, shallow body, scoliosis and/or kyphosis* (Fig. 1.22A), *sternal deformity, and valgus deformity of the forelimbs below the carpus, creating a "knock-kneed" appearance.* Hindlimb deformities may also be present, but are less severe than those involving the forelimbs. Facial deformities, including Roman nose (Fig. 1.22A), deviated nasal septum and shortening of the maxilla are common, but not consistent. The deformities of the limbs and spinal column become progressively more severe with age. *Diagnosis is best confirmed by demonstrating characteristic radiographic changes in the elbow, sternum, and shoulder.* Multiple, irregular islands of ossification are present consistently at these sites and there is malalignment and displacement of sternebrae.

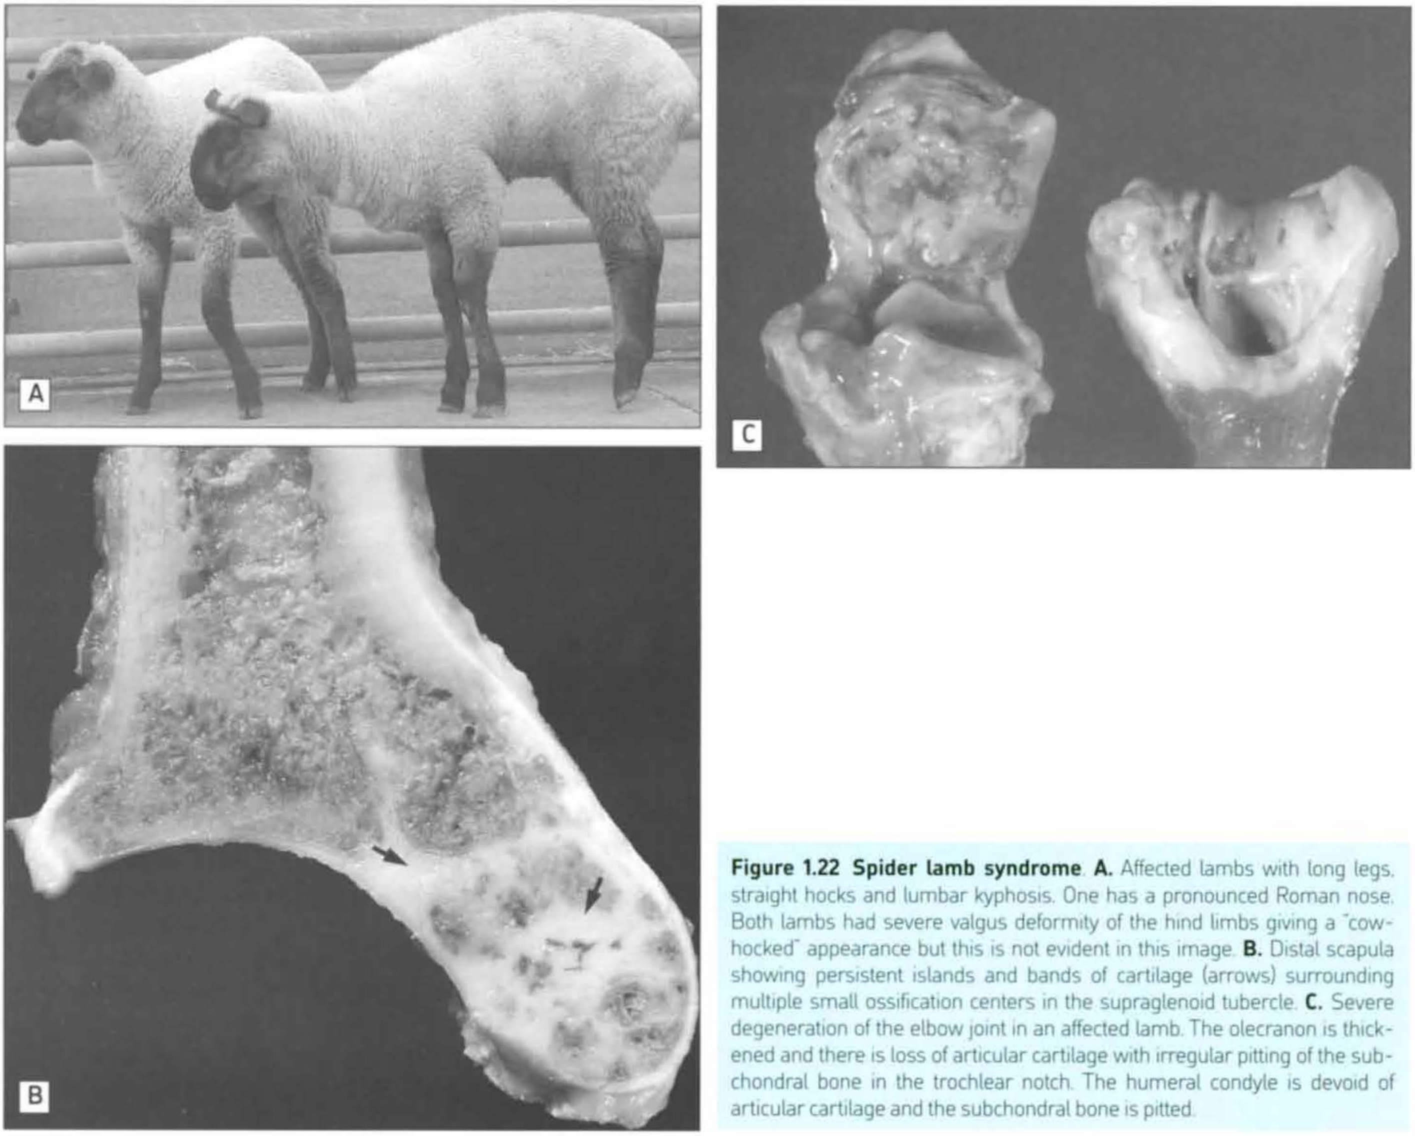

Figure 1.22 Spider lamb syndrome. **A.** Affected lambs with long legs, straight hocks and lumbar kyphosis. One has a pronounced Roman nose. Both lambs had severe valgus deformity of the hind limbs giving a "cow-hocked" appearance but this is not evident in this image. **B.** Distal scapula showing persistent islands and bands of cartilage (arrows) surrounding multiple small ossification centers in the supraglenoid tubercle. **C.** Severe degeneration of the elbow joint in an affected lamb. The olecranon is thickened and there is loss of articular cartilage with irregular pitting of the subchondral bone in the trochlear notch. The humeral condyle is devoid of articular cartilage and the subchondral bone is pitted.

In addition to the changes described above, other gross lesions may be detected at necropsy. In particular, there is *elongation of occipital condyles in a craniocaudal direction*, sometimes with erosion of the articular cartilage and dorsal deviation of the sternum between the second and sixth sternebrae. The caudal sternebrae often fail to fuse across the midline. Cervical and thoracic vertebral bodies contain excessive quantities of cartilage with disorganized arrangement, often accompanied by abnormalities in shape and symmetry. The olecranon and distal scapula also contain an excess of cartilage surrounding the multiple, irregular-shaped islands of ossification (Fig. 1.22B). Severe degenerative arthropathy, particularly involving the atlanto-occipital, elbow (Fig. 1.22C), and carpal joints, is present in lambs older than 3 months.

Histologically, the changes reflect abnormal development of ossification centers in bones developing by endochondral ossification. Multiple small ossification centers develop in nodules of hypertrophic cartilage but they fail to coalesce and expand in normal fashion towards articular surfaces (Fig. 1.23). The lack of subchondral bone predisposes to degenerative arthropathy. The proliferative and hypertrophic zones of growth plates in vertebrae and long bones are irregularly thickened and tongues of cartilage extend into the metaphysis or epiphysis. Chondrocyte columns in growth plates are often irregular. An interesting feature of the disease is that the ossification centers most severely affected are those that develop around the time of birth. Those that complete their development in utero, where they are not subjected to the mechanical forces of weight bearing and locomotion, appear normal. The lesions associated with spider lamb syndrome therefore may reflect the influence of mechanical stress on a defective cartilage model. This could help to explain the variable expressivity that is such a feature of the disease.

A *point mutation in ovine FGFR3* has been identified as the underlying defect in spider lamb syndrome. The gene encoding this receptor has largely been cloned and sequenced, and an accurate test for detecting heterozygous individuals is now available.

Chondrodysplastic syndromes characterized by **disproportionate dwarfism** do occur in sheep, but are rare. The best known of these is the *Ancon mutant*, which at one time gained popularity as a breed for its inability to jump walls. Although the breed is now extinct, the defect has reappeared on odd occasions, presumably due to new mutations. The Ancon abnormality is a *mesomelic, short-limbed dwarfism* caused by premature closure of certain growth plates.

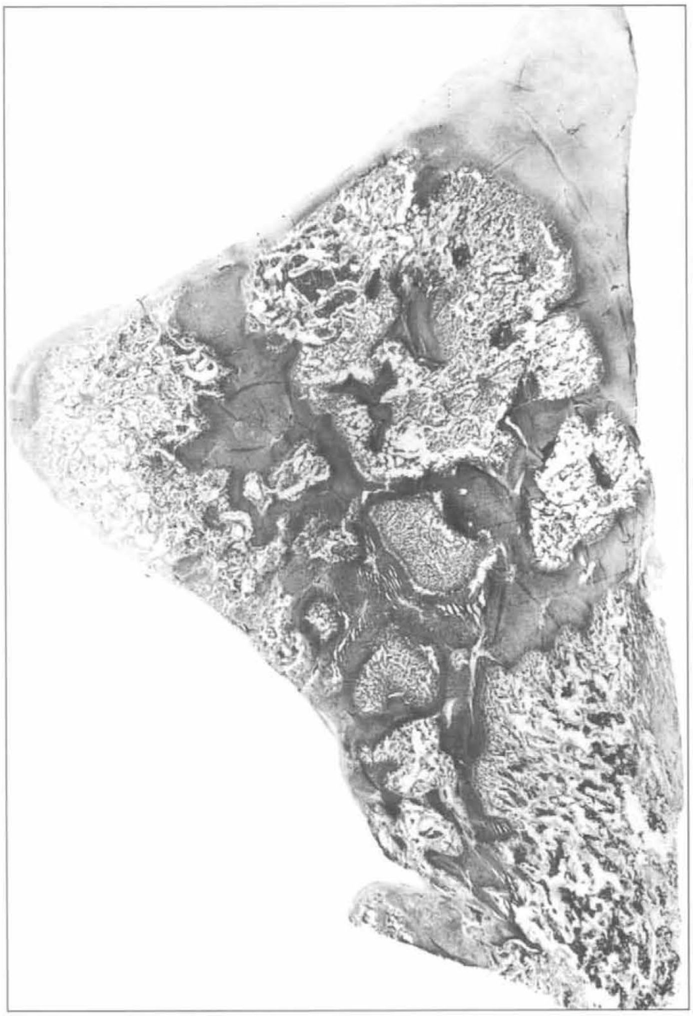

Figure 1.23 Subgross preparation of the olecranon from a **spider lamb** showing multiple ossification centers separated by irregular bands of cartilage.

Another form of chondrodysplasia reported in South Country Cheviot sheep in Scotland, was characterized by ectrodactyly, domed forehead and protruding eyes, together with shortened ears and tail. The syndrome was believed to be of genetic origin with recessive inheritance, but this was not proven.

A severe form of dwarfism affecting 27 of 110 lambs born to 70 mixed-breed ewes occurred in the United Kingdom. Most affected lambs were alive at birth but died within a few minutes. The abnormalities included a domed head, shortened nose, short, paddle-like limbs, narrow thorax, and swollen abdomen, and were said to resemble bulldog calves. Recessive inheritance could be eliminated due to the high incidence of affected lambs and the genetic diversity of the ewe flock. It is possible that a new, dominant mutation occurred in primordial germ cells of a ram in the flock.

A chondrodysplasia characterized by *dwarfism and varus deformity of the forelimbs* has recently been recognized in **Texel sheep** in New Zealand. The syndrome is inherited as an *autosomal recessive trait, but with variable expression.* Affected lambs appear normal at birth, but by 2–4 weeks of age show evidence of reduced growth rate, shortened neck and legs, varus forelimb deformities and a wide-based stance. Severely affected lambs show progressive reluctance to walk and often die within the first 4 months of life. In such cases, the articular cartilage on major weight-bearing surfaces of the hip and shoulder joints may be completely eroded, exposing the subchondral bone. The trachea is flaccid, sometimes kinked, and tracheal rings are partially flattened. *Histologically, there is disorganization of chondrocytes in articular and physeal cartilage and multiple foci of chondrolysis,* which sometimes coalesce to form large clefts. The matrix surrounding chondrocytes has an abnormal fibrillar and granular appearance. Similar microscopic changes are present in tracheal cartilage, confirming the generalized nature of the chondrodysplasia.

Chondrodysplasias of pigs

Disproportionate dwarfism was reported in three litters of Danish Landrace pigs sired by the same boar. The abnormalities were confined to the long bones of the limbs, and were most severe in the forelimbs. The bones of the skull and axial skeleton were unaffected. Signs of the disease were first apparent at 1–2 weeks of age and became more apparent with time. By weaning, affected pigs had an abnormal gait due to loose attachment of the limbs to the body and excessive mobility of joints. Few of them reached breeding age. Histologically, the growth plates had reduced thickness of the proliferative zone and irregularity of the hypertrophic zone, but the chondrocytes within each zone appeared normal. The disorder was inherited as an autosomal recessive trait.

In another report of dwarfism in pigs, almost 100 of 800 juvenile pigs developed gait abnormalities and marked shortening of limb bones, especially those of the hindlimb. The reduced length of limbs was due to premature closure of growth plates. The skull and axial skeleton were unaffected. In spite of the very high incidence, autosomal recessive inheritance was suspected.

Dwarfism also occurs in pig with vitamin A toxicosis (see later) but the lesions are more widespread than in this heritable form of chondrodysplasia, affecting vertebral bodies as well as limb bones.

Chondrodysplasias of dogs

A variety of different forms of inherited chondrodysplasia are recognized in dogs of different breeds. Some are clinically apparent at birth

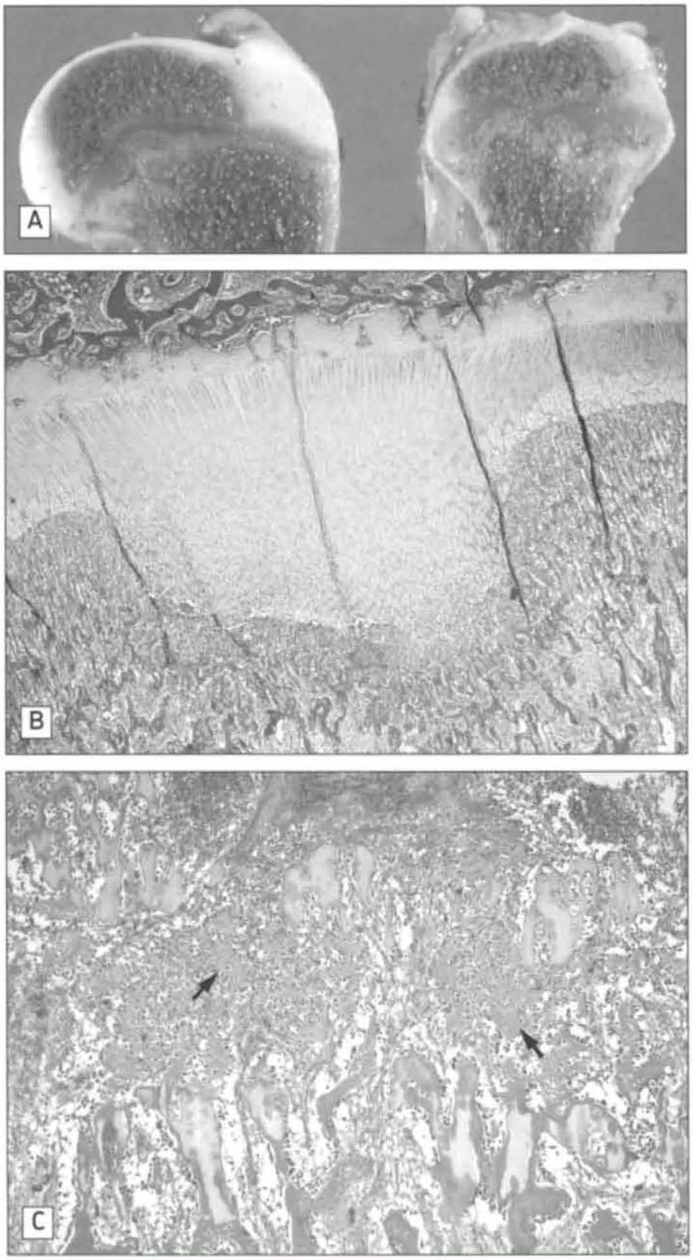

Figure 1.24 Alaskan Malamute chondrodysplasia. A. Proximal humerus (left) and distal radius of an affected pup showing irregular thickening of the physes. **B.** Marked, segmental thickening of the hypertrophic zone in the physis of an Alaskan Malamute pup with chondrodysplasia. **C.** Primary spongiosa immediately beneath a thickened segment of physis in the same Malamute pup. Note the disruption of the normal trabecular architecture and replacement by proliferating osteoblasts producing disorganized spicules of osteoid (arrows). An area of hemorrhage is present closer to the physis.

but others are not manifest for several weeks. **Chondrodysplasia in the Alaskan Malamute** is characterized by *disproportionate, short-legged dwarfism*, and *autosomal recessive inheritance* with complete penetrance and variable expression. At birth, the growth plates of affected puppies appear normal radiographically. Radiographic changes are apparent as early as 7–10 days of age but are more pronounced after 3 weeks. Similarly, there is little difference in growth plate and metaphyseal histology between dwarf and normal Malamutes at birth. During growth, the changes become marked, suggesting that mechanical force is required in order to create the clinical and pathological changes. Irregular thickening of growth plates in the limb bones is a feature of the disease (Fig. 1.24A). Broad tongues of hypertrophic cartilage extend into the metaphysis in close proximity to healing trabecular microfractures (Fig. 1.24B, C). Disruption of the metaphyseal blood supply, leading to impaired vascular invasion of the developing growth plate, is considered responsible for the physeal thickenings. *The lesions bear a remarkable resemblance to rickets*, both grossly and in demineralized bone sections, but the mineralization of cartilage is normal. Abnormal endochondral ossification occurs throughout the body, but *the most striking lesions occur in the distal ulna and radius*, resulting in enlarged carpal regions and valgus deformity of the forelimbs. This most likely reflects the proportionately greater weight-bearing responsibility of the forelimbs compared to the hindlimbs, and the greater susceptibility to injury. A reduction in the hydroxyproline content of cartilage, and in the stability of type II collagen cross-links, has been demonstrated in dwarf Alaskan Malamutes, the collagen defect possibly increasing the susceptibility of trabeculae in the primary spongiosa to fractures. Hemolytic anemia characterized by stomatocytosis, macrocytosis, and increased concentration of sodium within erythrocytes, accompanies the chondrodysplasia in this breed. Heterozygotes have intermediate hemoglobin concentrations, suggesting that this manifestation of the syndrome is inherited as an incompletely dominant trait.

Chondrodysplasia in the Norwegian Elkhound is a *disproportionate, short-legged dwarfism* similar to the disease in Malamutes but with significant morphologic differences. In Elkhounds, the vertebral bodies are also shortened and there is a marked reduction in the width of the proliferative zone in growth plates. *A highly distinctive feature is the presence of one or more large, intracytoplasmic inclusions in the chondrocytes of all zones* (Fig. 1.25). The inclusions stain deep blue by the Alcian Blue-periodic acid-Schiff method at pH 1.0 and 2.6. Inclusions that escape from degenerate chondrocytes persist and lie free in lacunae. The cell columns in the zone of hypertrophy and degeneration are generally disorganized and separated by wide matrix bars. Trabeculae in the primary spongiosa are coarse and shortened, with many horizontal bridges and thick osteoid seams. No inclusions are present in osteoblasts or osteocytes.

Chondrodysplasia in the English Pointer has been reported in the United Kingdom and Australia in related dogs. Inheritance appears to be *autosomal recessive*. Affected puppies are smaller than their normal littermates and develop locomotory abnormalities, including a bunny-hopping gait. Some also have inferior prognathism. Growth plates are irregularly thickened due to increased width of the hypertrophic zone, but the lesion varies in severity between different bones. Increased mineralization of laryngeal and tracheal cartilage occurs in some affected animals. At around 10 weeks of age, articular cartilages appear normal but by 16–18 weeks, there are abnormalities in the cartilage of all major limb joint, including wrinkles, projections and sometimes fibrillation. In the epiphyseal cartilage beneath these lesions there are irregular cavities containing degenerate chondrocytes and strands of collagen. Severe degenerative arthropathy develops in some joints.

Chondrodysplasia in the Great Pyrenees also appears to be inherited as *an autosomal recessive trait*. Affected pups are normal at birth but by 2 weeks they are shorter and lighter than their littermates. Mature dwarfs are less than half of normal size. Radiographic abnormalities are restricted to the metaphyses of long bones and vertebrae and are characterized by *delayed ossification*. Histologically, chondrocyte columns in growth plates are disorganized and many chondrocytes contain cytoplasmic vacuoles that consist of dilated cisternae of rough endoplasmic reticulum. Metaphyseal trabeculae are thicker than normal and are often joined by lateral bridges.

Pseudoachondroplastic dysplasia, a disease of **Miniature Poodles**, was originally named epiphyseal dysplasia. Inheritance of the trait is *probably autosomal recessive*. The disease is not apparent at birth but by 2–3 weeks of age affected pups are noticeably smaller than their normal littermates and have difficulty standing and walking. The skull is usually normal but mild inferior prognathism may be present. Vertebral bodies are short and show delayed ossification, costal cartilages are longer than normal and costochondral junctions are enlarged (Fig. 1.26). Severely affected pups have dorsoventral flattening of the rib cage, presumably due to persistent recumbency. The limb bones are also short, particularly those of the forelimbs, and possess enlarged epiphyses which are sometimes flared over the metaphyses (Fig. 1.27). Histologically, the cartilage matrix is sparse and lacks basophilia. Chondrocytes vary in size and are sometimes clumped together in enlarged lacunae. Chondrocyte

columns in growth plates are irregular and the proliferative zone is abnormal. Ossification centers develop later than normal and are multifocal, creating a stippled appearance radiographically in affected pups (Fig. 1.28). By 2 years of age, ossification is complete and the long bones are only half to two-thirds normal length. Interestingly, the lumbar vertebrae are longer than in normal dogs of the same age. Degenerative arthropathy and spondylosis may develop in pups less than a year of age. *The underlying defect in cartilage matrix formation not only causes defective endochondral ossification, but also results in abnormal formation of the trachea and nasal septum.* Collagen synthesis is normal but the defect appears to involve decreased sulfation of glycosaminoglycans.

Multiple epiphyseal dysplasia is a rare condition of **Beagle dogs**, probably inherited as an *autosomal recessive trait.* Affected puppies walk with a swaying gait but, in adults, lameness is only apparent after exercise. The earliest radiographic signs are not visible until 3 weeks of age and consist of *stippled epiphyseal mineralization* (Fig. 1.29), especially in the tarsal and carpal bones, the femoral, humeral, metacarpal and metatarsal epiphyses, and in the bodies of the sixth and seventh lumbar vertebrae. By 5 months the stippling is no longer apparent, having been incorporated into the normal ossification centers. The abnormal foci of epiphyseal mineralization develop in a specific subarticular zone of the epiphyses. The initial lesion is a floccular accumulation of chondroitin sulfate and glycoprotein in chondrocyte lacunae. As adjacent lacunae coalesce and liquefy to form cysts, their contents mineralize. The stippled radiographic appearance of epiphyses resembles that of pseudoachondroplastic dysplasia of Miniature Poodles but the histologic changes are distinct.

Osteochondrodysplasia in the Scottish Deerhound becomes apparent at around 4–5 weeks of age, with affected puppies showing exercise intolerance and retarded growth. These pups go on to develop a bunny-hopping gait, kyphosis, marked bowing of the limbs, and joint laxity. Mature dogs have shortened, porotic long bones, shortened vertebrae, distorted carpal and tarsal bones, incongruencies of hip and elbow joints, and enlargement of muscle attachment sites. Growth plates are irregular in width and physeal–metaphyseal junctions are uneven. Histologically, there are islands of basophilic, vacuolated chondrocytes in epiphyses, but physeal and metaphyseal lesions are intermittent. Physes contain some areas that are virtually normal, in addition to areas that are narrow and hypocellular, or lack proliferative or hypertrophic zones. A characteristic feature is the *presence of periodic acid-Schiff-positive, diastase-resistant cytoplasmic inclusions in proliferative and hypertrophic chondrocytes.* The metaphyses may consist of normal primary and secondary spongiosa in some areas, while elsewhere the trabeculae are thin, sparse and largely replaced by fibrovascular connective tissue. The irregularity of the physeal and metaphyseal lesions may reflect localized trauma. The condition is probably inherited as an *autosomal recessive trait.*

A syndrome with combined **ocular and skeletal dysplasia** occurs in the **Labrador Retriever** and **Samoyed** breeds. The bone lesions are confined to the appendicular skeleton and include *shortening of the limb bones, valgus deformity of the carpi, and abnormally shaped radii and ulnas.* Affected dogs have a *characteristic "downhill" conformation* due to more severe involvement of the forelimbs. In some dogs, the coronoid processes are ununited and there is hypoplasia of both the coronoid and anconeal processes, but these changes may be incidental as they also occur as separate defects in these breeds. Retained cartilage cores may be present in the distal ulna. Although clinical evidence of dwarfism may not be evident until about 8 weeks of age, *a radiographic image-classification system allows identification of affected puppies at birth.* The ocular lesions in both breeds consist of *cataracts and retinal detachment.* In Retrievers, there is also retinal dysplasia. The ocular and skeletal lesions appear to be inherited together, but the defective gene has recessive effects on the skeleton and incomplete dominance on the eye. Heterozygotes therefore possess mild eye lesions but a clinically normal skeleton.

Chondrodysplasias of cats

There are *few reports* of chondrodysplasias in cats. One report describes a severe form in a stillborn kitten *in association with homozygous Pelger–Huët anomaly.* The kitten was small and had a dome-shaped skull, flattened face, and protruding tongue. Vertebrae were shortened, as were ribs and long bones of the limbs. The limbs were thickened and had broad, mushroom-shaped epiphyses. Growth plates were incompletely formed with partial or irregular ossification at the center of the physis, and more normal peripheral regions. A live littermate, which was heterozygous for the Pelger–Huët anomaly, also had skeletal abnormalities, including pectus excavatum, lordosis, shortened vertebral bodies, and flared distal radial metaphyses. The skeletal lesions in the stillborn kitten were very similar to those seen in rabbits with homozygous Pelger–Huët anomaly.

A *possible metaphyseal chondrodysplasia* was also diagnosed in two unrelated kittens with shortened limbs, bowed forelimbs, marked widening of the growth plates and flaring of the metaphyses. The most severe growth plate lesions were present in the distal radius and proximal humerus. The radiographic changes in growth plates initially led to a diagnosis of rickets, but neither kitten responded to treatment and there was no evidence of defective mineralization. One kitten had two siblings with similar limb deformities and its probable sire was also known to have short, deformed forelimbs, suggesting a genetic etiology.

An osteochondrodysplasia characterized by a short, thick, inflexible tail and misshapen distal limbs with extensive new bone formation on the plantar aspect of the tarsi and metatarsi, is reported in **Scottish Fold** cats. Other abnormalities in affected cats include irregularity in the size and shape of tarsal, carpal, metatarsal, and metacarpal bones, phalanges, and caudal vertebrae, narrowing of joint spaces, progressive new bone formation around distal limb joints and diffuse osteopenia of adjacent bones. Histologically, there is evidence of defective endochondral ossification in physes and beneath articular cartilages. Cartilage columns in physes are disorganized and there is irregular thickening of physeal cartilage. Islands of cartilage may also extend from articular cartilage into epiphyses. Lesions can be detected in kittens as young as 7 weeks of age, but the bony changes are slowly progressive and may not be detected for several years. Originally, it was thought that affected cats were homozygous for the Fd (fold-eared) gene and resulted only from matings between fold-eared cats. Recent evidence suggests that the disease can also develop in heterozygous Scottish Folds and that significant lesions may be present in such animals as early as 6 months of age.

Osteogenesis imperfecta

Osteogenesis imperfecta is one of the most frequently observed inherited connective tissue disorders of humans, but *occurs rarely in domestic animals.* The disease is characterized by *excessive bone fragility,* which in severe cases may result in multiple intrauterine fractures, marked skeletal deformity, and either stillbirth or perinatal death. Milder forms may be inapparent at birth but lead to an increased incidence of postnatal fractures and bowing of the limbs. Other abnormalities may include fragile, opalescent teeth (dentinogenesis imperfecta), joint laxity, and blue sclerae. Based on clinical features and mode of inheritance, *at least four distinct forms of osteogenesis imperfecta are recognized in human patients.* Most human cases of osteogenesis imperfecta are inherited as autosomal dominant traits and represent new mutations, although rare recessive forms also exist. A quantitative or qualitative defect in type I collagen is the molecular basis of the disease and may be due to one of many mutations in either of the two genes, *COL1A1* or *COL1A2,* that code for the $\alpha1$ and $\alpha2$ chains, respectively. Type I collagen is the

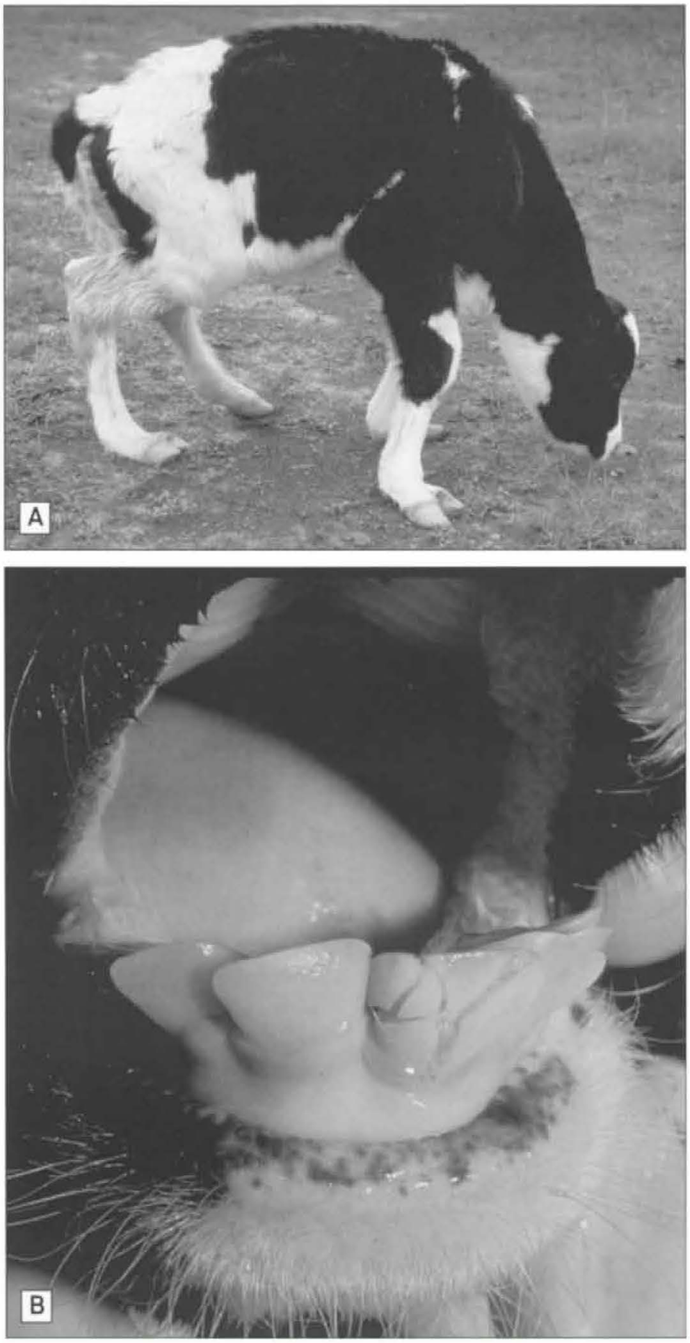

Figure 1.30 Bovine osteogenesis imperfecta **A.** Affected Holstein calf, 2 weeks old. Because of excessive joint laxity, the calf has a crouched stance and its pasterns almost touch the ground. **B.** Fractured incisor tooth due to dentinal dysplasia in the same calf.

predominant collagen type in bone, dentin, ligaments, tendons, and in the ocular sclera, thus accounting for the characteristic distribution of lesions.

Most reports of osteogenesis imperfecta in animals are in calves and lambs and appear analogous to the most severe form of the disease in humans. In **cattle**, the disease has occurred in Australia, the US, and Denmark in the offspring of three clinically normal, unrelated **Holstein-Friesian** bulls, and in **Charolais** calves in Denmark. A single crossbred **Hereford** calf with osteogenesis imperfecta has been identified in New Zealand. There is convincing evidence to support an *autosomal dominant* mode of inheritance, at least in Holstein-Friesian cattle, although the percentage of calves affected from the three Holstein-Friesian bulls varied from approximately 9% to 44%. This presumably reflects different degrees of gonadal mosaicism following mutations in the germ cell lines of each bull. The manifestations of the disease in each report in calves have been similar, but minor variations exist, suggesting that different mutations may be involved. Affected calves are usually born alive and are of normal size, but most are unable to stand due to marked hypermobility of the joints and, in some cases, the presence of limb fractures. Some affected Holstein-Friesian calves are able to stand and can walk with difficulty, but have a characteristic crouched stance with pasterns almost touching the ground (Fig. 1.30A). As in some forms of the human disease, calves with osteogenesis imperfecta have dentinal dysplasia characterized by small, translucent pink-gray teeth, which are barely erupted at birth and may fracture in calves that survive for a few weeks (Fig. 1.30B). In some calves the sclerae are distinctly blue, but this is more evident during postmortem examination following enucleation of the eye. Skin fragility is not a feature of the disease in calves.

The main findings during *postmortem examination* relate to the skeleton. *Although the bones are essentially normal in shape, they are extremely brittle* and can usually be broken with little effort. Acute fractures are common in the mandibles and major limb bones; the latter probably occurring during attempts to stand. Severely affected calves may have multiple, well-developed calluses on their ribs (Fig. 1.31A), indicating intrauterine fractures. In spite of their fragility, the cortices of long bones are similar in thickness to those of normal calves but the volume of trabecular bone in metaphyses and epiphyses is reduced and shows a finer, denser pattern. In calves that have stood and walked, infraction lines may be present in the epiphysis and metaphysis of major limb bones (Fig. 1.31B). These represent bands of healing trabecular microfractures presumably resulting from trauma during weight bearing. Tendons are thinner than normal and discolored pink.

Histologically, osteoblastic activity appears normal but calcified cartilage spicules in the primary spongiosa are lined by only a thin layer of basophilic bone matrix and there is little osteoclastic resorption or realignment of trabeculae. Infractions and trabecular microfractures are common (see Fig. 1.17). Bone cortices are porous due to incomplete compaction of primary osteons and consist predominantly of deeply basophilic woven bone with few lamellae (Fig. 1.32A, B). The dentin in affected calves is basophilic, coarsely laminated and approximately one fifth as thick as in control calves. Dentinal tubules are irregularly oriented and reduced in number, and there is an undulating margin with the pulp cavity. The sclera is approximately one half of normal thickness. Ultrastructurally, collagen fibrils in the tendons, dentin, sclera, and skin of affected calves are significantly narrower than normal.

Chemical analysis of bone from Holstein-Friesian calves with osteogenesis imperfecta has provided evidence that *different mutations are involved*. In bone tissue from both American and Australian calves there is reduced size of apatite crystals and a decrease in the amount of type I collagen and proteoglycans. The *main difference is in the concentration of osteonectin*, which is normal in the Australian calves with osteogenesis imperfecta, but only 10% of normal in the affected American calves. Phosphophoryn, a dentin-specific protein, and an osteonectin-like protein of dentin are also markedly deficient in these calves.

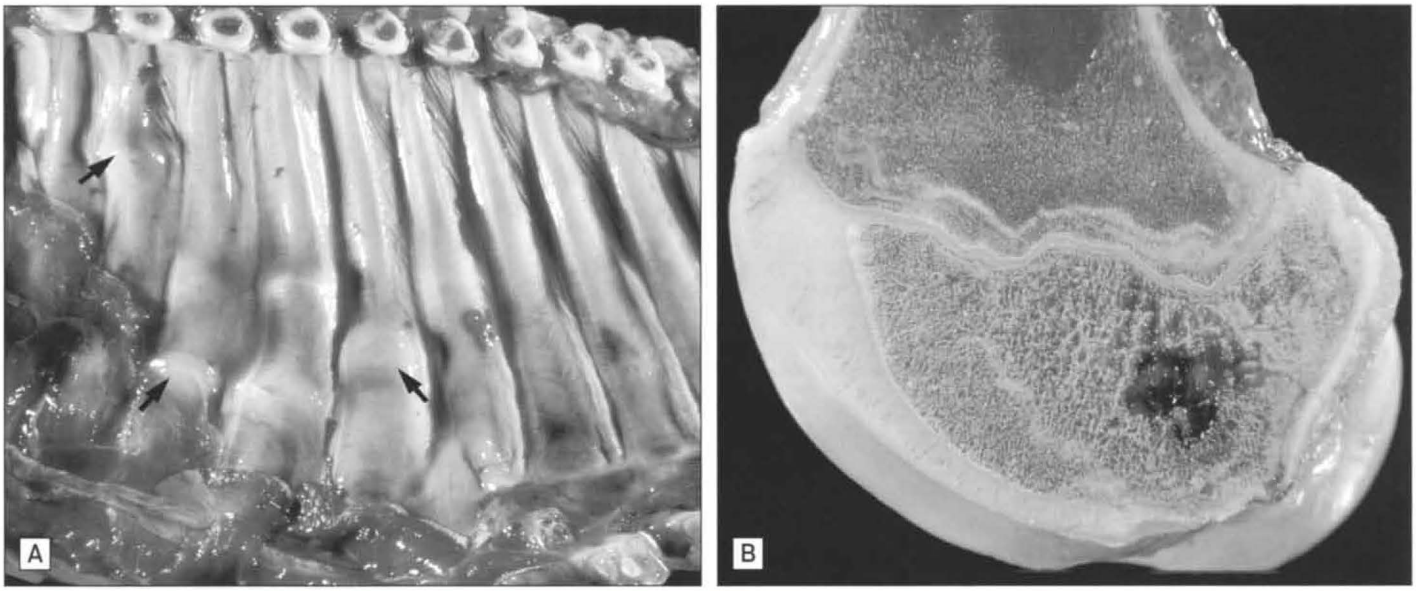

Figure 1.31 Bovine osteogenesis imperfecta. **A.** Several mature calluses (arrows) on the ribs of a newborn calf, indicating intrauterine fractures due to extreme bone fragility. **B.** Distal femur from a calf that had survived for a couple of weeks and had walked. Multiple infraction lines are present in the epiphysis and metaphysis. The cancellous bone is more porous than normal.

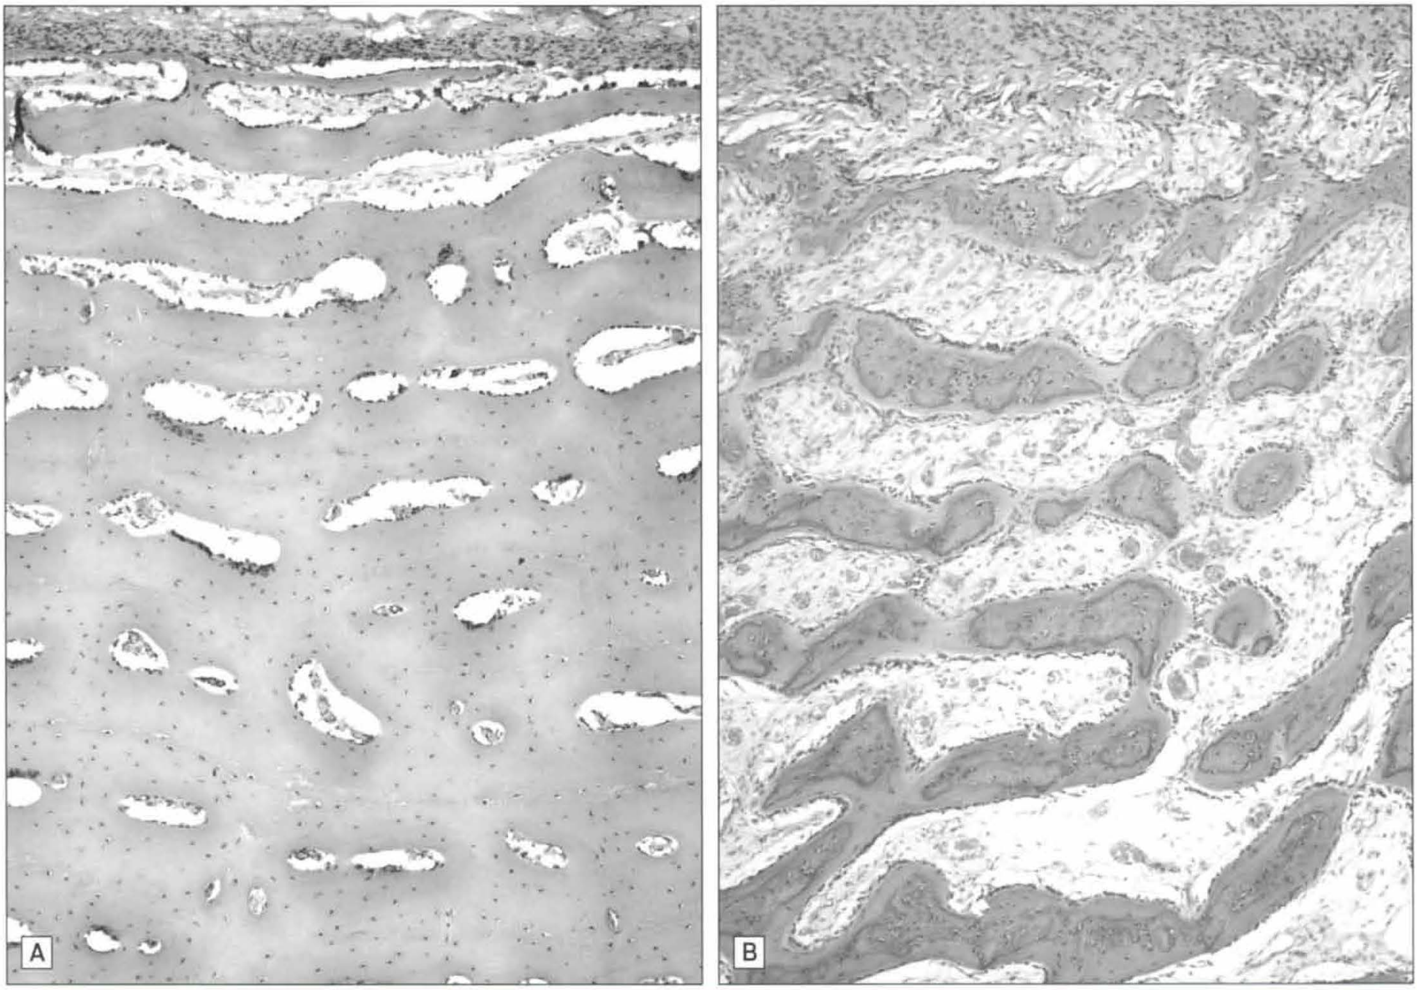

Figure 1.32 Bovine osteogenesis imperfecta. **A.** Microscopic view of periosteum and developing cortical bone in a **normal newborn calf**. **B.** Similar view of the developing cortex in an **affected calf** showing basophilic spicules of woven bone and minimal compaction by the addition of lamellar bone.

Skin fragility is not reported in calves with osteogenesis imperfecta, but Belgian calves with dermatosparaxis do have skeletal lesions. These calves are deficient in the activity of procollagen *N*-peptidase, an enzyme involved in the conversion of procollagen to collagen. Although the bones are grossly normal and not prone to spontaneous fractures, they are abnormally brittle when processed. Histologically, the cortical bone of periosteal origin is disorganized and hypermineralized, while that derived from compaction of the chondro–osseous complex is normal. **Arachnomelia**, a lethal defect in German Simmental and Brown Swiss-Braunvieh cattle, is also accompanied by increased bone fragility but affected calves also have arthrogryposis, distortion of the vertebral column and brachygnathia inferior, in addition to cardiovascular anomalies. The limbs are long and distorted, and the bones have very narrow diaphyses.

In **sheep**, severe forms of osteogenesis imperfecta have occurred in two flocks in New Zealand and one in the United Kingdom. In both New Zealand reports, one of which involved the **Romney** breed, affected lambs died either during parturition or soon after. The Romney lambs had a domed head (Fig. 1.33A) with brachygnathia inferior, dark blue sclerae, fragile, pink teeth, and marked joint laxity. A feature of the disease in Romneys, which involved about 50 lambs, was the presence of marked skin fragility. This has not been described in any of the other reports of osteogenesis imperfecta in humans or animals. Using DNA fingerprinting, the defect was traced to one of five clinically normal Romney rams being used in the flock and a suspicion of *dominant inheritance* was confirmed by test-matings with unrelated ewes of a different breed. In affected lambs, the bones could be easily bent or cut with a knife and were often abnormally shaped with thickened diaphyseal regions (Fig. 1.33B). Most lambs had recent fractures surrounded by hemorrhage and older (in utero) fractures with poorly formed calluses, especially involving the ribs. Microscopic changes are similar to those described in calves with osteogenesis imperfecta, but more severe. Persistent trabeculae of calcified cartilage, lined by a thin layer of basophilic bone, extend from growth plates deep into the diaphyses of long bones, filling the marrow cavities (Fig. 1.34A, B). Osteoclastic resorption of the primary spongiosa is impaired, and there is no formation of a recognizable secondary spongiosa. The cortices are extremely porous, but thicker than normal, and consist of narrow, basophilic trabeculae separated by loose connective tissue. There is no evidence of compaction into normal cortical bone.

Similar gross and microscopic bone lesions occurred in lambs from the other New Zealand flock, together with tooth abnormalities and skin fragility. The breed of these sheep was not disclosed and the mode of inheritance not determined, but circumstantial evidence favors a dominant trait. The United Kingdom outbreak occurred in lambs of the **Clun Forest** breed. These lambs often survived parturition and were bright and alert, but usually could not stand. Blue sclerae were reported but there was no mention of tooth abnormalities. Multiple recent and intrauterine bone fractures were present in most lambs, and the histological lesions in bone closely resembled those seen in the New Zealand lambs.

A milder form of osteogenesis imperfecta is described in **Barbados Blackbelly** sheep. Although fractures occur in utero, affected lambs are born alive and can stand, in spite of joint laxity. The teeth of these lambs are normal. Autosomal recessive inheritance is suspected in this breed.

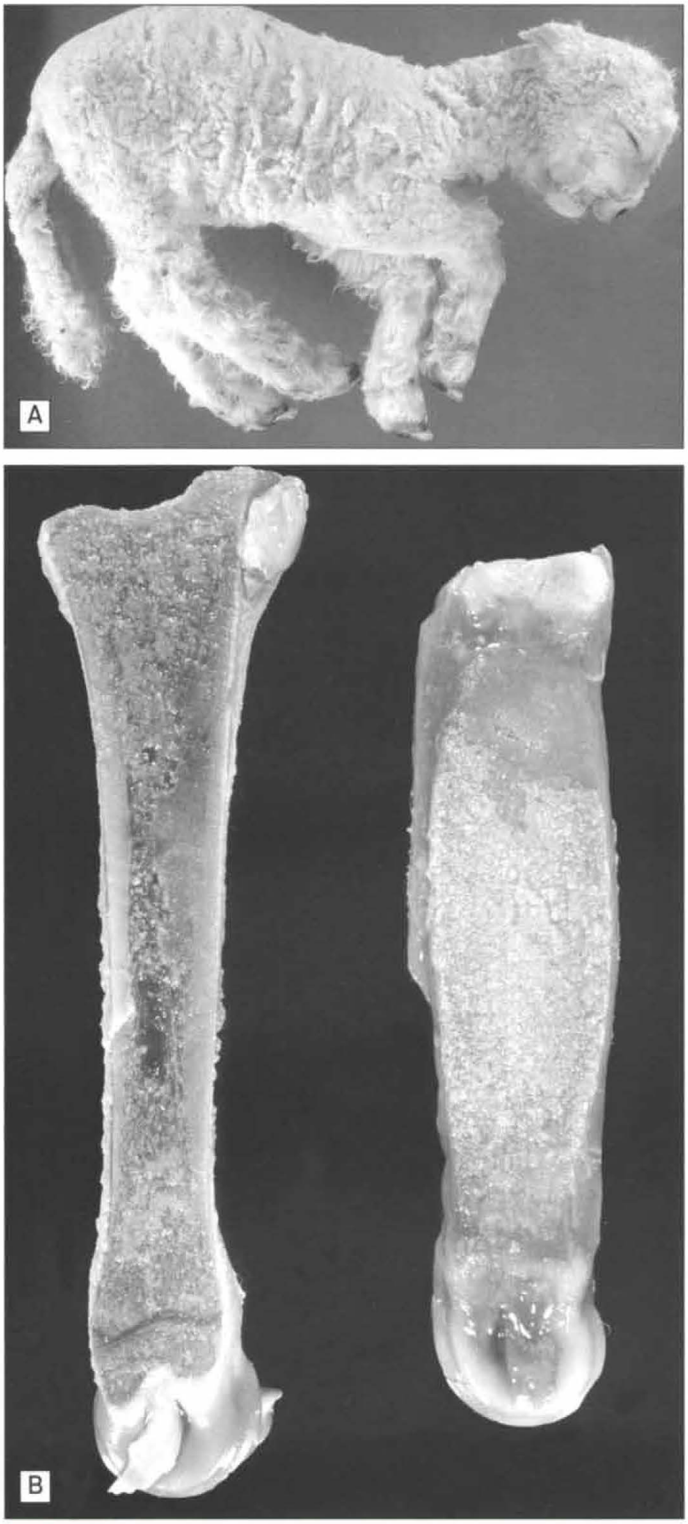

Figure 1.33 Ovine osteogenesis imperfecta in Romney lamb. **A.** Note the domed forehead and brachygnathia inferior. **B.** Sagittal sections of metatarsal bones from a **normal newborn lamb** (left) and a **lamb with osteogenesis imperfecta**. The bone from the affected lamb is shorter, has a thickened diaphysis and no medullary cavity.

Osteogenesis imperfecta has been described in **puppies** and **kittens**, although it appears likely that early reports of the disease in these species were misdiagnoses of fibrous osteodystrophy caused by nutritional secondary hyperparathyroidism. More recently,

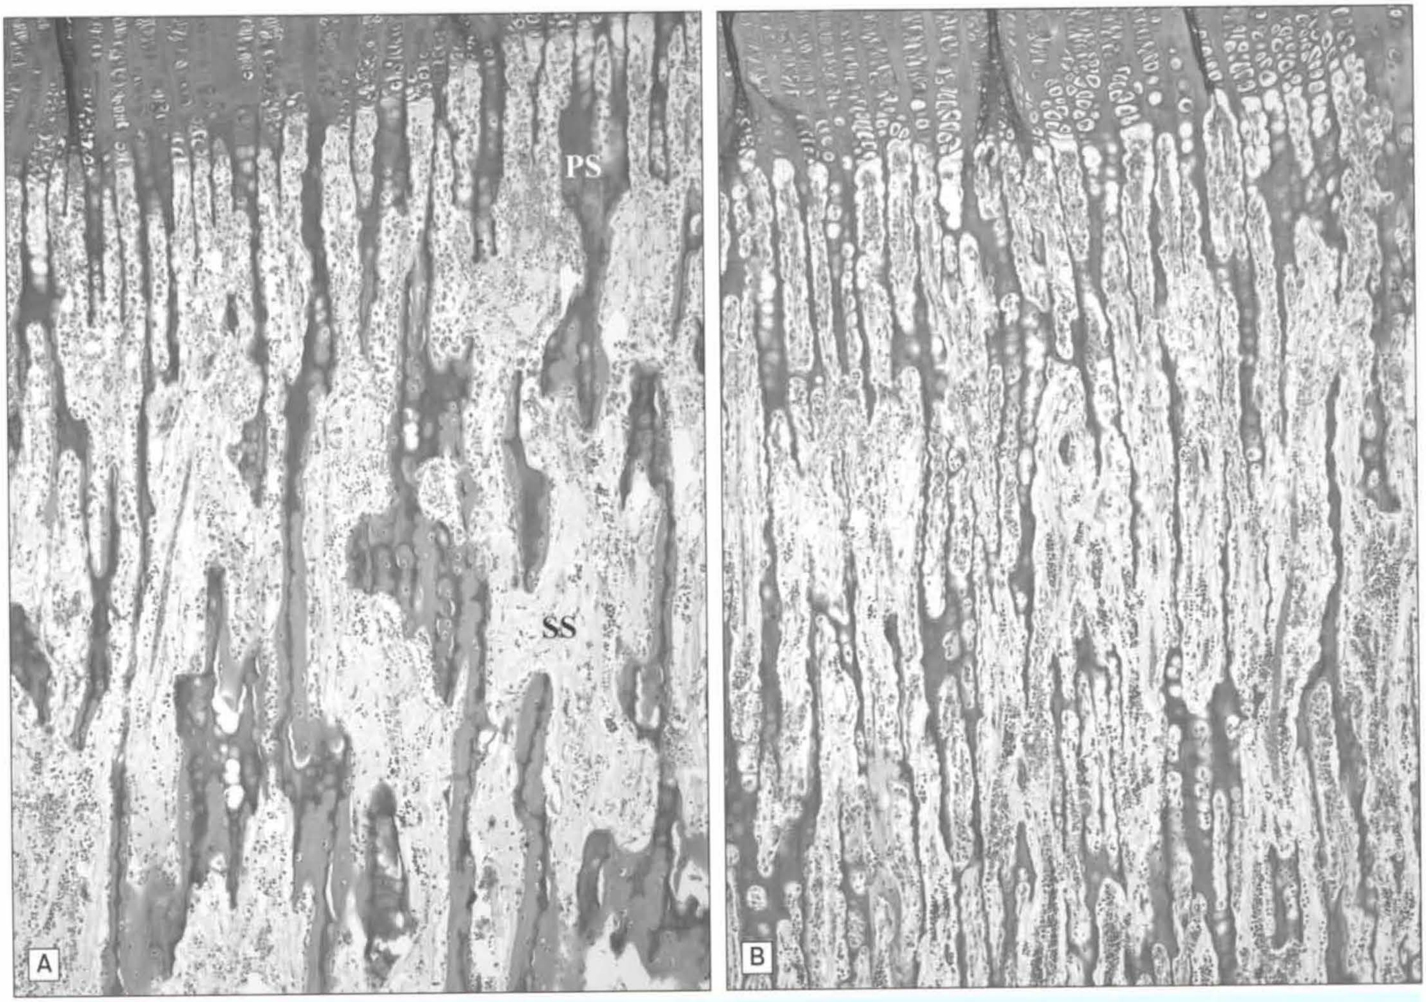

Figure 1.34 Ovine osteogenesis imperfecta. **A.** Metaphysis from a long bone of a **normal newborn lamb** showing primary spongiosa (PS) and secondary spongiosa (SS). **B.** Similar microscopic field from a **newborn lamb with osteogenesis imperfecta.** The primary spongiosa persists deep into the metaphysis and consists of delicate trabeculae lined by a thin layer of basophilic bone.

convincing cases have been recognized in both species. Multiple bone and tooth fractures, together with joint laxity, were reported in 2/4 and 3/6 pups from two litters of **Dachshunds** sired by the same dog. The disease was apparent from 3–4 weeks of age and histologic lesions in bone and dentine resembled those described in calves and lambs with osteogenesis imperfecta. Isolated cases of osteogenesis imperfecta have also occurred in **Golden Retriever, Beagle**, and **Standard Poodle** pups. Defective type I collagen formation was demonstrated in these three breeds using cultured skin fibroblasts. The disease was also diagnosed in a 12-week-old **domestic longhair** kitten that developed multiple spontaneous fractures of long bones. The kitten also had fractured teeth. Histologic examination of bones revealed a marked reduction in the quantity of cortical bone, most of which was woven bone, and an absence of well-developed osteons. These cases of osteogenesis imperfecta in the puppies and kitten appear analogous to the milder forms of the disease in humans.

Osteopetrosis

Osteopetrosis, or "*marble bone disease*," is a group of rare disorders occurring in humans, as well as in laboratory and domestic animals, characterized by *defective osteoclastic bone resorption and the accumulation of primary spongiosa in marrow cavities.* Two main forms of the disease are recognized in humans – a severe, recessively inherited, *lethal (malignant) form* with lesions present at birth, and a *dominant (benign) form* which becomes manifest later in life. Intermediate forms also exist. *In animals, most descriptions of osteopetrosis appear analogous to the malignant form and autosomal recessive inheritance is suspected in most cases.* Because of the complexity of osteoclast differentiation and function there are many points at which bone resorption can be interrupted, thus accounting for the clinical and morphologic variability associated with the osteopetroses. In some forms, osteoclasts are present in abundance but are incapable of resorbing bone, while in others osteoclasts are either absent or markedly reduced in number. For example, in the *op/op* osteopetrotic mouse, a deficiency in macrophage specific growth factor (M-CSF or CSF-1) results in an absence of osteoclasts. The disorder in these mice can be successfully treated with M-CSF. Deficiency of carbonic anhydrase II causes osteopetrosis in humans by interfering with the intracellular generation of protons by osteoclasts. Affected individuals have abundant osteoclasts, but acidification of the microenvironment at the cell–bone interface is not possible and resorption cannot occur. Patients with this form of osteopetrosis also have renal tubular acidosis and cerebral mineralization, reflecting a systemic deficiency of the enzyme.

In **cattle**, osteopetrosis is best studied in the **Angus** breed, where it is inherited as an *autosomal recessive trait.* Affected calves are small, premature (250–275 days of gestation) and usually stillborn. Clinically, they show brachygnathia inferior, impacted molar teeth and protruding tongue (Fig. 1.35A, B). The long bones are shorter than normal and easily fractured. Radiographically, the medullary cavities are dense, without clear differentiation between the cortex and medulla. Vertebrae are shortened, frontal and parietal bones are thick, and the bones of the cranial base are thick and dense. On cut surface, *the metaphyses and diaphyses of long bones, are filled with dense, unresorbed cones of primary spongiosa extending from the metaphysis to the center of the diaphysis* (Fig. 1.36A). In spite of their increased density, the bones are more fragile than normal and fractures are sometimes detected at necropsy. The fragility is much less marked than in osteogenesis imperfecta. Although the skeletal lesions of osteopetrosis are generalized, they vary in expression throughout the body. Nutrient foramina are either absent or hypoplastic. As a result of the abnormalities of the skull, the cerebral hemispheres are rectangular with flattened dorsal surfaces, the cerebellum is partially herniated through the foramen magnum, and optic nerves are hypoplastic.

Histologically, growth plates are essentially normal but metaphyses are relatively avascular. Dense chondro-osseous tissue, consisting of cartilage matrix lined by a thin layer of woven bone, occupies the medulla (Fig. 1.36B). Osteoclasts are rare and when present, appear to be inactive. *Failure to replace the primary spongiosa and its associated woven bone with thicker trabeculae of mature lamellar bone, presumably accounts for the increased fragility of osteopetrotic bones.* Cortical bone is apparently normal. In the brain, mineralized vessel walls and/or neurons may be found in the thalamus, cerebellum, meninges, choroid plexus, and around the aqueduct of Sylvius.

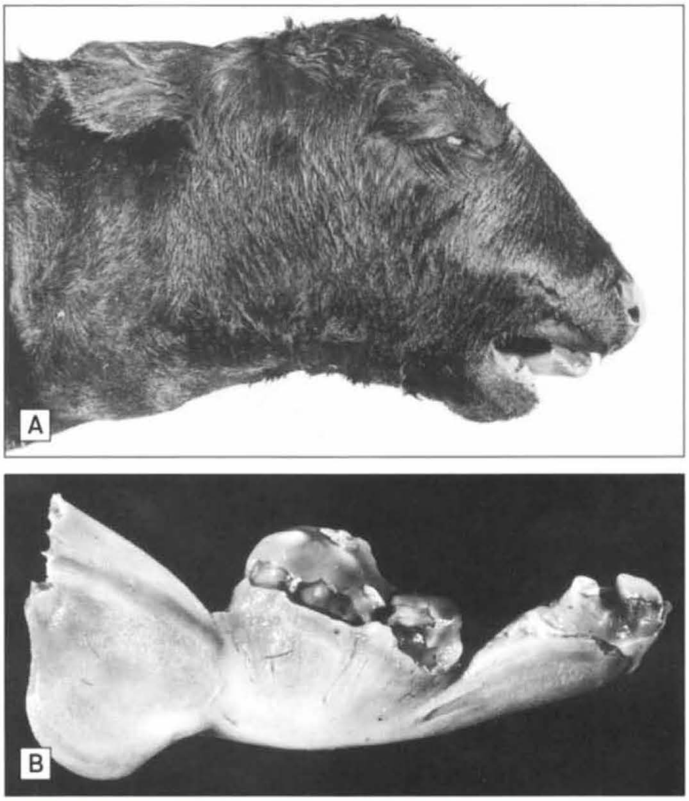

Figure 1.35 Bovine osteopetrosis. A. Stillborn Angus calf with inferior brachygnathia. **B.** Impacted molars in deformed, fragile mandible from the same calf.

Osteopetrosis of **Hereford** and **Simmental** breeds resembles that of Angus calves in most respects, including mode of inheritance, but in affected Herefords the frontal bones are markedly thickened and filled with cystic spaces. The domed forehead of these calves could be misinterpreted as hydrocephalus unless the skull is sectioned. An outbreak of an osteopetrosis-like disorder involving five of 16 Angus and Angus-Charolais cross fetuses has been reported but was associated with multiple skeletal deformities, including arthrogryposis and kyphoscoliosis in addition to frontal bone lesions similar to those of osteopetrosis in Hereford calves. Although a genetic etiology was suspected, the more likely possibility of a teratogenic agent was not excluded. In particular, infection of fetuses or young calves with ***Bovine viral diarrhea virus*** is capable of causing zonal osteopetrosis-like lesions, most likely secondary to transitory virus-induced osteoclast depletion. Acquired osteopetrosis-like lesions with varying degrees of metaphyseal sclerosis may also occur in association with ***Canine distemper virus*** infection in pups and in **lead poisoning** (see below).

A syndrome characterized by *persistence of the secondary spongiosa, perhaps analogous to metaphyseal dysplasia,* a rare human osteosclerotic disorder, was reported in three aborted or neonatal Hereford, Holstein, and Japanese Black calves. The macroscopic and histologic changes in these calves differed from those of osteopetrosis and

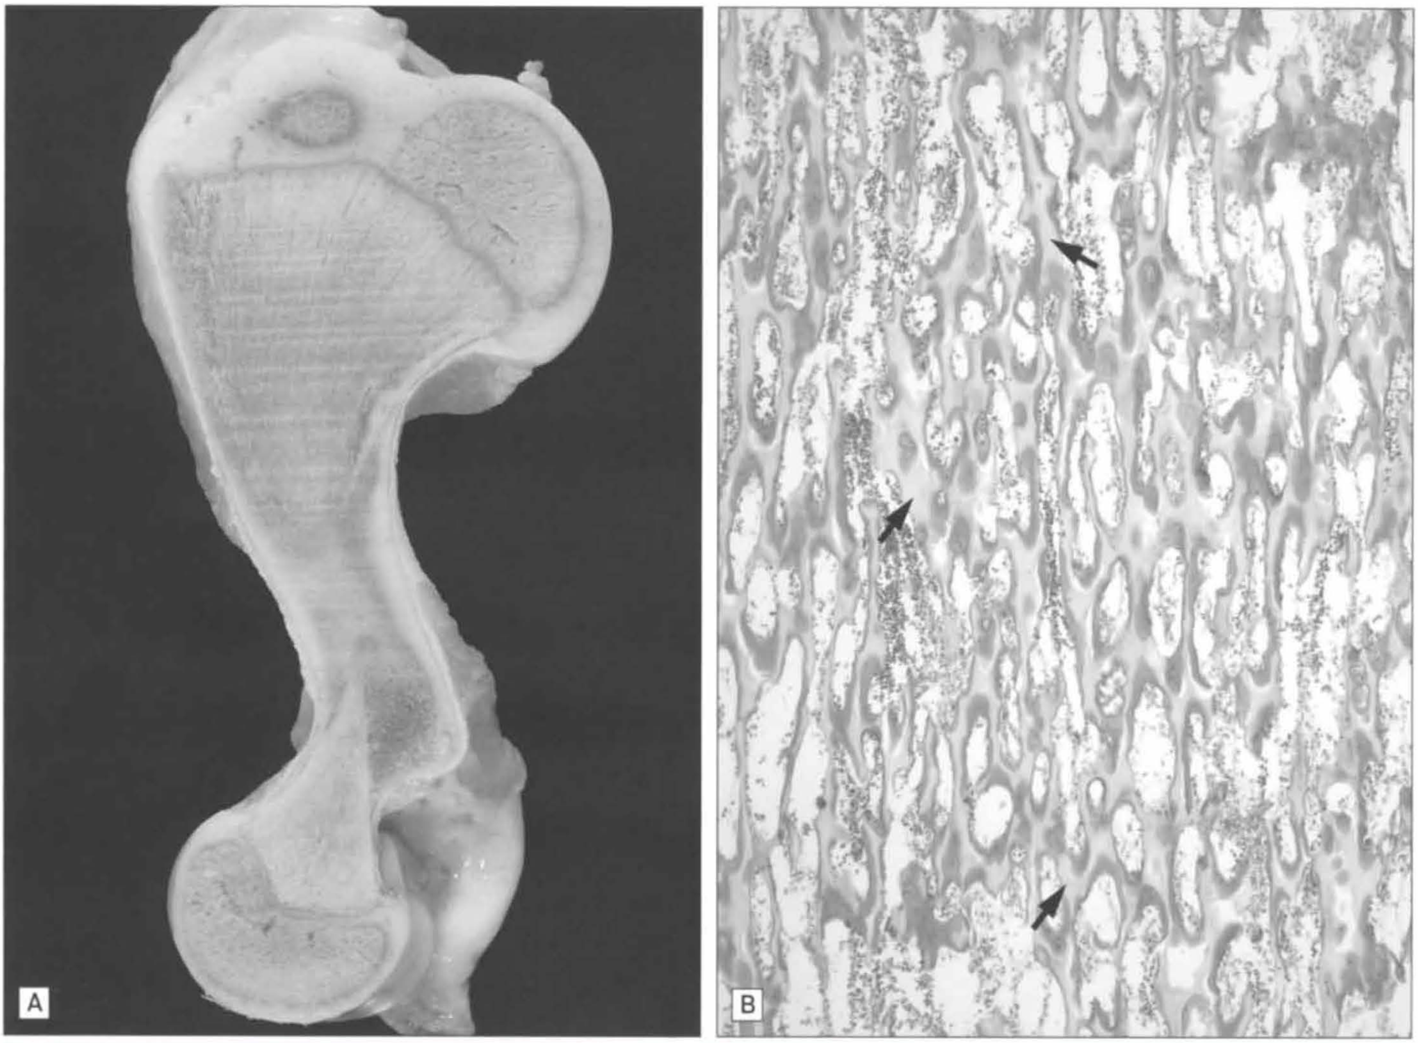

Figure 1.36 Bovine osteopetrosis. A. Sagittal section of humerus showing unresorbed cones of primary spongiosa extending from the proximal and distal growth plates into the diaphysis. No medullary cavity is evident. (Courtesy of RA Fairley.) **B.** Section of metaphysis showing a dense lattice of delicate interconnected trabeculae consisting of cartilage matrix (arrows) covered by a thin layer of bone.

their significance is questionable. In two of the calves, the shape of the bones was essentially normal and there was no mention of fragility. Osteoclast numbers were not reduced but those present were thin and inactive. Such subtle skeletal abnormalities could be much more common than is currently recognized, as without radiography or longitudinal sectioning of long bones they would remain undetected.

Osteopetrosis in **horses** with clinical, radiographic and pathologic features similar to the severe lethal form in Angus calves has been reported in four **Peruvian Paso foals** and one **Appaloosa**. Affected foals are of normal size at birth and are born alive but unable to stand. Brachygnathia inferior is a consistent finding and there is malpositioning and impaction of the teeth, reflecting the requirement of osteoclastic activity for normal tooth eruption. Long bones and vertebrae contain medullary cones of primary spongiosa extending from the physis to the center of the diaphysis, filling the medullary cavity (Fig. 1.37). The fragility of the bones is illustrated by the presence of multiple rib fractures, some of which probably occur in utero. Histologic changes are similar to those described for Angus calves except for the presence of normal to increased numbers of osteoclasts in affected foals. The osteoclasts appear larger than normal but no ruffled border is evident ultrastructurally, *suggesting a functional defect in osteoclasts as the basis of the disease in foals*. Although the total number of cases is small, it is likely that the disease in Peruvian Paso horses is inherited as an autosomal recessive trait.

Osteopetrosis has also been reported in an inbred captive herd of **white-tailed deer**. In addition to marked brachygnathia inferior, impacted teeth and protruding tongue, affected fawns had characteristic radiodense bones and calluses on several ribs, indicating in utero fractures.

In **dogs**, osteopetrosis is reported in three neonatal **Dachshund** puppies from the same litter. Their bones were of normal size and shape but had increased fragility. Isolated cases in an **Australian Shepherd** and a **Pekingese** were diagnosed at 12 months and 30 months of age respectively. Both dogs developed severe myelophthisic anemia.

In **cats**, osteopetrosis has been associated with chronic vitamin D toxicosis and subsequent to infection with *Feline leukemia virus*. Increased density of vertebrae and thickening of the cortices of long bones characterized an osteopetrosis-like disorder in two adult

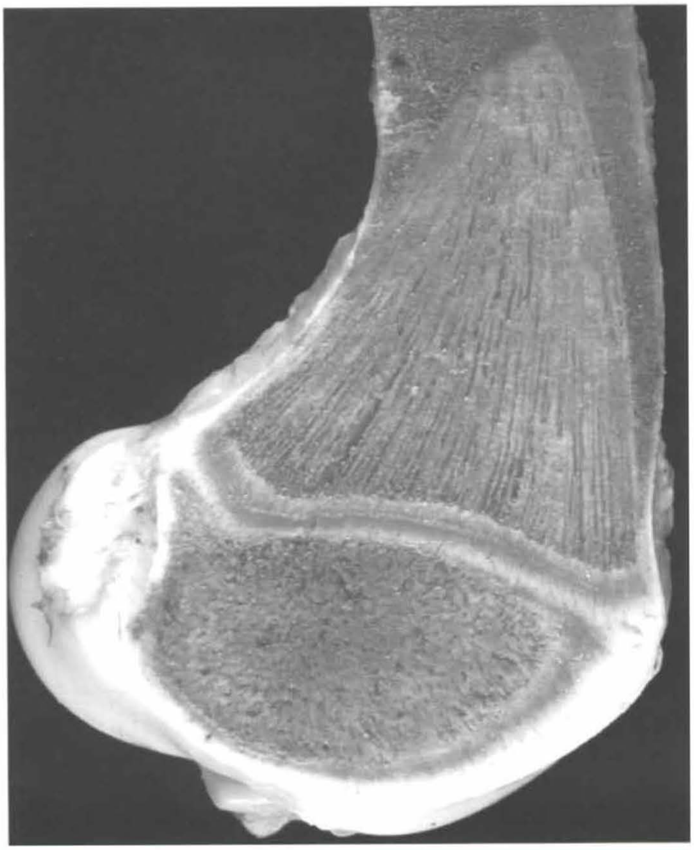

Figure 1.37 Equine osteopetrosis. Distal femur of an affected foal. Note the cone of unresorbed primary spongiosa extending into the metaphysis from the physis. (Courtesy of MW Leach.)

cats. The shape and size of the bones were normal. This syndrome, and that in the Australian Shepherd and Pekingese dogs, may be analogous to one of the benign forms of human osteopetrosis, or could be acquired lesions of undetermined pathogenesis.

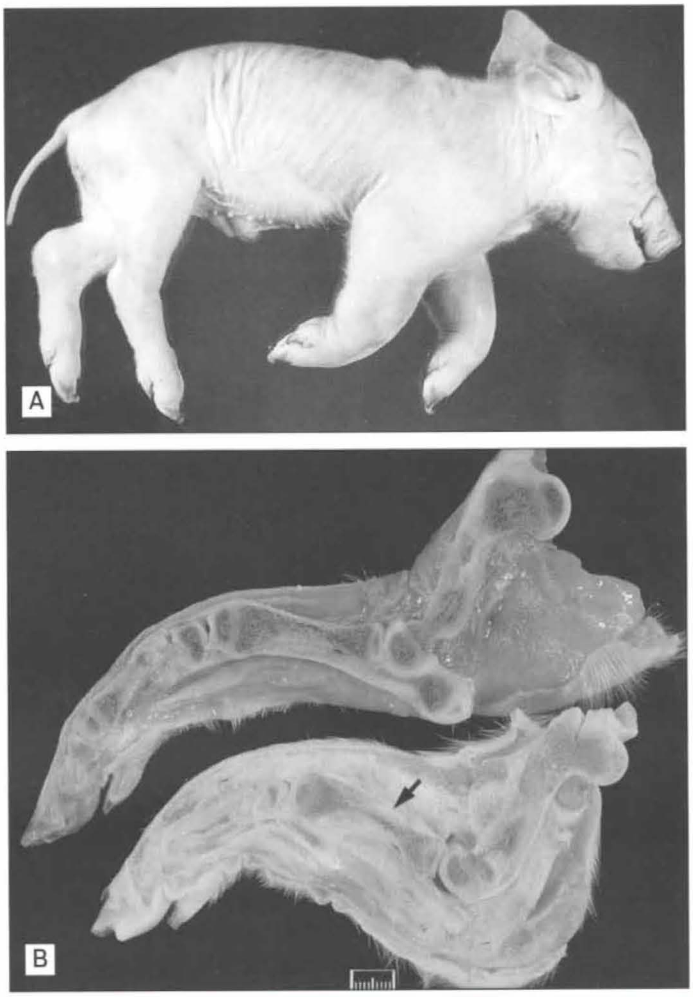

Figure 1.38 Porcine congenital hyperostosis. A. Marked swelling of both forelegs and less severe involvement of the left hindleg. **B.** Comparison of forelegs from a normal (above) and affected piglet. The radius of the affected limb is thickened due to increased periosteal bone (arrow). There is extensive edema and swelling of soft tissues throughout the entire limb. (Courtesy of RA Fairley.)

Congenital hyperostosis

Congenital hyperostosis (*cortical hyperostosis, diaphyseal dysplasia*) is a rare disease of newborn **pigs**. Affected piglets are either stillborn or die within the first few days of life, and show various degrees of thickening of one or more forelimbs (Fig. 1.38A), and sometimes the hindlimbs as well. The thickened limbs are hard and may be up to twice their normal size. The radius and ulna are the most severely affected and in some cases are the only bones involved. Grossly, *a thick layer of extracortical bone extends along the diaphyses* (Fig. 1.38B). Marked edema of the surrounding soft tissues contributes to the thickness of the limb. Histologically, radiating trabeculae of woven bone extend from the surface of apparently normal cortical bone beneath a thickened periosteum (Fig. 1.39A) containing multiple layers of active osteoblasts. The periosteum merges with edematous, poorly vascular connective tissue containing scattered, stellate fibroblasts, which infiltrate adjacent muscle bundles and the overlying dermis (Fig. 1.39B). No lesions are found in bones of the axial skeleton.

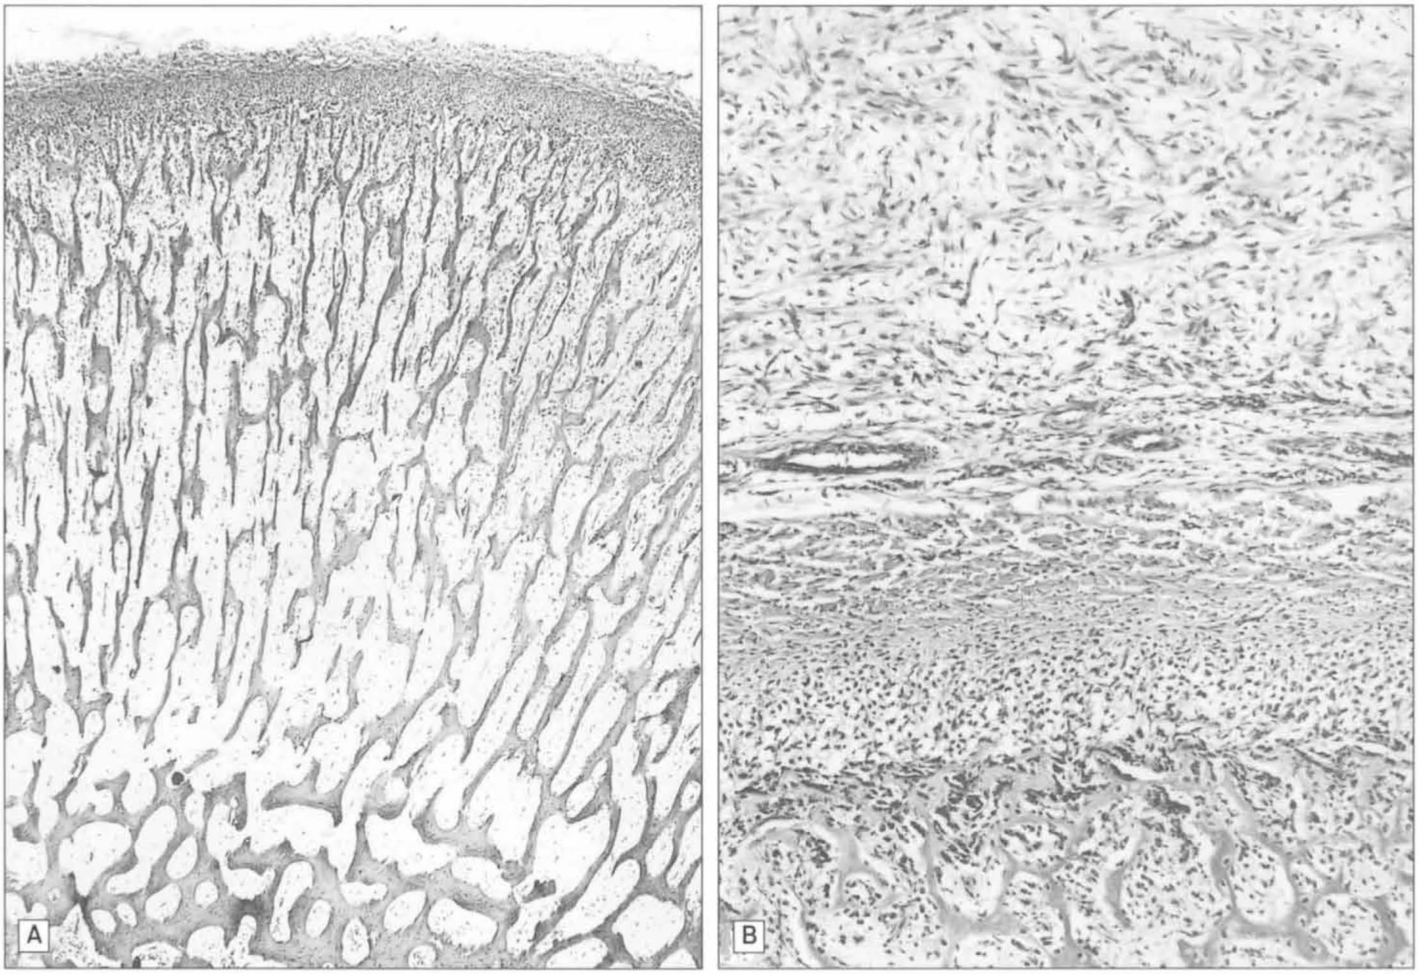

Figure 1.39 Porcine congenital hyperostosis **A.** Transverse section of bone showing radiating trabeculae of woven bone extending out from the cortex beneath a thickened periosteum. **B.** Closer view of reactive bone forming at the periosteal surface. The surrounding muscle is edematous, myofibers are atrophic and there are many stellate fibroblasts throughout.

Congenital hyperostosis of pigs is believed to be inherited as an autosomal recessive trait, but this has not been proven. In fact, the disease may not be inherited at all. The pathogenesis is not known, but the periosteal reaction is consistent with prolonged edema caused by a local circulatory disturbance. Arteriosclerotic lesions in small arteries and arterioles have been identified in vessels supplying the radioulnar region in affected piglets, supporting the possibility that the mechanism may involve localized hypertensive changes, perhaps due to abnormal intrauterine positioning of the fetus.

Infantile cortical hyperostosis, or Caffey's disease, is a disease of children, which resembles congenital hyperostosis of pigs. The disease may be congenital but more often develops in infancy and is characterized by extensive periosteal new bone formation at multiple sites, most commonly the mandible, clavicle, and long bones, including those of the forearm. However, the human syndrome is self-limiting and regresses over several years. A hyperostotic disease similar to infantile cortical hyperostosis was reported in a **West Highland White Terrier** dog that had periosteal new bone formation involving the pelvis, scapulae, humeri, ulnae, femora, radii, and tibiae when it was destroyed at 22 months of age.

Osteochondromatosis

Osteochondromatosis, also known as *multiple cartilaginous exostosis*, is a skeletal dysplasia characterized by the formation of single or multiple tumor-like exostoses. In humans, dogs, and horses, the disease is inherited as an *autosomal dominant trait*. In dogs, the lesions usually are not present at birth but arise in young animals on the surface of endochondral bones adjacent to physes or subarticular growth cartilages, and continue to enlarge until the skeleton matures. In affected horses, the lesions are often present at birth and tend to be bilaterally symmetrical. Because of their tumor-like appearance, these lesions are discussed in more detail in the section on cartilage-forming tumors (Tumors and tumor-like lesions of bones, p. 119).

Idiopathic multifocal osteopathy

This syndrome, characterized by *multifocal absence of bone in the skull, cervical vertebrae, and proximal regions of the radius, ulna and femur*, has recently been reported in four **Scottish Terriers**. Three of the four dogs were related, suggesting a genetic etiology. It was not clear whether the disorder was acquired or congenital as the abnormalities were not detected until the dogs were young adults, by which time the lesions were well developed. The localized areas of absent bone were replaced with fibrous tissue but whether this reflects abnormal development of the bone, or lysis of bone and replacement fibrosis, is not clear. Histological evidence of osteolysis was present in one case, supporting the latter option. A similar condition characterized by multicentric bone lysis and replacement fibrosis occurs in humans where it is referred to as *Winchester syndrome or "vanishing bone disease."*

Localized skeletal dysplasias

Skeletal dysplasias characterized by localized anomalies of the appendicular or axial skeleton are included in this section, together with discussion of the vertebral abnormalities associated with wobbler syndrome in dogs and horses.

Limb dysplasias

The most frequent malformations of the limbs are the localized chondrodysplasias seen in chondrodystrophoid breeds of dog. These are inherited as polygenic traits and are mediated by variations in receptor activities for hormones and other factors that regulate the proliferation of physeal chondrocytes. The defect is usually confined to the distal bones, producing the sort of dwarfism seen in such breeds as the Basset Hound and Dachshund. In some breeds, such as the Pekingese, chondrocytes of neural crest origin are also involved and there are basocranial abnormalities. In other breeds, such as the Boston Terrier and Boxer, only the basocranium is affected, the limbs being of normal length. The cartilage abnormality may also involve the intervertebral disks, the central or perinuclear portions of which develop as immature hyaline cartilage with only a gradual transition at the periphery towards the normal laminated fibrocartilage of the annulus fibrosus. Such disks are predisposed to degeneration of the hyaline cartilage followed by herniation of the disks (see disk degeneration and spondylosis, p. 154).

A wide range of defects of the limbs and/or digits has been reported in domestic animals, often as isolated cases of unknown etiology. Rather than attempt to present a comprehensive list, discussion in this section will focus on those conditions known or suspected to be genetic in origin.

Syndactyly, a defect characterized by *partial or complete fusion of functional digits*, occurs in several breeds of cattle, including Holstein-Friesian, Angus, Chianina, Hereford, Simmental, German Red Pied, Indian Hariana, and Japanese native cattle. Inheritance in cattle is *autosomal recessive with incomplete penetrance and variable expression.* The disorder became very common in the Holstein-Friesian breed following extensive use of a heterozygous bull by artificial breeding, but is rare in other breeds. In Holstein-Friesians, the disorder seldom affects all four digits. The right forelimb is most frequently affected, followed by the left forelimb then the right hindlimb. In contrast, the defect in Angus cattle usually affects all four digits. *The lesions of syndactyly may vary from complete horizontal fusion of paired phalanges to fusion of only one or none of the phalanges, but fusion of interdigital soft tissues.* Vertical fusion of phalanges is reported in some affected Angus cattle. The production of affected calves from Angus-Holstein matings suggests that the same gene locus is involved, at least in these breeds, but differences in the manifestations of syndactyly between affected Angus and Holstein-Friesian calves suggests the existence of two recessive alleles. In the Holstein-Friesian breed, syndactyly is linked to increased susceptibility to hyperthermia and affected cattle often die of heat stress. Syndactyly has been reported in Shorthorn cattle in association with **dactylomegaly**, a form of club foot (talipes). The condition was characterized by various degrees of dew claw enlargement. Syndactyly is also reported in pigs, where it is presumed to be caused by a simple dominant gene, and occasionally in sheep and dogs.

Incomplete fusion of the paw is reported in dogs and cats and referred to as **ectrodactyly**. In cats, a *dominant gene* with variable expressivity is responsible and the defect is bilateral. In dogs, dominant inheritance is likely and the defect is usually unilateral. The cleft in the paw extends to the level of the metacarpals, and occasionally reaches the carpus. Various other limb defects may accompany the ectrodactyly, including aplasia or hypoplasia of carpal and metacarpal bones, duplication of digits, fusion of metacarpals, and elbow joint luxation. Syndromes characterized by total or partial absence of phalanges have been reported as ectrodactyly in calves and lambs. These defects differ from the disease in cats and dogs and may be better termed **adactyly**, a condition characterized by the *absence of phalanges* and reported as a possible inherited defect in Southdown lambs.

Polydactyly *is an increase in the number of digits.* The anomaly is observed in all species but is perhaps best known in *cats, dogs, horses, and cattle.* Polydactyly is an inherited trait in various bovine breeds but the inheritance pattern is poorly understood. In most cases, it is the medial digit (digit 2) that is duplicated and although all four feet may be affected, the anomaly is more frequently confined to the forelimbs. A polygenic mode of inheritance requiring a dominant gene at one locus and two recessive genes at another is postulated in Simmental cattle. In horses, two forms of polydactyly occur. The *common, atavistic type* features an extra medial digit, usually involving a forelimb, which articulates with a second metacarpal. *The rare, teratogenic form* is characterized by duplication of bones distal to the fetlock joint, producing a cloven hoof. In goats, a Shami buck with two extra digits on both hindlegs sired a doe kid with a similar defect, suggesting a genetic etiology. An inherited syndrome of multiple skeletal defects including polydactyly and syndactyly together with cleft palate, shortened tibia, brachygnathism, and scoliosis occurred in a family of Australian Shepherd Dogs. An X-linked lethal gene was suspected. Polydactyly is also reported in pigs where it is usually associated with cleft palate and is believed, but not proven, to be inherited.

Hemimelia *refers to the partial absence of one or more limbs* and occurs as a recessively inherited lethal defect in Galloway calves. Affected calves have bilateral agenesis of the tibial bones and patellae. Other bones of the hindlimbs are apparently normal, highlighting the localized nature of the defect. A similar syndrome characterized by tibial hemimelia, meningocele, retained testicles and abdominal hernia is reported in Shorthorn calves and is also believed to be transmitted as an autosomal recessive trait. Bilateral tibial hypoplasia has been reported in a Simmental calf. A recessively inherited form of hemimelia involving distal forelimbs is reported in Chihuahua dogs. The abnormality may be either transverse, in which case the entire forearm is absent, or paraxial, where there is aplasia of only some metacarpals and digits. Paraxial hemimelia with bilateral agenesis of radial bones is reported in goat kids. In lambs, hemimelia characterized by incomplete development of distal limbs has been reported but in one "outbreak" was most likely due to ingestion of lupin alkaloids by pregnant ewes, rather than a genetic defect.

Peromelia, a term sometimes used synonymously with hemimelia, has been used to describe a syndrome characterized by *agenesis of distal parts of the limbs in Angora goats*. Affected kids lack the phalanges and parts of the metacarpus or metatarsus on one or more limbs. Autosomal recessive inheritance is suspected. In isolated cases where the distal limb is absent, it is important to exclude the possibility that the missing component was accidentally ingested by the dam when she was eating the placenta. This is most likely to occur in goats. *Congenital absence of one or more limbs*, **amelia**, has been reported in a foal and a calf.

Skull

Brachygnathia inferior, *shortening of the mandibles*, and **brachygnathia superior**, *shortening of the maxillae*, may occur alone or in combination with other skeletal defects. Brachygnathia inferior is commonly encountered in otherwise normal domestic animals and, while not life-threatening, is considered an undesirable characteristic. Genetic and teratogenic etiologies have been suggested and both are likely to occur. Brachygnathia superior occurs in association with degenerative joint disease as a lethal genetic defect in Angus calves. In addition to brachygnathia superior, affected calves have other skull changes similar to those of brachycephalic dogs and degenerative changes are present in articular cartilage throughout the body. The nature of the underlying defect is not known, but histologically there is degeneration of cartilage matrix and necrosis of chondrocytes in articular cartilage.

Sternum

Lateral curvature of the sternum occurs in association with vertebral scoliosis, especially when the latter shows simultaneous torsion. *Retraction of the caudal sternebrae and xiphoid* is seen in lambs and calves, and is apparently due to shortness of the tendinous portions of the diaphragm. *Clefts of the sternum* may occur as isolated defects, but are usually accompanied by ectopia cordis or form part of the defect known as *schistosomus reflexus*. In this syndrome, there is lordosis, dorsal reflection of the ribs with more-or-less total eventration, nonunion of the pelvic symphysis and dorsal reflection of the pelvic bones. *Sternal deformity* also occurs in "spider lamb" chondrodysplasia.

Ribs

Costal abnormalities are usually secondary to malformation of the vertebral column or sternum. Absent or fused ribs correspond to absent or fused vertebrae and may accompany severe scoliosis.

Pelvis

Lesions of the lumbosacral region, arising from abnormalities of the notochord failing to give rise to appropriate dermatomes, occur in humans and lead to various abnormalities often collectively termed the **caudal regression syndrome**. Abnormalities of this derivation result in lumbosacral agenesis, as seen in English bulldogs, but often are accompanied by anorectal abnormalities, urogenital anomalies, various anomalies of the spinal cord, and in humans the development of a variety of tumors and cysts. These include yolk sac cysts, cysts of urogenital origin, lipomas, teratomas, and nephroblastomas. The sacrum may be absent, or it may be hypoplastic or deviated in association with absence of the coccygeal vertebrae. Hypoplastic chondrodysplasia of the coccygeal vertebrae is a characteristic of French bulldogs and occurs occasionally, with kinking of the remnants, in cattle and cats. Malformations of the sacrum accompany other severe spinal defects. The pubic bones are separated and may be absent, in association with ectropion of the bladder.

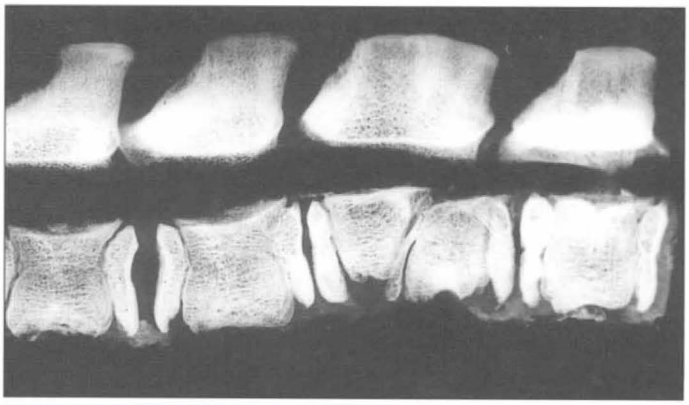

Figure 1.40 Block vertebra. Two vertebral bodies are incompletely separated and their dorsal processes are fused.

Vertebrae

The development of the vertebrae and intervertebral disks is a complex process involving interactions between ectodermal and mesodermal elements. Defects can arise from errors at many stages of development and, because of the proximity of the spinal cord, the consequences are often serious. **Spina bifida** *results from defective closure of dorsal vertebral laminae in a segment of the vertebral column.* It has been reported in several different breeds of cattle and there is some evidence to support autosomal recessive inheritance. Teratogenic agents acting early in pregnancy can no doubt produce similar lesions. The lesions vary markedly in severity and are often accompanied by defects in the overlying skin, meningocele, and sometimes myelodysplasia. The defect may occur at virtually any level of the vertebral column but appears to favor the lumbar and sacral regions. Various nonskeletal defects have been described in association with spina bifida, including arthrogryposis, due to spinal damage and defective innervation of some muscle groups, fusion of the kidneys, unilateral aplasia of one uterine horn, atresia ani, and kyphoscoliosis.

Perosomus elumbus, a rare congenital defect characterized by *agenesis of the lumbosacral spinal cord and vertebrae*, is reported in cattle, sheep, and pigs. In two affected Hereford calves, the spinal column terminated at the last thoracic vertebra. Both calves had arthrogryposis of the hindlimbs and one also had other skeletal defects, including absence of some ribs, unilateral agenesis of the scapula and humerus, and polydactyly involving one leg. The absence of the lumbar spinal cord in affected cattle is associated with extreme muscle atrophy and replacement with adipose tissue. In an affected stillborn Holstein heifer calf, the skeletal abnormalities were accompanied by anomalies in the urogenital system and distal colon/rectum. It has been suggested, but not proven, that perosomus elumbus in Holstein cattle is inherited.

Block vertebra *results from improper segmentation of the somites in the embryo, resulting in complete or partial fusion of adjacent vertebrae* (Fig. 1.40). The fused structure may be equal to or shorter than the pair of vertebrae it replaces. There are usually no clinical signs. **Butterfly vertebrae** are so called because of the *appearance of the indented vertebral end plates on ventrodorsal radiographs.* The cause is *persistence of notochord*, or a sagittal cleft of notochord, that leads to a dorsoventral, sagittal cleft in the vertebral body. The halves may spread laterally but the condition is usually an incidental radiographic finding in screw-tailed dogs such as Bulldogs, Pugs, and Boston Terriers. **Hemivertebrae** may arise as a result of displacement and inappropriate fusion of somites. In this case, *one member of a pair of somites fuses diagonally with a somite cranial or caudal to it*, forming a vertebra but leaving the other members of the pairs to persist as hemivertebrae.

Complex vertebral malformation is a lethal congenital defect of Holstein calves characterized by shortening of the cervical and thoracic vertebral column due to multiple hemivertebrae, fused and misshapen vertebrae, and scoliosis. Affected calves are smaller than normal, sometimes born premature, and consistently show symmetrical arthrogryposis of the forelimbs. The hindlimbs may also show mild arthrogryposis. Approximately 50% have heart malformations, including ventricular septal defects and dextraposition of the aorta. A genetic etiology is suspected. Two common ancestral sires were identified in the pedigrees of 18 affected calves in Denmark and it is suggested that one is a carrier. Both are former elite sires of US origin and it is possible therefore that the defect is present in several countries. There is one recent report of the syndrome in the USA.

Subluxations, fusions, and other anomalies of cervical vertebrae are described with developmental disturbances of joints.

Cervical vertebral stenotic myelopathy (wobbler syndrome)

Cervical vertebral stenotic myelopathy (cervical vertebral malformation, cervicospinal arthropathy, wobbler syndrome) is a neurological disease characterized by slow, progressive, ataxia of the hindlimbs, and occasionally the forelimbs, due to compression or stretching of the spinal cord as a result of a primary abnormality in the vertebral column. The syndrome occurs most commonly in horses and large breeds of dog, particularly Great Danes and Doberman Pinschers. In both species, male animals are affected much more often than females, and rapid growth is an apparent predisposing factor. The vertebral lesions reported in horses and dogs with the disease are similar, suggesting a common pathogenesis. In both species there are two pathologic syndromes, *cervical vertebral instability* and *cervical static stenosis*, the former damaging the cord only when the neck is extended or flexed, the latter resulting in cord compression no matter what position the neck is in. Usually the onset is insidious, but vague signs are often exacerbated following trauma or strenuous activity. The disease in

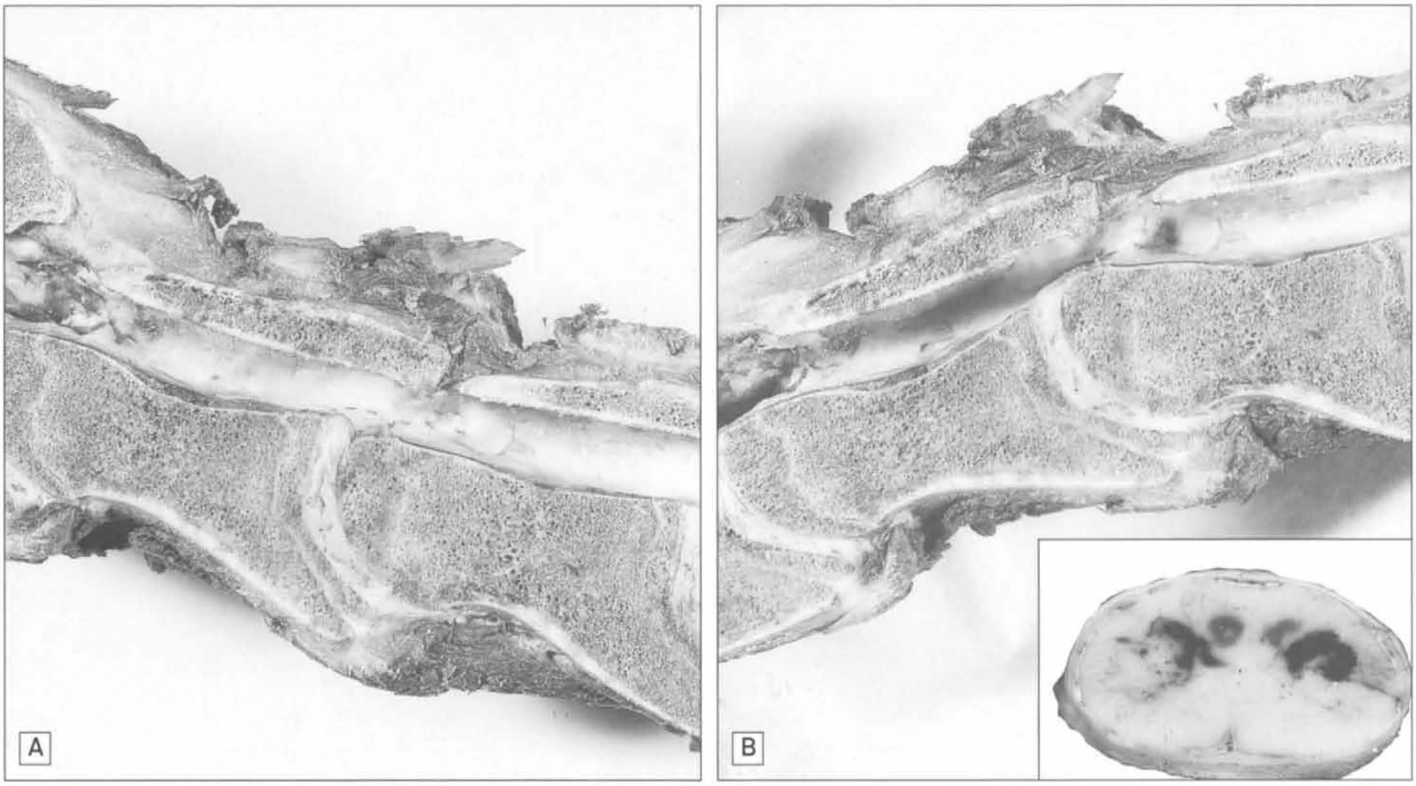

Figure 1.41 Cervical vertebral stenotic myelopathy. C-3 and C-4 from a "wobbler" horse. **A.** Neck extended. **B.** Neck ventroflexed to show stenosis of the spinal canal. Malacia of cervical cord is illustrated in the inset.

horses is not progressive, but if the signs are severe, recovery does not occur.

In **horses**, cervical vertebral stenotic myelopathy occurs most often in *Thoroughbreds* and *Quarter Horses*. **Cervical vertebral instability** usually affects fast growing young horses 8–18 months of age and is associated with lesions in the region of C-3 to C-5. The lesions vary and are not always easy to detect at necropsy, especially since the problem may only be apparent when the neck is ventroflexed (Fig. 1.41A, B). In a few cases, a lip may be palpated on the dorsal border of the vertebral body, apparently due to expansion of the cranial epiphysis. More often, a distinct lip is not palpable, but a mid-sagittal section of affected vertebrae shows that the floor of the spinal canal angles upwards and the roof angles downwards to produce a funnel-shaped canal with cranial stenosis. Occasionally, the cranial articular processes of the vertebral bodies project in a ventro-medial direction and impinge upon the spinal canal, compressing the dorsolateral parts of the cord. In a small proportion of cases, increased mobility of adjacent cervical vertebrae, which allows subluxation is apparently responsible for the cord compression. Although the lesions in cervical vertebral instability occur most often at C-3 to C-5, other vertebrae may also be affected, and more than one lesion may be present in a single animal.

Articular facets of vertebrae in horses with cervical vertebral instability often contain lesions typical of the degenerative arthropathy that follows osteochondrosis (see below). These lesions may be accompanied by osteophytic outgrowths at the articular margin, altering the size and shape of the facet and occasionally encroaching on the spinal canal. Similar changes can however be found in many clinically normal horses and their presence in a wobbler must be interpreted with caution. Asymmetry of articular facets is also present in many affected horses (Fig. 1.42), but this too is of questionable significance, since many clinically normal horses have similar changes. In some affected horses, there is also evidence for osteochondrosis affecting vertebral growth plates in the cervical

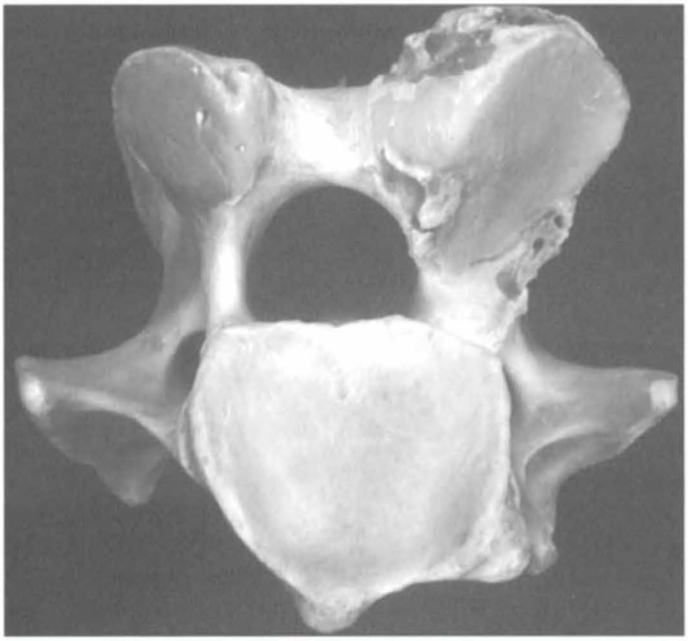

Figure 1.42 Asymmetry of articular facets in a "wobbler" horse. (Courtesy of JD Baird.)

region. Nonetheless, in some horses the spinal cord injury is likely to be due to vertebral malalignment created by asymmetry of articular facets.

The fundamental cause of cervical vertebral instability in horses is not clear. There is growing evidence that the multiple genetic factors that permit rapid growth, and the dietary excesses that encourage it, are responsible. In particular, the *ad libitum feeding of high-protein, high-energy rations to weanlings to produce maximum-sized yearlings seems to be the major influence.* Such feeding practices are commonly associated with osteochondrosis and many affected horses have lesions of this disease, but the significance of this to the overall incidence of cervical vertebral instability is presently undetermined.

Cervical static stenosis, the second, less common form of cervical vertebral stenotic myelopathy, usually occurs in large male horses between 1 and 4 years of age and is caused primarily by *thickening of the ligamentum flavum and the dorsal lamina of the vertebral arches.* The spinal cord is compressed by the encroachment of these structures on the spinal canal. Histologically, there is increased fibrocartilage at the attachment of the ligamentum flavum to the dorsal lamina, and deposition of fibrovascular tissue both in the ligamentum and the contiguous joint capsule. The thickening of the dorsal lamina is due to osteosclerosis, with the dense trabeculae being formed by compaction of the fibrocartilage of the ligamentum flavum. Degenerative arthropathy of articular facets is usually present and, although its severity is not correlated with the severity of signs, it may be the result of a primary vertebral instability that also subjects the ligaments and laminae to abnormal mechanical forces. The osteosclerosis and development of fibrocartilage are consistent with increased forces and joint movement. Compression of the spinal cord by synovial cysts has also been reported.

In the final analysis, *interpretation of osseous lesions depends on their linkage with spinal cord degeneration.* There is variation in the suddenness and the severity of cord injury, and in the immediate pathogenesis of injury, which may occur directly by pressure on the nervous tissues, or indirectly if local blood vessels are compromised. Thus, there may be one or more primary foci of softening in the cervical cord with Wallerian degeneration of the ascending and descending tracts. Careful examination of the cord, with the dura mater reflected, sometimes reveals a slight depression in the contour of the nervous tissue at the affected site. Sometimes, the primary foci of malacia are visible after fixation as brown areas in the gray matter, usually adjacent to an articulation (Fig. 1.41B). The fixed cord should be sliced at intervals of no more than 2 mm, otherwise a lesion may be missed. Histologic examination is necessary to confirm and demonstrate lesions.

Microscopically, there is more-or-less extensive demyelination in the cord. In severe cases with gross lesions, hemorrhagic and necrotic foci can be found in the gray matter in either the ventral or lateral horns, and may be either unilateral or bilateral. Even when lesions are absent from the gray matter, the primary focus or foci are visible in short segments of the white matter, which shows the moth-eaten appearance typical of demyelination. In the primary foci there are ragged microcavitations, which represent areas of liquefactive necrosis. Many adjacent degenerate fibers are swollen and basophilic. About the primary focus, demyelination may be present in all tracts while *cranial to the focus, the lesions can be seen in ascending fibers, most of which are in the dorsolateral funiculi. Caudal to the focus the demyelination is primarily in the ventral and ventrolateral funiculi*, symmetrical on either side of the ventromedian fissure, and extending as far as the lumbar region in some animals. As a consequence of localized edema, often there is striking astrocytosis in chronic lesions and cells are increased both in number and size, becoming gemistocytic in type.

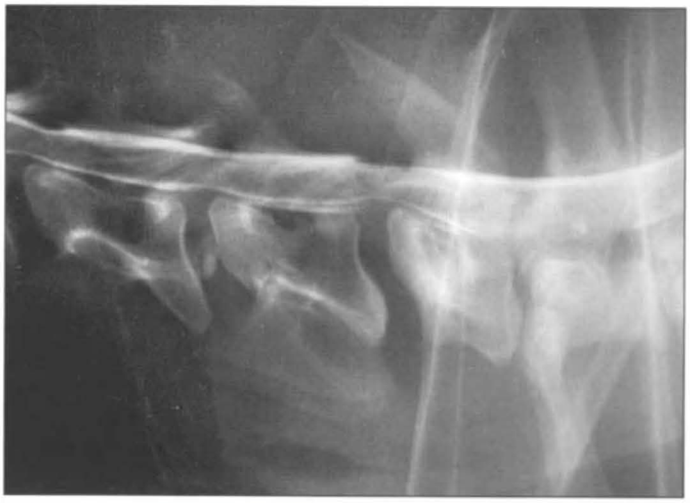

Figure 1.43 Caudal cervical spondylomyelopathy in a Doberman Pinscher. Myelogram showing compression of the spinal cord at the cranial opening of C-7. The body of this vertebra is malformed. (Courtesy of HM Burbidge.)

There are many similarities between cervical vertebral stenotic myelopathy in **dogs** and the disease in horses. The *age of onset varies from a few weeks to several years* although, in general, Great Danes develop signs at an earlier age than Dobermans. There is mounting evidence for an *inherited predisposition*, although overnutrition and abnormal biomechanical forces involving cervical vertebrae have also been suggested as contributing factors. *A variety of anatomical or functional abnormalities have been described in affected dogs, usually in the region of C-6 to C-7.* Malformation of vertebrae, including stenosis of the cranial opening (Fig. 1.43), degeneration and asymmetry of articular facets, and misshapen vertebral bodies caused by early closure of the dorsal part of the caudal physis with elongation of the ventral part of the body, are detected in some affected dogs. Instability of cervical vertebrae, particularly of those that are misshapen, is also reported but is difficult to assess objectively. There is no doubt that some cases of wobbler syndrome in dogs are caused by alterations in the supporting ligaments rather than the vertebrae. In one study, the most common cause of spinal cord compression in dogs was considered to be hyperplasia of the ligamentum flavum with protrusion into the spinal canal. Compression of the cord by the bulging ligament is greatest when the neck is extended and is relieved when the neck undergoes traction or full flexion.

Stenosis of the cervical vertebral canal also occurs in **sheep** and although little is known about the syndrome in this species, it is probably linked to heavy feeding and perhaps the trauma associated with fighting.

GENETIC DISEASES INDIRECTLY AFFECTING THE SKELETON

Lysosomal storage diseases

The lysosomal storage diseases are a large group of inherited or acquired deficiencies in the activity of specific lysosomal enzymes, culminating in the accumulation of otherwise digestible substrates in the lysosomal system of various cell types. Although many such diseases have been reported in domestic animals, only the mucopolysaccharidoses and the gangliosidoses affect the skeleton. In both groups of diseases there are lesions of greater significance in other organ systems, particularly the central nervous system (see Vol. 1, Nervous system).

The **mucopolysaccharidoses** (MPS) are characterized by the *accumulation of partially catabolized glycosaminoglycans in lysosomes* and, in human medicine, are classified on the basis of the specific enzyme defect and clinical phenotype as MPS I through MPS VII (with several subgroups):

- **MPS I** (Hurler's syndrome), caused by a deficiency of α-L-iduronidase,
- **MPS VI** (Maroteaux-Lamy syndrome), caused by arylsulfatase-B deficiency, and
- **MPS VII**, caused by β-glucuronidase deficiency.

All three have all been associated with skeletal deformities in **cats**.

MPS VI occurs in Siamese cats where it is inherited as an autosomal recessive trait. By 2 months of age the typical features of the syndrome, including broad flattened face, small ears, diffuse corneal clouding, large forepaws, and pectus excavatum are evident. Radiographic lesions are present in the axial and distal skeleton by 6 months of age and are progressive. Most affected cats have symmetrical epiphyseal dysplasia, short stature, and develop degenerative joint disease. Thoracic vertebral bodies are short and there are fusions of cervical and lumbar vertebrae, absence or dysplasia of cervical and thoracic vertebral spinous processes, and increased width of intervertebral spaces. The ribs broaden at the costochondral junctions. In older animals, the epiphyses and metaphyses of long bones are distorted by bony proliferation, and articular surfaces are irregular. Some animals develop posterior ataxia and paresis at less than a year of age due to compression of the spinal cord by osteophytes, which project into the vertebral canal between T-12 and L-2. Affected kittens can be recognized at 1 week of age by their excessive concentrations of urinary dermatan sulfate. Metachromatic granules are present in the cytoplasm of circulating neutrophils. *Microscopic abnormalities in the skeleton are centered on articular and physeal cartilage.* Growth plates have poorly organized proliferative zones, lack of column formation in hypertrophic zones, disorganized zones of mineralization, and uneven chondro–osseous junctions. Chondrocytes are swollen with abundant, finely vacuolated cytoplasm. Osteoclast numbers in the primary spongiosa are reduced. Membrane-bound cytoplasmic inclusions are present in hepatocytes, bone marrow granulocytes, vascular smooth muscle cells and fibroblasts of the skin, heart valves, and cornea. This disease of cats closely resembles MPS VI of human patients.

Feline MPS I is reported in domestic shorthaired cats and most likely has an autosomal recessive mode of inheritance. The bony lesions in this disease are milder than those of MPS VI and are not accompanied by epiphyseal dysplasia of long bones. Nor are there metachromatic granules in circulating neutrophils. Although the number of cases is small, cats with MPS I appear to have a high incidence of meningiomas. Only *isolated cases of MPS VII* are reported in domestic shorthaired cats but the skeletal lesions are severe and resemble those of MPS VI.

MPS I also occurs in **Plott Hounds**, probably as an autosomal recessive trait. Affected dogs are stunted and develop progressive lameness in addition to diffuse, bilateral corneal opacity. A feature of the canine disease is the development of *severe degenerative joint disease* with extensive periarticular bone proliferation. Cytologic evaluation of synovial fluid may reveal mononuclear and multinucleated cells containing abundant basophilic granules (on Wright-Giemsa stain). Allogeneic bone marrow transplantation of irradiated dogs reduces the neurovisceral lesions of MPS I but the effect is minimal in chondrocytes, except those near the articular surface.

GM$_1$ gangliosidosis *occurs in cats, calves, sheep, and dogs, and is due to a deficiency of beta-galactosidase.* In sheep, there is a concomitant deficiency of α-neuraminidase. In dogs, skeletal lesions are present in **English Springer Spaniels** but in the Beagle, only the neurovisceral changes are present. Also, the stored undegraded oligosaccharides differ between the two breeds. In both breeds, the trait is autosomal recessive. Affected Springers develop neurologic signs at 4–6 months. Skeletal lesions may include proportional dwarfism with frontal bossing and hypertelorism, irregular intervertebral spaces, and degenerative changes in the femoral and tibial articular cartilages.

A storage-like disease with visceral and skeletal (but not neural) involvement occurred in a **Rhodesian Ridgeback dog**. The dog was lame from an early age and showed multiple osteolytic lesions in radiographs of long bones and vertebrae. Osteoarthritic changes, especially in the elbow, hip, and stifle, were accompanied by marked enlargement of acetabular and olecranon fossae. The liver, lymph nodes, and synovial villi were enlarged due to accumulation of cells with abundant vacuolated cytoplasm. Similar cells were seen in endocrine glands and vertebrae. The stored material, which appeared to be confined to the monocyte–macrophage system and synovial lining cells, was not identified but was variably oil red O-positive.

Congenital erythropoietic porphyria

Red-brown discoloration of the teeth and bones, caused by a recessively inherited defect in porphyrin metabolism, is reported in several breeds of cattle, including Hereford, Holstein, Ayrshire, Shorthorn, and Jamaica Red and Black. A deficiency of uroporphyrin III cosynthetase leads to the accumulation of uroporphyrin I and coproporphyrin I in blood, bone, and a variety of other tissues. The urine may also be red-brown or turn red on exposure to sunlight. The action of sunlight on porphyrins accumulated in the skin results in photodynamic dermatitis. The teeth, bones, and urine of affected animals show bright cherry-red fluorescence on exposure to ultraviolet light in a darkened room. Congenital erythropoietic protoporphyria in Limousin cattle, caused by a deficiency of the mitochondrial enzyme ferrochelatase, is associated with photosensitivity but no discoloration of the bones or teeth.

Inherited forms of porphyria associated with discoloration of the bones and teeth have been reported in cats and Duroc pigs, but the enzyme defect is unknown.

Acquired porphyria with pink discoloration of bones was recognized at slaughter in approximately 300 of 390 *crossbred lambs in Australia*. Similar "outbreaks" have also occurred in lambs and young deer in New Zealand. The discoloration was most prominent in the cortex of long bones and fluoresced on exposure to ultraviolet light, but teeth were not affected. On cut surfaces of long bones in a sample of affected lambs and deer, the pink discoloration was confined to areas of bone that had formed in the weeks prior to death, in particular the outer cortex. This reflects the fact that *porphyrins are only deposited at sites of active mineralization*. In congenital porphyria, the constant availability of porphyrins during dental and skeletal mineralization results in diffuse discoloration of all mineralized tissues. The extraction of coproporphyrin and protoporphyrin from the bones of lambs in the Australian outbreak suggested an enzyme block towards the end of the heme synthetic pathway, most likely induced by a toxin. Although lead toxicity can induce porphyrin accumulation, no lead was detected in affected lambs. Toxicity caused by some chlorinated hydrocarbons can also result in impaired heme synthesis and the detection of 1,2,4-trichlorobenzene in fat samples supported this possibility in the lambs. This compound is a *major metabolite of lindane*, an organochlorine insecticide that was widely used in parts of Australia and New Zealand before being banned. The occurrence of acquired porphyria in grazing animals may therefore reflect environmental contamination due to leakage from chemical dumpsites.

ACQUIRED ABNORMALITIES IN SKELETAL GROWTH, DEVELOPMENT, AND REMODELING

Bone growth and maturation is a complex process, requiring an interaction between genetic factors, local and systemic hormones, dietary nutrients, and mechanical forces. Anything that interferes with the synthesis of proteoglycans or collagen by chondroblasts or osteoblasts, the differentiation of precursor cells, or the resorption of bone by osteoclasts can result in a skeletal abnormality. The expression of an abnormality depends on many factors, including the phase of skeletal development that is altered, the severity of the defect, the age of the animal at the time of the insult, and how long it persists. As a result, the range of possible skeletal defects is huge, and a single etiology may vary considerably in its manifestations.

An accurate etiological diagnosis is not always possible in an animal with a skeletal defect, particularly since the inciting cause is often no longer present at the time of examination. In many cases the pathologist is presented with lesions reflecting an insult that occurred several weeks or months earlier and can only speculate as to its cause. It may not even be possible to determine with confidence whether a defect is genetic or acquired. Such decisions should not be taken lightly as they can greatly influence the actions of the owner, sometimes leading to unnecessary culling of related animals, resulting in considerable wastage of valuable breeding stock. *Many teratogenic agents have been shown to mimic genetic diseases of the skeleton and other organ systems*, and unless there is clear evidence that the problem is inherited, or it resembles an established genetic disorder, any temptation to attribute a genetic etiology should be resisted.

The term "*developmental orthopedic disease*" has been used to encompass a complex and important group of skeletal problems in horses, including osteochondrosis, subchondral cystic lesions, physeal dysplasia, wobbler syndrome, acquired angular limb deformities, flexural deformities, and cuboidal bone deformities. These disorders are associated with abnormalities in endochondral ossification at either the articular/epiphyseal cartilage complex or the growth plate of developing bones, but their etiology and pathogenesis are obscure. Although a genetic component is suspected, at least in some of these conditions, most appear to have a multifactorial etiology that includes nutritional and biomechanical factors. Rather than discuss the developmental orthopedic diseases as a group they will be included as separate entities in this chapter, reflecting the fact that although some of them may be different manifestations of the same underlying problem, their clinical and pathological presentation varies. Although osteochondrosis is a disorder of endochondral ossification, its clinical and pathological

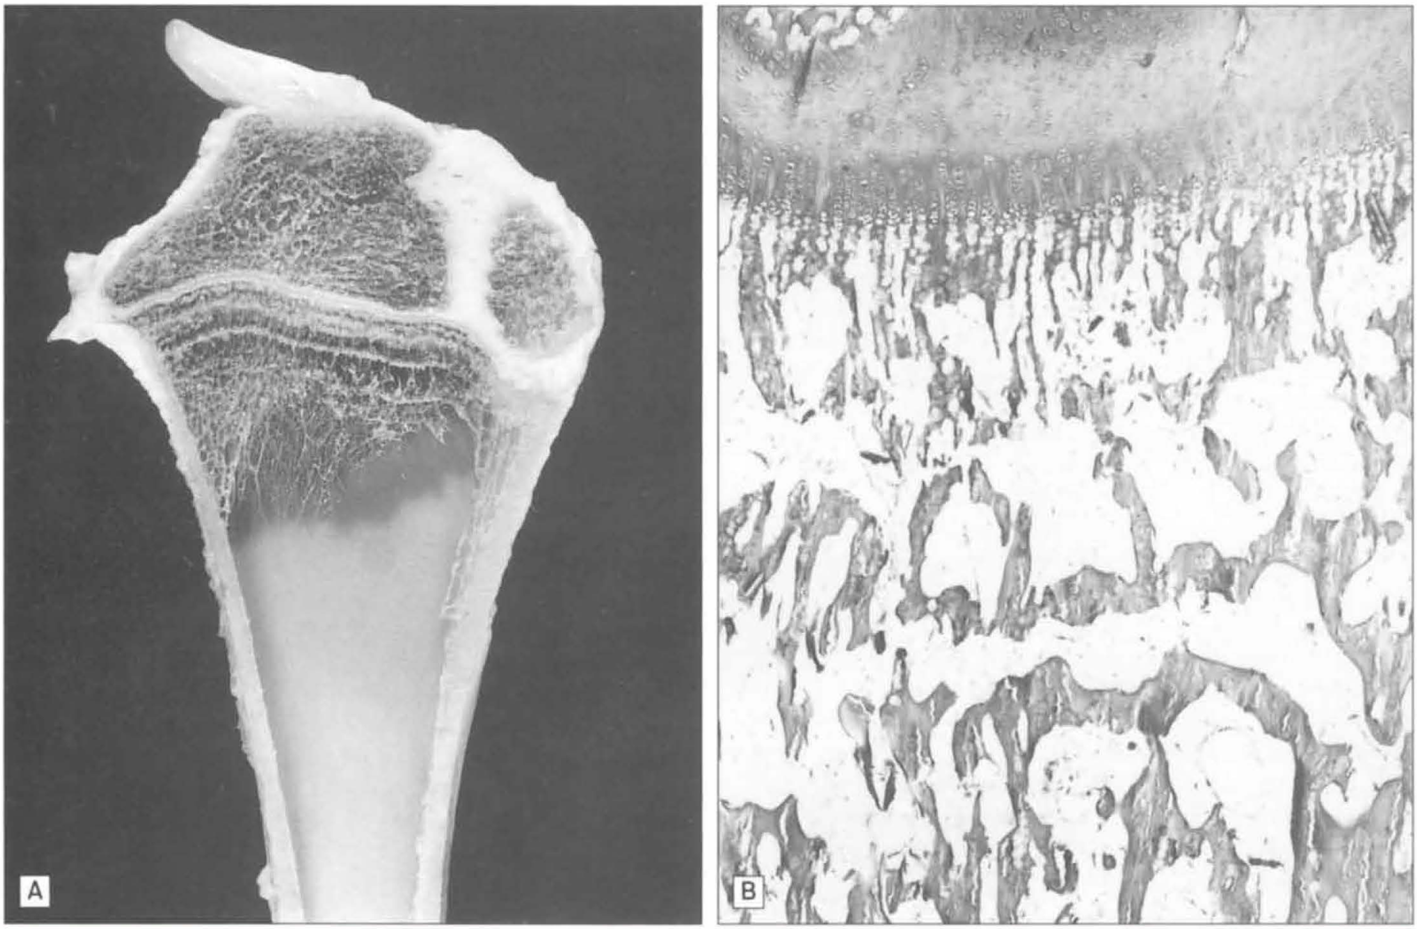

Figure 1.44 Growth arrest lines A. Proximal tibia from a lamb with osteoporosis. Several growth arrest lines are parallel to the physis. **B.** Microscopic section showing the **transverse trabeculae** that form during periods of growth arrest. These are left behind in the metaphysis once growth at the physis

manifestations in most species relate principally to its effect on joints, and is therefore included in a later section (Developmental diseases of joints).

Nutritional imbalances and toxins affecting skeletal growth

Bone development by endochondral ossification is sensitive to quantitative and qualitative alterations in nutrition, both in fetal and postnatal life. *Malnutrition or starvation*, if severe enough, will retard longitudinal bone growth, resulting in narrow growth plates that may become sealed by a horizontal plate of bone on the metaphyseal side. If the nutritional abnormality is corrected, physeal growth will resume and the plate of bone will be displaced into the metaphysis, persisting for some time as a radiographically and grossly visible **growth arrest line**, parallel to the growth plate. The presence of several parallel lines of transverse trabeculae (Fig. 1.44A, B) indicates recurrent episodes of retarded growth. Growth arrest lines are often accompanied by osteoporosis due to reduced bone formation and increased resorption in response to starvation, and the contents of the marrow cavity may be gelatinous due to serous atrophy of medullary adipose tissue. *Growth arrest lines may be detected in fetuses*, in which case they imply either defective maternal nutrition or retarded fetal development due to some other cause, such as intrauterine infection. Similar, but less well-defined lines in the metaphysis also occur in fetuses and in postnatal animals in association with certain infectious or toxic agents that interfere with osteoclastic resorption of the primary or secondary spongiosa and must be differentiated from growth arrest lines. These bands of metaphyseal sclerosis are discussed later in this section.

Overnutrition, in particular chronic excess of dietary calcium, in rapidly growing young dogs of large breeds, has been linked to a range of skeletal disorders, including osteochondrosis, metaphyseal osteopathy, and hip dysplasia. It is proposed that hypercalcitoninism, secondary to persistent stimulation by gastrointestinal hormones and post-prandial elevations in plasma calcium concentration, causes impaired osteoclastic activity and defective bone remodeling. The possibility that this may impair the development of bony foramina and predispose to conditions such as wobbler syndrome and eosinophilic panosteitis has been suggested, but remains to be proven.

Deficiencies or excesses of specific nutrients, including minerals and vitamins, can have a major impact on the developing skeleton. So too can a variety of toxic principles, primarily of plant origin, that an animal is exposed to during skeletal development. These will be discussed in some detail in this section, drawing comparisons between different animal species where appropriate. The so-called metabolic bone diseases, rickets, osteomalacia, fibrous osteodystrophy, and osteoporosis, caused by deficiencies or imbalances of vitamin D, calcium, or phosphorus, are discussed in detail in a later section of this chapter.

Mineral imbalances

Manganese is an essential trace element in animals, being required for the activation of xylosyltransferase, the first enzyme in the biosynthetic pathway of sulfated glycosaminoglycans. *A deficiency of manganese causes decreased production and increased degradation of cartilage glycosaminoglycans* and therefore potentially affects all bones that develop by endochondral ossification.

Manganese deficiency has been incriminated as the cause of skeletal deformities in newborn calves and other farmed livestock in several countries. The deficiency does not appear to affect adult animals but calves born to cows fed on manganese-deficient rations during pregnancy may show various degrees of **skeletal deformity**. The syndrome resembles that described as "*crooked calf disease*," which is discussed in more detail below under "Plant toxicities." In one study, pregnant cows fed 183 mg of manganese per day produced normal calves whereas those fed 115–123 mg manganese per day produced calves with deformities of the limbs, including reduced length and breaking strength of humeri, enlarged joints, and twisted legs. Similar skeletal defects occur in lambs and kids. The reduced breaking strength of bones in this syndrome may reflect the fact that manganese is necessary for the glycosylation of collagen as well as in the synthesis of cartilage glycosaminoglycans.

In New Zealand, manganese deficiency was incriminated in a naturally occurring "outbreak" of **chondrodystrophy** involving 32 purebred Charolais calves to various degrees. Because of severe drought, the pregnant cows had been fed a diet of apple pulp and corn silage, both of which are low in manganese. The calves had short limbs with enlarged joints, and collapsed tracheas with thick cartilage rings. The limb bones were short and had large mushroom-shaped epiphyses (Fig. 1.45). Microscopic lesions included irregular alignment and degeneration of physeal chondrocytes, absence of hypertrophic cells, and degeneration of matrix with unmasking of collagen fibers. Calves with mild lesions that were able to walk gradually recovered, but their legs remained bent and shortened for several months.

Manganese deficiency is also suggested as a possible cause of unusual skeletal deformities in calves from several properties in western Canada. **Congenital spinal stenosis** and myelomalacia, together with focal premature closure of growth plates, malformations of the cranial base and shortening of long bones characterize the syndrome. The spinal stenosis appears to be the result of flaring of the ends of vertebral bodies and protrusion of vertebral articular processes. Focal closure of growth plates is found in the offspring of manganese-deficient rats.

Congenital skeletal malformations in 47 Holstein calves on a property in South Africa were also suggested as being due to manganese deficiency, but the evidence was not convincing. Affected calves were small and showed variable joint laxity, doming of the forehead, brachygnathia superior, and shortening of their long bones. These outbreaks of skeletal deformities highlight the difficulty in establishing a definitive etiologic diagnosis in a disease that is not discovered until several months after the initial damage has occurred.

There is no doubt that **copper deficiency** influences skeletal development, but full appreciation of the range of manifestations and the mechanisms involved is lacking. The role of copper deficiency in **osteoporosis** and its association with **osteochondrosis** in some species are discussed further elsewhere in this chapter. *As a component of the enzyme lysyl oxidase, copper is required for cross-linkage of collagen molecules.* This is an important step in strengthening the matrix elements of bone tissue, cartilage, and other connective tissues that rely on collagen for support. It is not surprising therefore that increased fragility of bone, and possibly cartilage, is a feature of copper deficiency. Studies in dogs and swine have demonstrated reduced osteoblastic activity in animals with copper deficiency, leading to narrow cortices of long bones and reduced deposition of bone on persistent spicules of mineralized cartilage in the primary spongiosa. These metaphyseal changes resemble those of vitamin C deficiency, which is not surprising since both deficiencies interfere with collagen synthesis and cross-linkage.

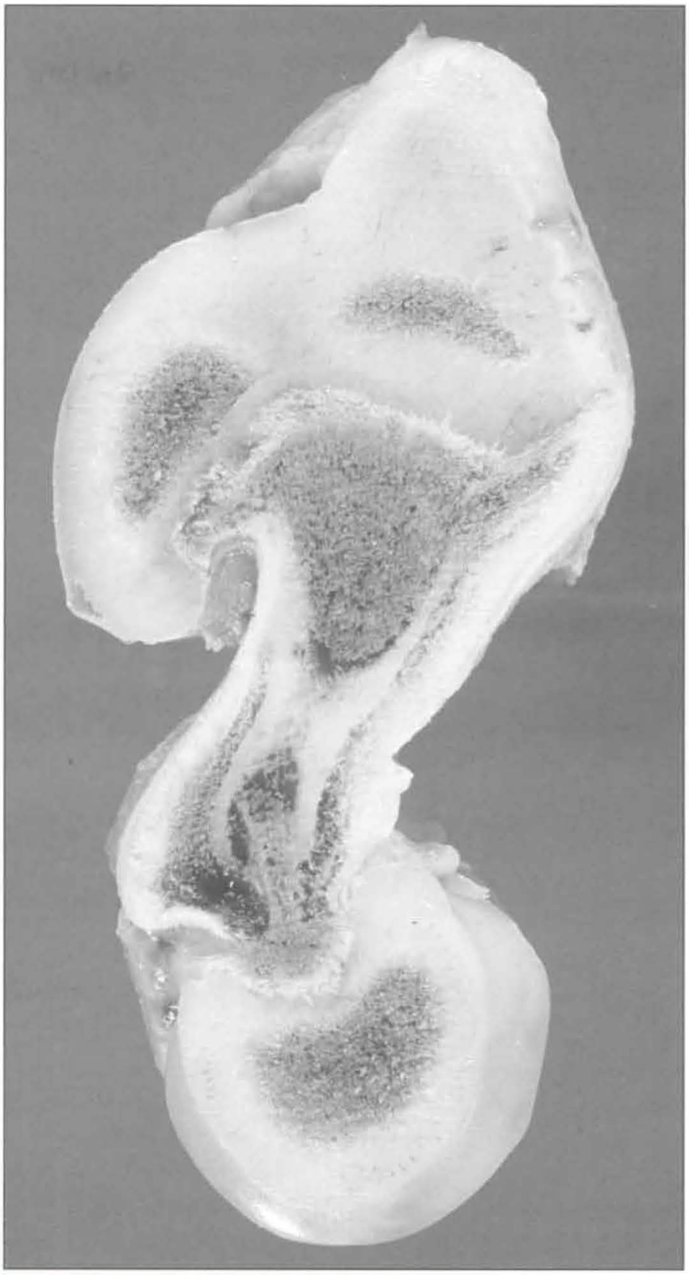

Figure 1.45 Chondrodystrophy in a newborn calf caused by intrauterine **manganese deficiency**. The humerus is considerably shorter than normal and the epiphyses are excessively large in comparison.

In calves, foals, pigs, and dogs, copper deficiency has been associated with grossly visible focal thickenings in rapidly growing growth plates. These foci consist of *retention of hypertrophic zone chondrocytes*, which protrude into the metaphysis, but the mechanism for this lesion in copper deficiency is not clear. It is possible that the stress of weight bearing causes microfractures of fragile trabeculae in the primary spongiosa with local disruption of the metaphyseal blood supply and impaired invasion of the mineralized cartilage. A similar mechanism has been proposed for the focal thickening of growth plates observed in chondrodystrophic Alaskan Malamutes and for the physeal thickening seen in some cases of osteochondrosis. In support of this hypothesis, trabecular microfractures, adjacent to foci of physeal thickening, are described in copper-deficient swine, calves, and foals, but it is seldom possible to accurately assign cause and effect in natural cases as the lesions are frequently too advanced to provide clues as to their origin. Whatever the mechanism, *these growth plate lesions bear a strong resemblance, grossly and histologically, to those of rickets and osteochondrosis*. Differentiation from rickets may be further complicated by the possibility of spontaneous long-bone fractures in copper-deficient animals due to osteoporosis and increased bone fragility.

Physeal changes are not a feature of copper deficiency in lambs. In one report, lambs with experimentally induced copper deficiency developed osteoporosis, but no lesions were detected in growth plates. Nor are there any descriptions of growth plate thickening in sheep with natural copper deficiency, suggesting either a species difference, or the fact that lambs, because of their lower bodyweight, are less likely to develop trabecular microfractures than foals, calves, or pigs.

Copper deficiency may be either *primary*, due to inadequate dietary copper, or *secondary* to increased dietary levels of copper antagonists, but the mechanisms vary between species. Absorption of copper is reduced by the presence of divalent cations such as zinc, iron, and cadmium that compete with copper for a common transport mechanism. Zinc may also induce the formation of metallothionine, a protein that binds copper in the intestine, liver, and kidney and reduces its availability. Phytates in the carbohydrate diets may form insoluble ligands with copper and prevent its absorption. Skeletal lesions consistent with osteochondrosis are described in pigs and foals fed experimental diets high in zinc, and in foals grazing pastures contaminated with zinc close to industrial plants. The possibility of a direct toxic effect of zinc on developing bone or cartilage must be considered, but a secondary effect through induction of copper deficiency is favored.

Calves and lambs grazing pastures containing high levels of *molybdenum* have developed skeletal lesions consistent with copper deficiency. This is believed to be due to the formation of thiomolybdates in the sulfide-rich environment of the rumen and *induction of secondary copper deficiency*. Thiomolybdates do not form in the digestive tract of nonruminants, providing a possible explanation for the higher tolerance of monogastric species to dietary molybdenum. However, although dietary molybdenum has little effect on copper uptake in horses, skeletal lesions resembling those of copper deficiency have been reproduced in rats and rabbits fed on rations with high levels of molybdenum.

Molybdenosis in sheep is associated with *epiphysiolysis of the greater trochanter and sub-periosteal hemorrhages of long bones*, leading to formation of bony excrescences. Sub-periosteal new bone formation at sites of muscle and tendon insertion has also been described in rats fed a low-copper diet supplemented with tetrathiomolybdate. In feedlot cattle, molybdenum poisoning caused weight loss and animals died over many months despite a short exposure to toxic levels, with both severe nephrosis and hepatotoxicity found in fatal cases. Although it has been suggested that bone lesions, at least in lambs, may be due to molybdenum toxicity rather than copper deficiency, the latter seems to be a better option. In ruminants, molybdenum may also interfere with the metabolism of sulfur, and affect ruminal microflora. Weakening of connective tissues with tearing of insertion sites due to reduced strength of tendons and ligaments would not be surprising in copper-deficient animals with reduced cross-linkage of collagen. The formation of reactive bone would be an expected response to periosteal elevation induced by hemorrhage at such sites. In affected animals, the other commonly associated lesions of copper deficiency are absent, so the exact pathogenesis of bone lesions in molybdenosis remains uncertain.

Fluorine is an essential trace element but, when present in chronic excess, is capable of inducing *characteristic dental and/or bony changes*. **Fluorosis** *is the term used to denote chronic fluoride toxicity*. All species are susceptible but because of the manner in which chronic poisoning occurs, *fluorosis is most common in herbivorous animals*. Discussion here is based on fluorosis in cattle, which are more susceptible than sheep and horses and for which the abnormalities are better described.

Toxic levels may be obtained from subsurface waters, especially where *rock phosphate* is plentiful. Rock phosphates vary considerably in their fluoride content, and chronic poisoning has been observed in cattle and sheep given rock phosphates as "licks." Contamination of pastures adjacent to *mineral ore refineries* may also cause toxicity, either directly or by uptake of fluorine by plants, since fluorine is volatile at high temperatures and is part of the gaseous and particulate effluent of many industrial processes. *Dust from volcanic eruptions* also contains abundant fluorides. Because of the widespread distribution of fluorine in nature, many animals obtain small nontoxic doses, partly from drinking water and partly from wind-blown dust, which settles on pasture.

Fluoride is removed rapidly from the blood, by renal excretion and deposition in bones and teeth. A small amount is deposited in soft tissues. Some fluorine crosses the placental barrier and although plasma levels are lower in fetal than maternal circulation, under certain circumstances fetal fluorosis may develop. Evidence regarding fluorine levels in milk is conflicting. The deposition of fluoride in bone may be functionally comparable to that of other elements, such as lead and strontium, and *may represent a detoxification mechanism*. Unless the intake of fluoride is very low, there is a steady accumulation of the element since it is deposited as calcium fluoride or fluorapatite, which are of low solubility. Many normal cattle have 600–900 μg/g in their bones but fetal lesions apparently occur at concentrations as low as 100–200 μg/g. Evidence of fluorosis does not develop in older cattle until the concentration reaches 2500–3000 μg/g. A level of 40–60 mg/kg (dry matter) in feed will produce such concentrations in the bone of cattle after 2–3 years. In general, the toxicity of fluorine depends on the aqueous solubility of the compound fed; sodium compounds are more soluble and more toxic than calcium compounds.

Fluoride toxicity is enhanced by poor nutrition, and alleviated somewhat by high dietary intakes of calcium and aluminum. While ingesting toxic levels of fluorine, urine of cattle usually contains

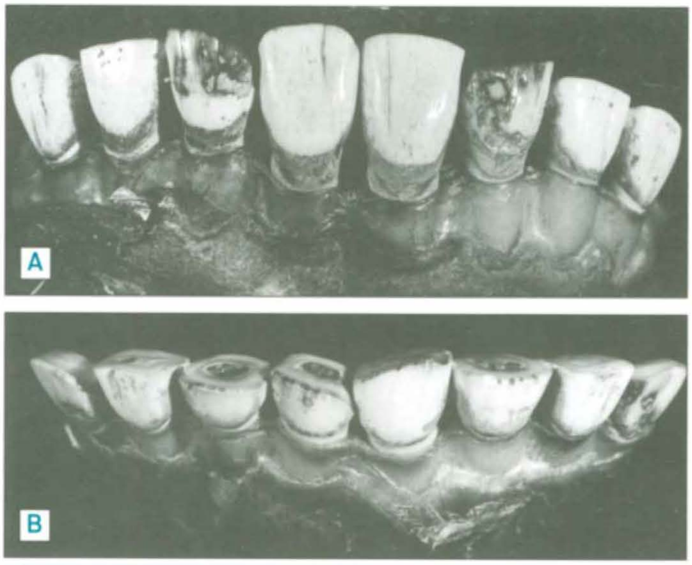

Figure 1.46 Fluorosis. (Courtesy of JL Shupe.) **A.** Dark brown discoloration and hypoplasia of enamel in the incisors of a cow. The variable involvement of the teeth reflects variation in levels of the toxin during enamel formation. **B.** Accelerated wear of incisor teeth in a cow with fluorosis.

10 μg/g or more although high urinary concentrations may persist for some time after excess fluorine is removed from the diet. Plasma fluorine is also elevated during periods of exposure but declines a few days after fluorine is removed from the diet.

The characteristic changes of severe fluorosis occur in teeth and bones and are accompanied by shifting lameness, loss of production, and a variety of nonspecific signs of debility. **Dental lesions** develop only if intoxication occurs while teeth are in the developmental stages and enamel is forming. Ameloblasts and odontoblasts are extremely sensitive to fluorine, which causes them to produce a matrix that mineralizes abnormally and is reduced in quality and quantity. In particular, *the outer layer of enamel is hypomineralized.* The incremental lines in the enamel are disrupted and the normal subsurface pigment band of bovine incisors is distorted.

The mildest macroscopic evidence of dental fluorosis is the *presence of small foci with a dry, chalky appearance compared to the normal glistening surface of enamel.* These mottled areas are readily visible as opacities when the tooth is transilluminated. In more severe cases, *all the enamel in affected teeth may be chalky, opaque and show various degrees of yellow, dark brown, or black discoloration* (Fig. 1.46A), *which is virtually pathognomonic for fluorosis.* Affected teeth show accelerated wear (Fig. 1.46B) and may develop chip fractures. In chronic cases, they may be worn to the gum line. The pigment is present in the enamel layer and possibly in the dentin, and may reflect oxidation of the organic matrices of the teeth. Unlike the pigment of food stains and tartar, it is not limited to the surface and cannot be removed by scraping. Hypoplasia of enamel may occur in severe fluorosis and is evident as punctate pits or as horizontal grooves, usually most prominent on the lateral aspect of the tooth. The horizontal disposition of the grooves and pits is attributable to periodic interference with mineralization of enamel during odontogenesis.

Although the fetus does not accumulate high levels of fluorine, under some circumstances lesions may develop in the deciduous teeth of calves exposed during gestation. Microscopically the odontoblasts are disorganized and have vacuolated cytoplasm. There is excessive predentin and formation of globular dentin. Fibrosis of the pulp cavity with ectopic bone formation is also seen. Lesions in permanent teeth, especially those that are last to erupt, are much more common, those that erupt first showing little or no damage. In cattle, the permanent teeth are sensitive to fluorosis from about 6–36 months of age. The most severe effects occur when exposure coincides with initiation of crown formation. In areas of endemic fluorosis, where ingestion of the element is more-or-less continuous, the lateral incisors of cattle show the most obvious lesions and, together with the second premolars and second and third molars, the most severe lesions. Lesions of similar severity should be present in teeth that develop simultaneously. These associations include the first incisor with the second molar, second incisor with the third molar, and the third incisor with the second premolar. Lesions in the second incisor must be severe before lesions are prominent in the third molar, and in general, incisor abrasion develops prior to molar abrasion. Lesions may develop in the fourth incisor in the absence of changes in other teeth.

The bone lesions of fluorine toxicity, **osteofluorosis**, are generalized but not uniform and, in severe cases, are characterized grossly by the formation of *periosteal hyperostoses*, which give the macerated bones a chalky roughened appearance (Fig. 1.47A, B, C). Lesions occur first on the medial surface of the proximal third of the metatarsal and later on the mandible, metacarpals, and ribs. The pelvis, vertebrae, and other bones of the distal limbs are also affected. In chronically affected cattle, fracture of the digital bones in the medial claw is common, leading to lameness and a preference for affected animals to stand cross-legged. A similar pattern of development occurs in horses. Although exostoses often develop at sites of tendinous or fascial insertions, this is not the rule and the reasons for their occurrence and distribution are unknown. Endostoses seldom occur in farm animals. Articular surfaces are normal, and lameness is due to involvement of the periosteum, encroachment of osteophytes on tendons and ligaments and, in some cases, to mineralization and even ossification of the latter structures. Fluorine is incorporated into bone matrix during mineralization and will therefore be most abundant in young animals at sites of active formation but is also deposited in older animals during remodeling. Exposure of cattle after 3 years of age may therefore produce osteofluorosis but not dental fluorosis.

Depending on the level of exposure to fluoride, and its concentration in bone, the bones may appear grossly and radiographically normal. A characteristic microscopic feature that may be detected in ground bone sections in such cases is the presence of brown discoloration of osteons, similar to that in enamel. The discoloration is apparently due to the effect of fluoride on osteoblasts, and its extent depends on the rates of bone growth or remodeling. Both endosteal and periosteal osteoblasts are affected and produce an abnormal matrix, which mineralizes abnormally. Sections of cortex may have a mottled appearance with some lamellae in some osteons showing discoloration and others appearing normal, depending on whether they were exposed to toxic levels of fluorine during formation. In fetuses, brown mottling of lamellar bone occurs at much lower concentrations of fluorine than in older cattle.

At *highly toxic levels*, the gross lesions of osteofluorosis occur rapidly. Not only is any new bone abnormal, preformed bone is apparently

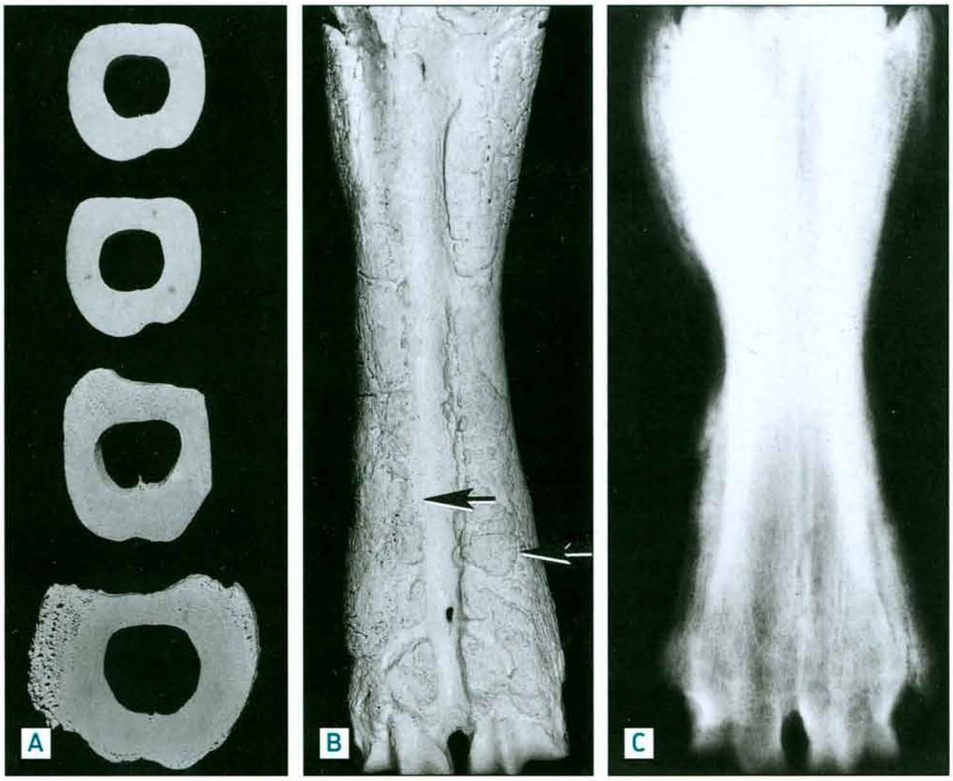

Figure 1.47 Chronic osteofluorosis in a cow. (Courtesy of JL Shupe.) **A.** Transverse sections of the diaphysis of metatarsals from cattle with increasing severity of osteofluorosis (top to bottom). Note the increased thickness of the cortex due to periosteal new bone formation. **B. altered in its mechanical properties and has a reduced life span. The rate of remodeling is correspondingly increased both for fluoridated normal bone and for bone formed under the influence of fluoride. The medullary cavity is enlarged and resorption spreads progressively outward through the cortex, and may involve the laminar periosteal bone. Resorption cavities may be excavated much more rapidly than they can be refilled, and the cortex becomes porotic. The impaired mechanical properties induce periosteal reinforcement with laminar bone or, if the need is greater and the deposition of new bone more rapid, by coarse woven cancellous bone. When fluoride levels are very high, the new matrices produced are abnormal and remain unmineralized, as in osteomalacia.

In young, growing dogs and pigs, and presumably in other species, fluorine intoxication produces lesions, which, in many respects, resemble rickets. This is presumably due to inhibition of mineralization when fluorine is present in high doses. The ends of long bones and the costochondral junctions are enlarged while physes are usually increased in depth, softer than normal, and yield to the pressure of weight bearing. The change at osteochondral junctions appears to be due to continued proliferation of chondrocytes, which fail to mature and align themselves. Associated with immaturity, there is a reduced amount of cartilaginous matrix and, although this appears to mineralize normally, albeit intermittently, the mineralized spicules are thin and fragile. The wide seams of osteoid that are deposited are poorly and irregularly mineralized.

Lead toxicity is better recognized for its effects on the nervous system, but also causes bone lesions. *The characteristic lesion is a band of sclerosis, referred to as a* **"lead line,"** visible radiographically and grossly in the metaphysis of developing bones. This is a relatively early morphological lesion in children with lead poisoning, and also occurs in animals (Fig. 1.48A). The sclerosis is due to persistence of mineralized cartilage trabeculae in the metaphysis (Fig. 1.48B) because of impaired osteoclastic resorption. Microscopically, many osteoclasts are present but they may be separated from the surface of bone trabeculae (Fig. 1.48C) and appear poorly able to degrade mineralized matrix. Some osteoclasts may contain *acid-fast intranuclear inclusions.* Ultrastructurally, a large amount of mineralized cartilage matrix is present in the cytoplasm of osteoclasts suggesting a defect in intracellular processing of the matrix. The metaphyseal sclerosis associated with lead toxicity radiographically and grossly resembles that seen in association with some cases of canine distemper viral infection and intrauterine *Bovine viral diarrhea virus* infection, both of which may interfere with osteoclast function or number.

Vitamin imbalances

Deficiencies and excesses of vitamins A and D can significantly influence skeletal development and remodeling, as can deficiency of vitamin C. The skeletal manifestations of imbalances in these vitamins will be discussed here, except for vitamin D deficiency, which will be included with the metabolic bone diseases because of its role in the etiology of rickets and osteomalacia.

Vitamin A in the diet originates from both plant and animal sources. Retinyl esters of animal origin are hydrolyzed in the gut to retinol, which is bound to lipid and absorbed, then re-esterified and transported to the liver. Retinol is transported from the liver to target tissues bound to a specific transport protein, retinol-binding protein, an α1-globulin. Provitamins such as carotenes and carotenoids of plant origin are absorbed in the small intestine, where a molecule of β-carotene, for example, can be converted enzymatically in epithelial cells to two molecules of retinaldehyde (retinal). Most of this is reduced to the alcohol form, retinol. A small proportion of retinaldehyde is oxidized to retinoic acid, which is not converted to retinol in the body and is not stored in the liver. Instead, it is excreted in bile and urine after being transported in plasma bound to albumin. Retinol is essentially synonymous with vitamin A since it, or its derivatives, can supply all the requirements for reproduction, vision, and growth supplied by the vitamin. Retinoic acid, and its natural and synthetic derivatives, are classified as retinoids. These compounds do not support the visual functions of vitamin A and only some of its reproductive functions.

The functions of vitamin A, other than that of retinal in relation to vision (see Vol. 1, Eye and ear), are incompletely understood. *Retinol and retinoic acid stimulate the activity of osteoclasts*, causing them to increase their acid phosphatase content and resorb bone. *Development and differentiation of epithelial structures and bone are sustained by retinol, retinyl esters, retinal, and retinoic acid*, but the mechanisms are unclear. It is postulated that retinol and retinoids may either act as carriers of sugar for glycoprotein biosynthesis or function through a specific receptor protein. The metabolically active form is also unknown – the model of 11-*cis*-retinal in the rhodopsin cycle does not apply to other functions. Retinyl phosphate, retinoic acid, or some other metabolite, may be the active compound.

Vitamin A deficiency *occurs in cattle and pigs fed unsupplemented rations of grain and/or old hay.* Yellow corn, new hay, and fresh silage are adequate sources of carotene but potency decreases with storage. Animals grazing green pasture or crops are unlikely to suffer from vitamin A deficiency, but dry summer pastures may be deficient. Although deficiency of vitamin A affects many tissues, the emphasis here is on the skeletal manifestations and their sequelae. *The underlying skeletal abnormality in vitamin A deficiency involves defective remodeling of membranous bone, presumably due to the stimulatory effect of vitamin A on osteoclastic activity.* Consequently, there is asynchrony between the developing central nervous system and the bones of the skull and spinal column. Failure of the cranial cavity and spinal canal to enlarge sufficiently to accommodate the brain, cranial nerves, and spinal cord results in secondary changes in the central nervous system and a variety of nervous signs. Membrane bones in other locations, including the periosteal surface of long bones, are also affected and may develop a coarse profile, but these changes are not significant clinically.

In the cranium, the defect is particularly severe in the bones of the caudal fossa, and *the cerebellum may herniate into the foramen magnum.* In puppies with vitamin A deficiency, deafness is a prominent sign because of changes in the internal auditory meatus, while affected *calves and pigs develop blindness due to narrowing of the optic foramina and compression of optic nerves.* The basis for these variations between species is not clear but lesions are modified according to the severity of the deficiency and the stage of skeletal growth. Spinal nerve roots, especially those in the cervical cord, may herniate into the intervertebral foramina, although the lesions are not always bilaterally symmetrical.

The pathogenesis of the asynchrony in development between the nervous system and skeleton is complex and is related to altered patterns of drift in bones that are growing during the period of deficiency. Normally osteoclasts are responsive to vitamin A, and in the cranium of deficient animals, there is inadequate resorption of endosteal bone. Often, bone is produced at sites where resorption should be occurring thus exacerbating the retarded expansion of the cranial cavity and the various foramina. Endochondral bone does not appear to be directly influenced by vitamin A deficiency.

The nervous signs in growing animals with vitamin A deficiency may be related to cranial and spinal nerve degeneration and to hydrocephalus. The hydrocephalus probably is due mainly to decreased absorption of cerebrospinal fluid into the blood, a process that occurs in the arachnoid granulations and villi. The granulations are located in the tentorium cerebelli, which is severely affected by the thickening that occurs in the dura mater in vitamin A deficiency. Hypersecretion of cerebrospinal fluid with vitamin A deficiency also contributes to the development of hydrocephalus.

Clinical signs of deficiency in growing cattle may include edema of the brisket and limbs, irreversible blindness, night blindness, and the neurologic effects of increased intracranial pressure. Growing pigs may show incoordination and posterior paresis. Pigs less than a week old may be affected if maternal supplies are low but signs usually are seen in older animals. Gross neurologic lesions include osseous thickening of the tentorium cerebelli, cerebral edema and coning of the cerebellum. Microscopically, there is Wallerian degeneration in the spinal cord and brain (see Vol. 1, Nervous system).

The most characteristic extraskeletal lesion of vitamin A deficiency is squamous metaplasia of various glandular or ductular epithelia. *In cattle, squamous metaplasia of the parotid salivary duct is virtually pathognomonic for vitamin A deficiency*, but this resolves within a few weeks following correction of the deficiency. In vitamin A-deficient pigs, focal squamous metaplasia in the urinary bladder may be grossly visible as 1–2 mm light-yellow nodules on the mucosa.

The effect of vitamin A deficiency on dental development is well studied in the continuously growing incisors of rats and guinea pigs, but not in teeth of other species. Inadequate differentiation and spatial organization of odontoblasts lead to irregular formation of poor-quality dentin. Ameloblastic differentiation is also suboptimal and results in enamel hypoplasia. In addition, undifferentiated ameloblasts invade the dental pulp where they induce the odontoblasts to form concretions.

Vitamin A deficiency, like excess, is **teratogenic**, and swine and large Felidae appear to be very susceptible. Abortions, stillbirths, and a variety of lesions, including subcutaneous edema, microphthalmia, retinal dysplasia, hypotrichosis, supernumerary ears, polydactyly, arthrogryposis, cleft palate, pulmonary hypoplasia, diaphragmatic hernia, hepatic cysts, and cardiac, renal, and gonadal malformations may occur in the offspring of vitamin A-deficient swine. Hydrocephalus, and protrusions of spinal cord through intervertebral foramina, may also occur. The frontal and parietal bones may be thin and the basioccipital bone thicker than normal. The latter bone is also thickened in neonatal calves from vitamin A-deficient dams, as are the squamous occipital, basisphenoid and presphenoid bones. Stillbirths, and congenital blindness, incoordination and thickened carpal joints are also seen in calves as well as hydrocephalus, with herniation of cerebellar vermis through the foramen magnum, constriction and degeneration of optic nerves, and retinal dysplasia.

Vitamin A toxicity is well recognized as a cause of skeletal disease in man and animals. Natural cases of toxicity usually follow an accidental overdose with vitamin A concentrate or excessive feeding of diets containing high concentrations of the vitamin, such as liver. Depending on the age and species of animal, and the duration and level of exposure to excess vitamin A, *the manifestations of toxicity may include physeal damage, osteoporosis, or the development of exostoses (osteophytes).* High concentrations of carotenes in green feed oats may predispose to rickets in lambs through inhibition of vitamin D activity.

The **physeal lesions** of vitamin A toxicity are characterized by reduced chondrocyte proliferation and reduced size of hypertrophic chondrocytes, resulting in narrowing of growth plates. Loss of proteoglycans and unmasking of collagen fibers occur, and sometimes with high doses there is complete destruction of segments of growth plates. Rapidly growing physes, especially those subjected to the greatest compressive forces are most likely to show changes, resulting in reduced length of certain long bones. In organ culture, vitamin A inhibits chondrocyte proliferation and reduces RNA and protein synthesis. Lysis of matrix may be the result of destabilization of lysosomal membranes with the release of acid proteases that attack matrix proteins.

The **osteoporosis** of vitamin A toxicity is associated with decreased numbers of osteoblasts and fewer, thinner osteoid seams than normal, and is most severe in cortical bone and some of the membranous bones of the skull. Periosteal bone formation is more severely affected than endosteal and intracortical formation. In long bones, this results in thin cortices, reduced diaphyseal diameter and an exaggerated metaphyseal flare. Metaphyseal trabeculae tend to be reduced in number but thicker than normal. Hypervitaminosis A interferes with cell differentiation in the embryonic skeleton and may have similar effects on osteoblasts in postnatal bone. The decrease in osteoid production also suggests a direct toxic effect on osteoblasts. The osteoporosis may be exacerbated by continued bone resorption, osteoclasts apparently being less sensitive than osteoblasts to the effects of increased vitamin A. Fractures are not a feature of vitamin A toxicity in farm animals and pets as they are in some laboratory species. Osteoporosis is reversible in animals removed from diets high in vitamin A but the physeal damage is permanent and the consequences emphasized with time.

The *formation of exostoses* in association with vitamin A toxicity is often extensive. The pathogenesis of this lesion is not clear but may be associated with fragility of periosteal attachments, and provoked by tensions and minor trauma.

Toxicity associated with *single, large doses of vitamin A* has been recognized in pigs and calves. In baby **pigs** given excess vitamin A orally as part of disease prevention programs, a characteristic syndrome develops. Grossly there is shortening of long bones and prolongation of the traction epiphyses of the tibial tuberosity, the greater trochanter of the femur, and the humeral tuberosity. Rotation of epiphyses, particularly those of the distal femur and proximal and distal humerus, is also described, and tarsal and carpal bones may be distorted. The medial and lateral metatarsal bones, and to a lesser extent the metacarpal bones, may be of different lengths. Pigs treated shortly after birth show an abnormal gait and possess noticeably short legs by 6–8 weeks of age. The condition occurs with as little as twice the recommended dose of vitamin A. *The basis for the gross lesions is destruction and focal closure of growth plates.* Continued growth of the intact parts of the physis, and superimposed adaptational deformities, account for the characteristic appearance of the bones.

Similar lesions occur in **kittens** given daily oral doses of 40–100 μg/g body weight of vitamin A for 4 to 5 weeks, followed by a 6–15 week recovery period. The metacarpal lesions tend to be more severe than in piglets, the tibial lesions are similar, while those in the distal femur and other sites are less severe.

In 7-week-old **pigs** given about 20 μg/g body weight for 5 weeks then killed, osteoporosis is prominent. Lesions are especially severe in the squamous occipital bone, which may be so thin that the cerebellum can be crushed by manual pressure to the overlying skin. The long bones are short and fragile with thin cortices, flared metaphyses, and typical physeal lesions, but the latter are less severe than at higher dose rates and gross deformities do not occur. Exostoses may be present, especially near the insertion of the brachialis muscle on the proximal radius.

Vitamin A toxicity has been incriminated as the cause of **"hyena disease"** in **calves**. This unusual form of dwarfism is characterized

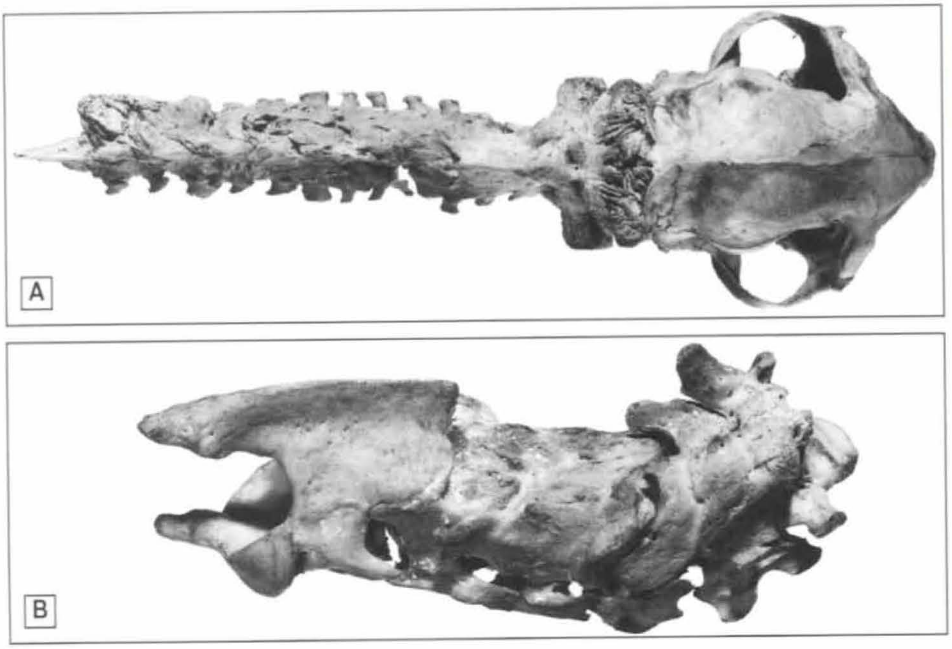

Figure 1.49 Vitamin A toxicity in a cat. **A, B.** Dorsal and lateral views of cervical vertebrae showing extensive exostoses leading to ankylosis. (Courtesy of AA Seawright.)

by *relative underdevelopment of the caudal body structures* due to premature closure of growth plates, particularly in the pelvic limbs, and has been associated with the injection of newborn calves with vitamins A and D. Affected calves have a characteristic "bunny-hopping" gait and a sloped back with small hindquarters, resembling a hyena. Although the lesions are most severe in the bones of the pelvic limbs and lumbosacral vertebrae, the pectoral limbs are also affected. Physes are narrow, but many focal triangular projections of physeal cartilage may protrude into the metaphysis. Administration of excess vitamin A to calves has been shown to induce premature mineralization of physeal cartilage leading to early closure of growth plates and impaired longitudinal bone growth, supporting vitamin A toxicity as the cause of hyena disease. An autoimmune mechanism associated with *Bovine viral diarrhea virus* has also been suggested but is not supported by convincing evidence.

Osteophyte formation is the hallmark of prolonged exposure to excess vitamin A in many species and is the outstanding feature of *chronic vitamin A poisoning in* **cats**, producing the syndrome referred to as **deforming cervical spondylosis.** The syndrome results from prolonged feeding of bovine livers to adult cats, which ordinarily contain large amounts of vitamin A when derived from grazing animals. The disease was common in Australia and Uruguay where beef livers are plentiful and relatively cheap, but also occurs sporadically in other countries when domestic cats are given unconventional diets. In young growing cats, this same diet would be expected to result in fibrous osteodystrophy because of the imbalance in calcium and phosphorus.

Deforming cervical spondylosis is typically *seen in cats after 2 years of age* and is characterized by postural changes, cervical ankylosis and forelimb lameness, sometimes accompanied by cutaneous hyperesthesia or anesthesia. The vertebral lesions are similar to those of mucopolysaccharidosis VI but the age of the cat should prevent confusion. *Extensive confluent exostoses develop, especially on the dorsal and lateral aspects of the cervical vertebrae and sometimes on the occipital bone.* In general, the exostoses do not encroach on the neural canal and only occasionally involve ventral aspects of the vertebrae (Fig. 1.49A, B). The intervertebral foramina are considerably altered in shape and reduced in size, causing compression and degeneration of nerves leading to denervation atrophy of muscles. Exostoses occasionally occur on the cranial thoracic vertebrae and may be accompanied by similar outgrowths on the sternum and fixation of the ribs. Periarticular osteophytes also occur about the proximal joints of one or both forelimbs and, if extensive, may cause fixation of the shoulder and elbow joints, usually in the flexed position. Lumbar vertebrae and pelvic limbs are seldom affected. The osteophytes consist initially of either osteocartilaginous tissue that overgrows joints and causes ankylosis, or of woven bone that develops at the site of muscle insertions and extends into the perimysium. Later, the woven bone and cartilage are replaced by lamellar bone. The stress on cervical intervertebral joints associated with regular grooming probably accounts for the concentration of exostoses in the cervical region of cats. In animals with chronic lesions, patches of ungroomed fur may develop in inaccessible sites. Interestingly, cats fed bovine liver tend to have higher and more persistently elevated plasma vitamin A concentration than cats supplemented with the vitamin, even at a higher equivalent dosage.

Oral and dental lesions, including hypermobility and loss of incisor teeth, may also occur in older cats in association with vitamin A toxicity and cervical spondylosis, but it is difficult to determine whether the changes are primary or secondary. Liver has a low calcium content, which could lead to resorption of alveolar bone, but excess vitamin A causes dental lesions even when dietary calcium is normal.

Several *other lesions* are associated with vitamin A toxicity. In some species, including humans, rats, rabbits, and dogs, it causes *ectopic mineralization* in internal organs. In cattle, pigs, and dogs there is decreased cerebrospinal fluid pressure and, in calves at least, this is associated with *thinning of the fibrous cap of arachnoid granulations.* Vitamin A is stored in the liver in *Ito cells*, which increase in size with dietary excess. Peliosis-like changes in the liver, in addition to hemorrhages around joints and hair loss, are reported in people with hypervitaminosis A. *Alopecia and dermatitis* are features of toxicity in horses.

Like vitamin A deficiency, *excess vitamin A is* **teratogenic**, the effects depending to some extent on dose, stage of gestation, and the compound administered. Teratogenicity is increased by protein or protein-energy malnutrition. Vitamin A is used extensively to treat skin disease in people and to a lesser extent in dogs. The half-life of some retinoids is many months, and anomalies in children exposed in utero are well recognized, but are not reported in puppies. *Experimental hypervitaminosis A during pregnancy produces defects in many systems in a variety of animals.* Vitamin A toxicity was incriminated as the cause of continued high prevalence of cleft palate and lip, pulmonary hypoplasia, and abortions near term in a swine herd. The problem in this herd ceased following reduction of vitamin A supplementation to normal levels. The mechanism of teratogenesis is unknown, but excess vitamin A in the embryo inhibits chondrogenesis and osteogenesis, possibly by modifying the differentiation of mesenchyme.

Vitamin D is essential for normal bone development, in particular mineralization of cartilage during endochondral ossification and of newly formed osteoid, but in excess, it is highly toxic. **Vitamin D toxicity** may result from accidental over-supplementation of young animals, ingestion of plants that contain the active form of the vitamin, or accidental ingestion of rodenticide containing cholecalciferol (vitamin D_3). The potency of the latter toxin is illustrated by the fact that cats and dogs may be poisoned by ingesting the carcasses of poisoned rats. Cats appear to be more sensitive to vitamin D toxicity than dogs. When administered as one or two massive doses shortly before parturition, vitamin D appears to prevent postparturient hypocalcemia ("milk fever") in cows but mineralization of soft tissues may result, particularly in pregnant Jersey cows, and in this breed its use is contraindicated. Vitamin D is stored in muscle and fat, and meat from vitamin D-treated "downer cows" is a potential hazard to dogs and cats. Significant amounts of vitamin D may be secreted in milk, and soft tissue mineralization in suckling puppies has been attributed to high dietary levels in the bitch.

Several plants, including *Solanum malacoxylon* (syn. *glaucum, glaucophyllum*), *Cestrum diurnum* and *Trisetum flavescens* cause diseases similar to hypervitaminosis D in grazing animals in various parts of the world (see Enteque seco and Manchester wasting disease, in Vol. 3, Endocrine glands). Traditionally, vitamin D_2 (ergocalciferol) is regarded as the plant form of vitamin D, but *the toxic principle in these plants is 1,25-dihydroxycholecalciferol-glycoside.* Lesions in poisoned animals are indistinguishable from those produced by excess vitamin D. Other calcinogenic plants in which the active principle is less well defined include *Solanum torvum, S. verbascifolium*, possibly *S. esuriale*, and *Dactylis glomerata*. Alfalfa (*Medicago sativa*) contains vitamin D_3 in addition to vitamin D_2.

The *mechanism of vitamin D toxicity* is related primarily to its effect on increasing calcium absorption from the intestine, mobilizing it from bone and reducing its excretion by the kidney. The end result is *hypercalcemia* together with *hyperphosphatemia*, which, if persistent, will lead to widespread mineralization of soft tissues, in particular the kidneys, gastric mucosa, lungs, endocardium, and arterial walls. Death from renal failure is likely to occur before noticeable changes develop in the skeleton. In fact, there are few reports of the skeletal lesions of vitamin D toxicity in animals.

The skeletal changes in hypervitaminosis D may be characterized by either sclerosis or rarefaction, depending on the level of dietary calcium and the pattern of exposure. An early response in bone is widespread, intense osteoclastic activity, which may remove most of the primary spongiosa and cause active resorption in other sites. With continued administration, the matrix produced by osteoblasts accumulates, sometimes in large amounts and in a distinctive pattern. It often has a tangled fibrillary arrangement and appears somewhat mucoid, floccular, and intensely basophilic (Fig. 1.50). Osteoblasts are abundant. Mineralization of this basophilic matrix is delayed but it is gradually converted to a relatively homogeneous eosinophilic substance resembling osteoid. Initially, the maturation of the matrix is local and irregular in distribution, and is unrelated to normal patterns of osteogenesis. If toxicity is prolonged, the abnormal matrices continue to accumulate and virtually obliterate the marrow spaces. This produces a mosaic of basophilic and acidophilic matrix, and newly formed woven bone. *The presence of abundant basophilic matrix is virtually pathognomonic for vitamin D toxicity* and is valuable diagnostically when plasma levels of the vitamin are not known.

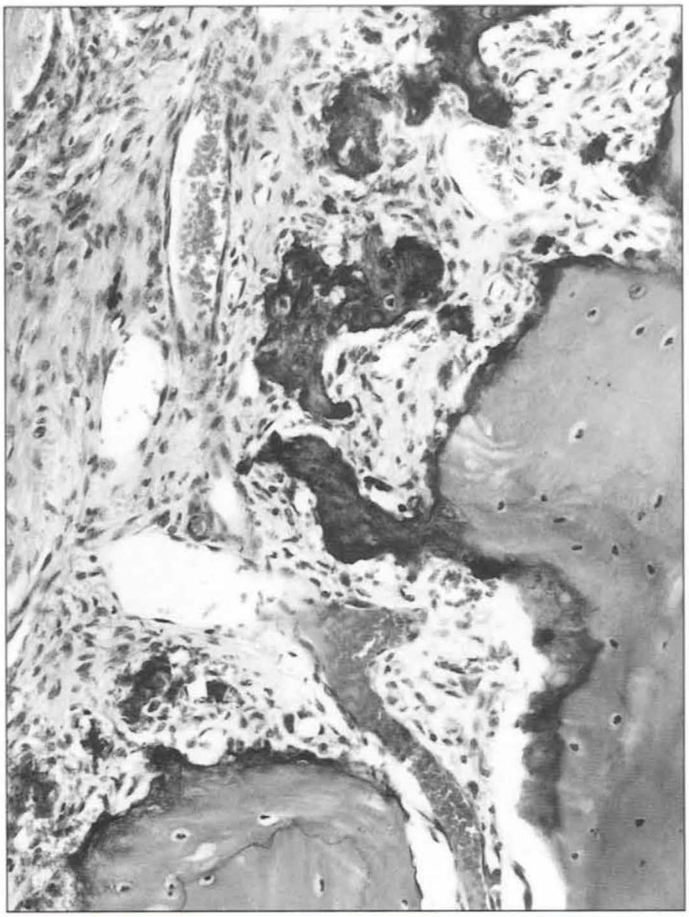

Figure 1.50 Vitamin D toxicity. Intensely basophilic bone matrix deposited on surface of trabeculae and in marrow spaces.

Vitamin D poisoning is usually associated with intermittent toxic doses of the vitamin. This results in surges of osteoblastic activity during periods of withdrawal with rapid production of large amounts of abnormal matrix. This matrix may slowly mature and mineralize, but the process is hastened by further administration of the vitamin. With continued intermittent administration of vitamin D, there are further cycles of matrix deposition, maturation, and mineralization. *Broad, basophilic, resting lines separate the layers of* *bone produced in each cycle.* Necrosis of osteocytes occurs with high doses of vitamin D and groups of empty lacunae are often present in cortical bone and in the center of trabeculae.

Virtually all bones are affected to some extent in vitamin D toxicity, but *the outstanding changes occur in long bones, especially in the ends where growth is most rapid.* The epiphyses are usually normal and appear to escape even the resorptive changes. The growth plates are also normal. The lesions involve the metaphyseal spongiosa and extend well into the diaphysis to fill the medullary cavity. Little active bone marrow remains and is gradually replaced by dilated veins and loose fibrous tissue, which is sparsely populated with hematopoietic cells. Areas of sclerosis may alternate with transverse bands of resorption, indicating intermittent toxicity. Active resorption of primary spongiosa may be accompanied by an intense neutrophilic reaction. Both the periosteum and endosteum are involved, and new periosteal bone contributes to the thickness of the metaphysis. Usually, the perichondrium is not affected, but sometimes it produces new cartilage and bone. In addition, there is rapid metaplastic bone formation in the thickened fibrous layer of the periosteum, producing a collar of new bone around the metaphysis.

Vitamin D deficiency is discussed in the section Metabolic bone diseases (Rickets and osteomalacia).

Vitamin C (ascorbic acid) is a co-factor for the enzymes prolyl and lysyl hydroxylase, which are required for the hydroxylation of proline and lysine during collagen synthesis, and is also an important antioxidant. In **vitamin C deficiency**, *there is reduction or failure in the secretion and deposition of collagen.* Furthermore, the deficiency of hydroxylysine results in impaired formation of intermolecular crosslinks and any collagen that is produced is of reduced strength. Vitamin C also promotes the differentiation of osteoblasts from their progenitors and the hypertrophy of chondrocytes, both of which are critical to the process of endochondral ossification. Most mammals synthesize ascorbic acid from glucose via glucuronic acid and gulonic acid. Some species, including humans, certain nonhuman primates, and guinea pigs, lack the hepatic microsomal enzyme L-gulonolactone oxidase and, in the absence of a dietary source of ascorbic acid, develop **scurvy**. The disease normally does not occur in other species except as a result of genetic defects in vitamin C synthesis. *A spontaneous mutation involving L-gulonolactone oxidase is recorded in pigs.* The defect in pigs is inherited as an autosomal recessive trait and homozygous recessive piglets develop classic scorbutic lesions shortly after weaning. Maternal milk is a rich source of vitamin C and prevents signs of deficiency prior to weaning. A similar defect is also recognized in ODS rats.

The lesions of scurvy in guinea pigs with dietary vitamin C deficiency and in pigs with an inherited deficiency of L-gulonolactone oxidase are similar, although the lesions described in pigs are more severe. This probably reflects the complete absence of vitamin C in affected pigs, and the effect of greater body mass on weakened connective tissues. In guinea pigs, a dietary deficiency of vitamin C may be partial rather than absolute, or may be sporadic, and the bone lesions therefore vary in severity. Pigs with inherited L-gulonolactone oxidase deficiency are normal at birth but lose condition, become reluctant to stand or move, and develop swellings around their joints. Gross lesions are dominated by *sub-periosteal accumulations of clotted blood* around the shafts of the long bones, the scapulas, the bones of the head, especially the mandible, and on the ribs. The metaphyses are fragile, discolored by hemorrhage and separate easily from the adjacent physes. Similar hemorrhages occur around major joints, along costochondral junctions and on mandibles of affected guinea pigs. The bones are osteopenic and fragile. Subclinical scurvy in guinea pigs is accompanied by such nonspecific signs as diarrhea, weight loss, and dehydration, and may be more common than is generally appreciated as the early bone lesions may not be detected clinically or on gross postmortem examination.

The most characteristic microscopic lesion of scurvy is in the metaphysis. *Naked spicules of calcified cartilage, derived from the zone of provisional calcification in the growth plate, persist as a "scorbutic lattice"* (Fig. 1.51A, B). The layer of bone that is normally deposited on this cartilage framework by active osteoblasts is absent or deficient. Osteoblasts are sparse and appear to have lost their polarity. The marrow cavity may be filled with a population of poorly differentiated mesenchymal cells showing little if any collagen formation (Fig. 1.51B). In some cases, apparently normal bone trabeculae are present in the secondary spongiosa, representing bone formed during a period when dietary vitamin C was adequate. The cartilage spicules of the scorbutic lattice do not have the strength of normal trabeculae. Microfractures or infractions associated with hemorrhage and fibrin, but with little evidence of normal repair (Fig. 1.51A, B), are often present. Mechanical forces no doubt influence the development of such lesions.

Physes are generally thin and contain a reduced number of chondrocytes, poorly organized into columns. Cortices of long bones are thin and the periosteum may be elevated with hemorrhage or thin, irregular spicules of basophilic, woven bone separated by loose connective tissue.

The cartilage spicules of the scorbutic lattice have a high mineral content and may be visible radiographically as a radiodense band in the metaphysis.

Early suggestions that vitamin C deficiency may be a cause of metaphyseal osteopathy (hypertrophic osteodystrophy) in young dogs have been refuted. Dogs are capable of manufacturing their own vitamin C and although there are radiographic similarities between scurvy and metaphyseal osteopathy, the histologic lesions are quite different.

Plant toxicities

Many plant species are known, or suspected, to cause skeletal abnormalities, either by inducing a teratogenic effect on the developing fetus, or influencing skeletal remodeling in young growing animals. Those with a teratogenic action typically exert their influence early in pregnancy and require ingestion by the dam during a specific stage of fetal development. The classic example is ***Veratrum californicum*** (false hellebore, wild corn, or skunk cabbage), which causes **cyclopia** (Fig. 1.52) in the progeny of ewes that consume the plant on day 14 of gestation. Similar anomalies also occur in calves and kids whose dams are fed the plant at this stage of gestation, when the neural groove has formed and the first cranial somites are developing. Ingestion of *V. californicum* by pregnant ewes near day 29 produces marked shortening of the metacarpals, metatarsals, and tibiae, and sometimes the radii, while tracheal and laryngeal stenosis occurs in the offspring of ewes ingesting the plant on or about day 31 of gestation. There is variation in the degree of susceptibility, but lesions are usually bilaterally symmetrical and twins tend to be affected equally. Fusion of metacarpals may result in postnatal bowing of the legs and fusion or deformities of joints may cause **arthrogryposis**. Obviously not all ewes will graze the plant at precisely the same time of gestation and in a natural outbreak the changes detected in affected lambs would be expected to include a range of abnormalities. Prolonged gestation is also a feature of malformed fetal lambs and embryonic losses may be substantial. Death of about 17% of embryos occurs with maternal ingestion of *V. californicum* on days 19–21 of gestation, and up to 75% of embryos when the plant is ingested on day 14.

Ingestion of *V. californicum* by *pregnant cows* between days 12 and 30 of gestation may induce a range of anomalies, including cleft palate, harelip, brachygnathia, hypermobility of hock joints, and

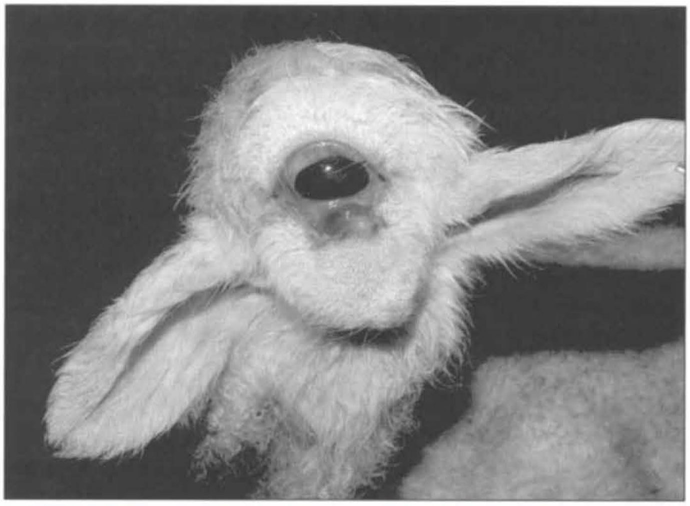

Figure 1.52 Cyclopia in a lamb. This deformity has been associated with ingestion of *Veratrum californicum* by pregnant ewes at around day 14 of gestation.

syndactyly and reduced number of coccygeal vertebrae. The length and diameter of all limb bones may be reduced, or the changes may be restricted to the metacarpals and metatarsals. Between days 30–36 of gestation, the teratogens selectively inhibit growth in length of the metacarpal and metatarsal bones.

V. californicum contains several steroidal alkaloids, the most active being cyclopamine, cycloposine, and jervine. *Cyclopamine is most abundant in the plant and is responsible for the craniofacial defects*, but the cause of the other anomalies is unknown.

A syndrome referred to as **crooked-calf disease** occurs when pregnant cows ingest certain **wild lupins**, including *Lupinus caudatus, L. sericeus,* and *L. formosus*, especially between days 40 and 80 of gestation. Malformation of the limbs, notably the forelimbs, is the most common alteration, but the axial skeleton may also be involved. *The limb abnormalities consist of flexion contracture and arthrogryposis associated with disordered growth of joints*, in addition to shortening and variable rotation of the bones. *Torticollis, and either scoliosis or kyphosis are common*, involvement of the thoracic spine being associated with costal deformities. There are various subtle and often asymmetric changes in the skull, where *the most definable malformations are cleft palate, or brachygnathia superior.* Affected calves are usually born alive and may survive, depending on the nature and severity of their malformations, but growth is retarded and the malformations persist, often becoming more severe with age. Neuromuscular structure and function are regarded as normal, or at least not primarily responsible for the skeletal deformity. No remarkable or consistent histological changes are reported in crooked calves.

Lupins contain several alkaloids, some of which are teratogenic. The quinolizidine alkaloid *anagyrine* is present in *L. caudatus* and *L. sericeus* and is almost certainly a teratogen. In *L. formosus* the piperidine alkaloid *ammodendrine* may be responsible. Inhibition of fetal movement caused by a sedative or anesthetic effect of the alkaloids may be the basis for the skeletal deformities. Alternatively, secondary effects of direct toxicity to the dam may be involved; sustained uterine contractions producing deformities in the fetus have been suggested. *Lupinus caudatus* (tailcup lupine) does not produce lesions in fetal lambs or kids, suggesting differences between cattle and other species in the metabolism of anagyrine.

Lupins cause two other distinct diseases in animals; a nervous disorder associated with the alkaloids in bitter lupins (see Vol. 1, Nervous system) and a mycotoxicosis caused by *Phomopsis leptostromiformis* (see Vol. 2, Liver and biliary system).

Conium maculatum (poison hemlock, European hemlock, spotted hemlock) is toxic to various species and causes a syndrome characterized by excitation and subsequent depression. There are five piperidine alkaloids in *C. maculatum*, the major ones being *coniine and* γ*-coniceine*. Both are thought to be toxic, and the latter teratogenic. Cattle are most susceptible, and there is decreasing susceptibility through sheep, horses, and pigs. *Conium maculatum* is also teratogenic, especially for cattle, with pigs being less susceptible and sheep relatively resistant. The plant causes *arthrogryposis and spinal deformities in the offspring of sows and cows* when fed between days 43–53 and 55–75 of gestation, respectively. *Cleft palate* occurs in the offspring of pigs exposed to the plant between days 30–45 and goats exposed between days 30 and 60 of gestation. *Carpal flexure* occurred in lambs and kids when *Conium* was fed to pregnant ewes and goats from days 30–60 of gestation, but resolved spontaneously as they grew.

Nicotiana tabacum (burley tobacco) causes arthrogryposis and sometimes brachygnathia and kyphosis in piglets exposed to the plant in utero. ***Nicotiana glauca*** (wild tree tobacco) causes similar lesions and also produces arthrogryposis and spinal deformities in calves exposed between days 45–75 of gestation. The teratogen is an α-substituted piperidine alkaloid, anabasine, which is present also in *N. tabacum*. It produces the lesions when given between days 43 and 53 of gestation and causes cleft palate when administered between days 30 and 37.

Jimsonweed (*Datura stramonium*) and **wild black cherry** (*Prunus serotina*) are suspected teratogens in sows, both being linked to *arthrogryposis*.

Various etiologies, including plant toxicities, have been incriminated in a limb deformity syndrome of lambs referred to as **"bent leg."** In Australia, the syndrome has been associated with ingestion of *Trachymene ochracea* (white parsnip), *T. cyanantha* and *T. glaucifolia* (wild parsnip) by ewes, which preferentially graze the inflorescence of *Trachymene* sp. The toxic principle is unknown, but the deformity may either be congenital, due to exposure of lambs in utero, or may develop during postnatal growth, probably following exposure of lambs through the milk. Gross deformities are usually most prominent in the forelimbs, and include outward bowing, flexion, and lateral rotation of the carpal joints and medial or lateral rotation of the fetlocks. Similar syndromes are described in New Zealand (where it is called **"bowie"**) and South Africa, but plant toxicities are not suspected. In both of these conditions, calcium deficiency and osteoporotic bone disease play a major role in the weakening and deformity that develop. Further discussion of these syndromes is included later in this chapter under the heading "Angular limb deformity."

Outbreaks of congenital limb deformity and abortion have been reported in cattle, sheep, and horses in association with ingestion of **locoweed** (species of *Astragalus* and *Oxytropis*) by pregnant animals. The abnormalities include *brachygnathia, contracture or over-extension of joints, limb rotations, osteoporosis, and bone fragility.* The toxic agent responsible for the skeletal defects is not known but is most likely unrelated to that responsible for the neurological manifestations of locoweed toxicity (see Vol. 1, Nervous system), which inhibits the lysosomal enzyme α-mannosidase, inducing a lysosomal storage disease.

The leguminous plant ***Lathyrus odoratus*** (sweet pea) contains the amino acid β-aminopropionitrile, which inhibits lysyl oxidase and interferes with the formation of intermolecular cross-links in collagen and elastin. Skeletal deformities have been produced experimentally when the plant was fed to young rats, but natural disease associated with ingestion by grazing animals is unlikely.

Fetal ankylosis and abortion are recorded in foals whose dams graze **hybrid sorghum and Sudan grass** (*Sorghum sudanense*) during days 20–50 of gestation, and a similar association has been made in cattle. The lesions in foals involve many joints but are not well described. It is not clear whether the foals have ankylosis or arthrogryposis.

Other toxicities

Overdosing of ewes with the anthelmintic **parbendazole** between days 12–24 of gestation may produce skeletal abnormalities in a high proportion of lambs. Neurologic lesions may also be present (see Vol. 1, Nervous system). The skeletal malformations include compression and/or fusion of vertebral bodies, fusion of proximal ribs, curvature of long bones, hypoplasia of articular surfaces and absence of various bones such as ulna, humerus, and metacarpals. Lesions are reliably reproduced by a double dose of the drug and may even occur with less than twice the recommended dose.

A range of fetal abnormalities, including twisted limbs, brachygnathia inferior, and arthrogryposis is reported in several sheep flocks in New Zealand where ewes had been affected by **nitrate toxicity** during early pregnancy. The ewes had been fed during the winter on crops containing high levels of nitrate and although the evidence to incriminate nitrate toxicity as the cause of fetal abnormalities was circumstantial, the possible involvement of agents such as pestivirus and *Akabane virus* was excluded. The problem occurred on seven properties and the incidence of abnormal lambs varied from 1 to 11%.

Skeletal anomalies of unknown etiology

A syndrome of neonatal foals, characterized by **thyroid hyperplasia** *accompanied by* **musculoskeletal deformities,** has been recognized in western Canada for several years. The skeletal abnormalities include mandibular prognathia, flexural deformities of the forelimbs, ruptured common and deep digital extensor tendons, and delayed ossification of carpal and tarsal bones. In some affected foals, abnormal development of carpal bones, especially the third carpal, is considered to cause angular limb deformity. Lesions typical of osteochondrosis are sometimes present on articular surfaces of carpal bones, perhaps secondary to delayed ossification and increased susceptibility to injury during weight bearing. Hyperplasia of the thyroid gland is a consistent finding in affected foals, and similar abnormalities have been reproduced in partially thyroidectomized foals, but the etiology is not known. Unlike iodine deficiency goiter, the thyroid glands in foals with this syndrome usually are only slightly enlarged, if at all, and could easily be overlooked if not examined microscopically. The syndrome is not genetic and it is considered that *some factor in the feed, perhaps a mycotoxin or plant toxin*, is responsible for interfering with thyroid function, leading to skeletal and other changes normally associated with hypothyroidism. Exposure to cruciferous plants may be responsible.

A syndrome characterized by the birth of deformed calves with a range of abnormalities including joint laxity, disproportionate dwarfism, and sometimes varus or valgus forelimb deformities is well recognized in the western United States, Canada, and Australia. Severely affected calves walk on the palmar and plantar surfaces of their phalanges and some have brachygnathia superior. Originally called **"acorn calves"** because the defect was attributed to ingestion of acorns by pregnant cows, this etiology has now been dispelled, but the name persists in the literature. In Canada, the disease has been referred to as **congenital joint laxity and dwarfism.** Although the actual cause is not known, nutritional deficiency or possibly ingestion of a toxin by the dam, probably between 3 and 6 months of gestation, is suspected. Up to 10% of calves may be affected in herds grazing native pastures of foothills in the western United States. Similar environmental conditions occur in Australia, but the disease incidence tends to be lower, and in Canada where 2–40% of calves in a herd may be affected. The calves usually survive but do not prosper.

In Canada the disease is produced by feeding grass/legume silage during gestation and prevented by adding hay and grain to the silage ration. Timothy grass, fed as silage, produces the disease while timothy from the same fields fed as hay does not. It is suspected that fermentation of silage leading to production of mycotoxins, in particular those from *Fusarium*, is responsible.

Other, isolated examples of generalized abnormalities do occur sporadically. For example, forelimb abnormalities, resembling human "thalidomide babies," affected up to 29% of beef calves in two herds in Australia. There was an axial malformation in one calf and congenital blindness in another, but otherwise the lesions were restricted to the forelimbs. The scapulae were present and usually completely cartilaginous, but distal portions of the limbs were either vestigial or absent. A teratogen was suspected but health and management records provided no clues.

A disproportionate dwarfism in two dairy Shorthorn siblings also occurred in Australia, and was characterized by marked shortening of the pelvic limbs, mild shortening of pectoral limbs, and a normal axial skeleton. Retardation of growth in the femurs, tibias, and metatarsals was prominent, and there was deformity of the femorotibial joints. The calves were affected at birth, suggesting that this syndrome may be *different from hyena disease* (see above), which may be a manifestation of vitamin A toxicity. In hyena disease, the abnormality is usually not apparent until 3–4 months of age.

Angular limb deformity

Angular limb deformities are relatively common in young animals of several domestic species, particularly in fast-growing breeds. In many cases, the deformity can be traced to an asymmetric lesion involving an active growth plate, such as the distal radius, but growth plate damage is not always the underlying cause, and even when it is, the etiology is often not apparent. Abnormal development of carpal or tarsal bones is also reported as causing limb deformities, especially in horses, as has joint instability due to laxity of supporting structures. *Lateral deviation* of the limb distal to the affected growth plate or joint is referred to as a **valgus deformity** and *medial deviation* as a **varus deformity**.

In **horses**, angular limb deformities occur primarily in young foals and are included with a group of disorders referred to as *developmental orthopedic diseases*. A variety of congenital and acquired lesions have been identified in foals with limb deformities and in many cases it is not possible to determine which changes are primary and which are secondary. The abnormality is often centered on the carpal, tarsal, or fetlock joints. Many foals are born with weakness of the supporting periarticular tissues of these joints and have minor structural abnormalities in the osteochondral junctions of developing joint surfaces or the physes of adjacent bones. These minor defects are often clinically manifest as angular limb deformities at birth but most resolve spontaneously within the first week or two of life. During this period, the periarticular attachments strengthen and any regions of physis or developing joint surface that are subjected to extra strain or compressive force during locomotion or weight bearing compensate by an increase in the rate of endochondral ossification. This allows correction of most minor structural abnormalities. If the deformity is more severe, the compensatory mechanisms are exceeded and the deformity will persist without intervention.

Congenital **defects in carpal and tarsal bones** are reported as a *cause of angular limb deformity in newborn foals*. The bones may be abnormal in size or contour, or may possess osteochondrosis-like lesions, both of which can alter the alignment of bones within the joint and therefore the angle of the lower limb. As described above, these lesions may occur in association with other musculoskeletal abnormalities and thyroid hyperplasia. Delayed ossification of affected bones due to hypothyroidism is suggested as a possible mechanism. Even in foals with no evidence of hypothyroidism, the bones of the carpus and tarsus vary considerably in their degree of ossification at birth. In premature foals, or foals with inadequate mineralization of these bones, any minor conformational defects associated with joint laxity may become permanent due to abnormal compression and plastic deformation of the thick cartilaginous layer.

Physeal lesions are occasionally present at birth but are more often the cause of acquired angular limb deformities during the first 6 months of life. *Physes are the weakest structure in the developing ends of long bones and are very susceptible to injury.* In rapidly growing young foals, physeal lesions may also occur as a manifestation of osteochondrosis. The physes most at risk of both trauma and osteochondrosis are those that grow most rapidly, such as the distal radius. Other common sites are the distal physes of the metacarpals and metatarsals, the distal physis of the tibia and the proximal physis of the first phalanx. Such lesions, if detected radiographically as thickened foci in the growth plate, are *often termed "physitis" or "epiphysitis,"* both of which create the misleading impression that they are primarily inflammatory. *These are essentially clinical terms and should not be used by pathologists.* Although many lesions of this type resolve spontaneously without causing clinical disease, some will predispose to angular limb deformity. Microscopically, the lesions of "physitis" reflect focal disruption of endochondral ossification and resemble those associated with osteochondrosis. Septic infection of bone in young foals may also involve physes, causing destruction of the growth cartilage (Fig. 1.53) (see osteomyelitis, in Inflammatory diseases of bones). Foals that survive such infections may develop angular limb deformity.

In **dogs**, angular limb deformity is most commonly associated with *premature closure of the distal ulnar physis*, which is particularly susceptible to trauma, presumably because of its conical shape. If the physis of the adjacent radius continues to grow, the resultant asynchrony will induce valgus deformity. The syndrome occurs most often in large breeds but is described as an autosomal recessive trait in the Skye Terrier. Less frequently, angular limb deformity in young pups results from a lesion in either the proximal or distal physis of the radius, the latter being the most common. Such lesions may be due to a fracture through the hypertrophic zone of the

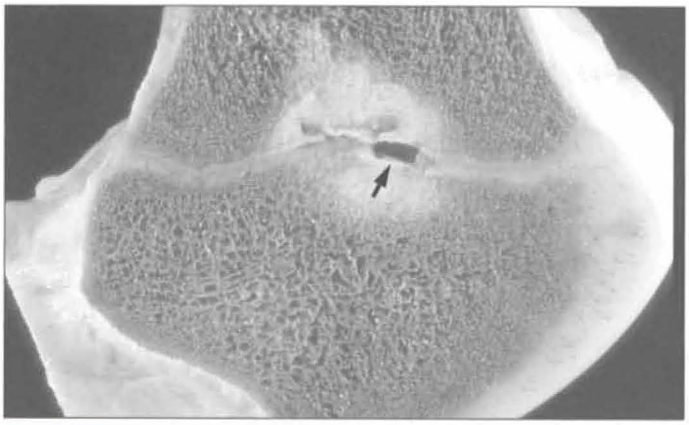

Figure 1.53 Septic physitis and osteomyelitis causing disruption of the distal femoral growth plate in a young foal. Had the foal survived, there would have been fusion between the epiphysis and metaphysis in the area of physeal disruption (arrow) possibly leading to angular limb deformity.

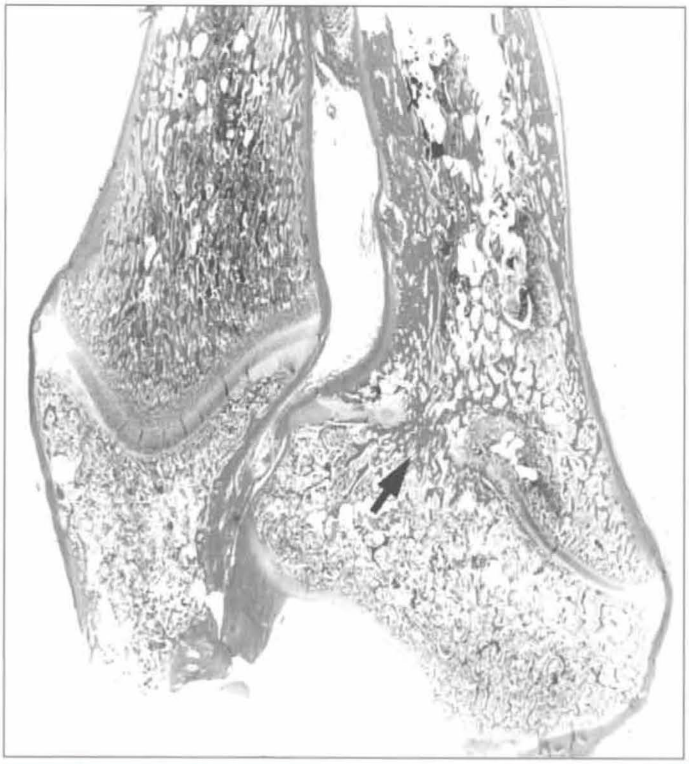

Figure 1.54 Distal radius and ulna from a pup with **angular limb deformity** secondary to traumatic damage to the radial physis. One side of the physis has been destroyed and is penetrated by thick bony trabeculae (arrow). Fusion of the epiphysis and metaphysis on this side has prevented further growth, while growth has continued from the undamaged segment of physis, resulting in angular deformity. (Courtesy of DH Read.)

growth plate, or to a crushing force transmitted through the epiphyseal bone. If the injury affects just one side of the growth plate, and growth continues on the other side, angular deformity will result (Fig. 1.54). Premature closure of the distal tibial physis, resulting in curvature of the tibia/fibula, also occurs occasionally in pups.

In large dogs, especially Great Danes, *closure of the distal ulnar growth plate can be confused with retarded endochondral ossification* (retained endochondral cartilage core). Although the clinical manifestations are often similar, the underlying lesion and its pathogenesis are different. The lesion is bilateral, often clinically silent, and may heal uneventfully. Large retained cores are more likely to interfere with longitudinal growth of the ulna and cause angular deformity. The lesion consists of a cone-shaped mass of unmineralized hypertrophic cartilage with its base at the center of the ulnar growth plate and its apex projecting into the metaphysis (Fig. 1.55A, B). The periphery of the plate is normal. The cause of the abnormality is not known but it could be a manifestation of osteochondrosis, or perhaps due to a temporary interruption or insufficiency in the metaphyseal blood supply. Retained cartilage in the distal ulna occurred in nine of nine pups in two successive litters of captive Mackenzie Valley timber wolves and was associated with limb deformities in all animals.

Angular limb deformity is also described in young, rapidly growing **sheep**, in different parts of the world and is often referred to as **"bent leg"** or **"bowie."** It is relatively common in ram lambs in feedlots, but also occurs in pasture-fed lambs. The forelimbs are affected more frequently than the hindlimbs and the deformity be either unilateral or bilateral, and either valgus or varus (Fig. 1.56A). The etiology is not known, but there is a *strong association with high-energy rations and rapid growth*, suggesting a nutritional component. Dietary imbalances of calcium and phosphorus have been implicated but not proven. One outbreak involved approximately 100 of 160 lambs, 6–9 weeks of age, some of which had been implanted with an anabolic hormone to increase growth rate. Bowie was common in sheep grazing unimproved hill country in New Zealand during the 1950s, involving up to 40% of lambs on some properties, but is now rare. The etiology was never identified but superphosphate topdressing was partially effective in controlling the disease.

Most reports of angular limb deformity in sheep describe gross and microscopic lesions in the *fast-growing physis of the distal radius*, and to a lesser extent in the *distal metacarpals or metatarsals*. The lesions typically consist of *focal or segmental thickening of the physis* (Fig. 1.56B) due to expansion of the hypertrophic zone with extension into the proximal metaphysis. These lesions closely resemble the physeal manifestations of osteochondrosis in foals and pigs, a syndrome that also occurs in rapidly growing young animals, predominantly males (see later in this chapter), and it is likely that the etiology and pathogenesis are similar. Although rickets may also produce similar lesions, there is no evidence of impaired provisional mineralization of cartilage in animals with bent leg, or of reduced bone strength, as would be expected in rickets.

Angular limb deformity is also described in young **goats**, especially those of *fast-growing dairy breeds*, when fed concentrate rations. Males are affected more often than females. The signs of deformity usually are first noticed around the time of weaning at 2–3 months of age, but occasionally in kids only a few days old. Many affected kids recover spontaneously by the time they are 5 months old. *Focal thickening of the physes of the distal radius or distal metacarpal is the characteristic gross lesion* and microscopically these consist of persistent hypertrophic chondrocytes. The syndrome is probably analogous to that in lambs and may be a manifestation of osteochondrosis.

In contrast, limb deformities reported in **llamas** and **fallow deer** have been in animals that are in poor condition and small for their age, suggesting a different mechanism. In llamas, the deformity is almost invariably valgus and centered on the distal radial physis. Radiographic evidence suggests that the deformities in this species

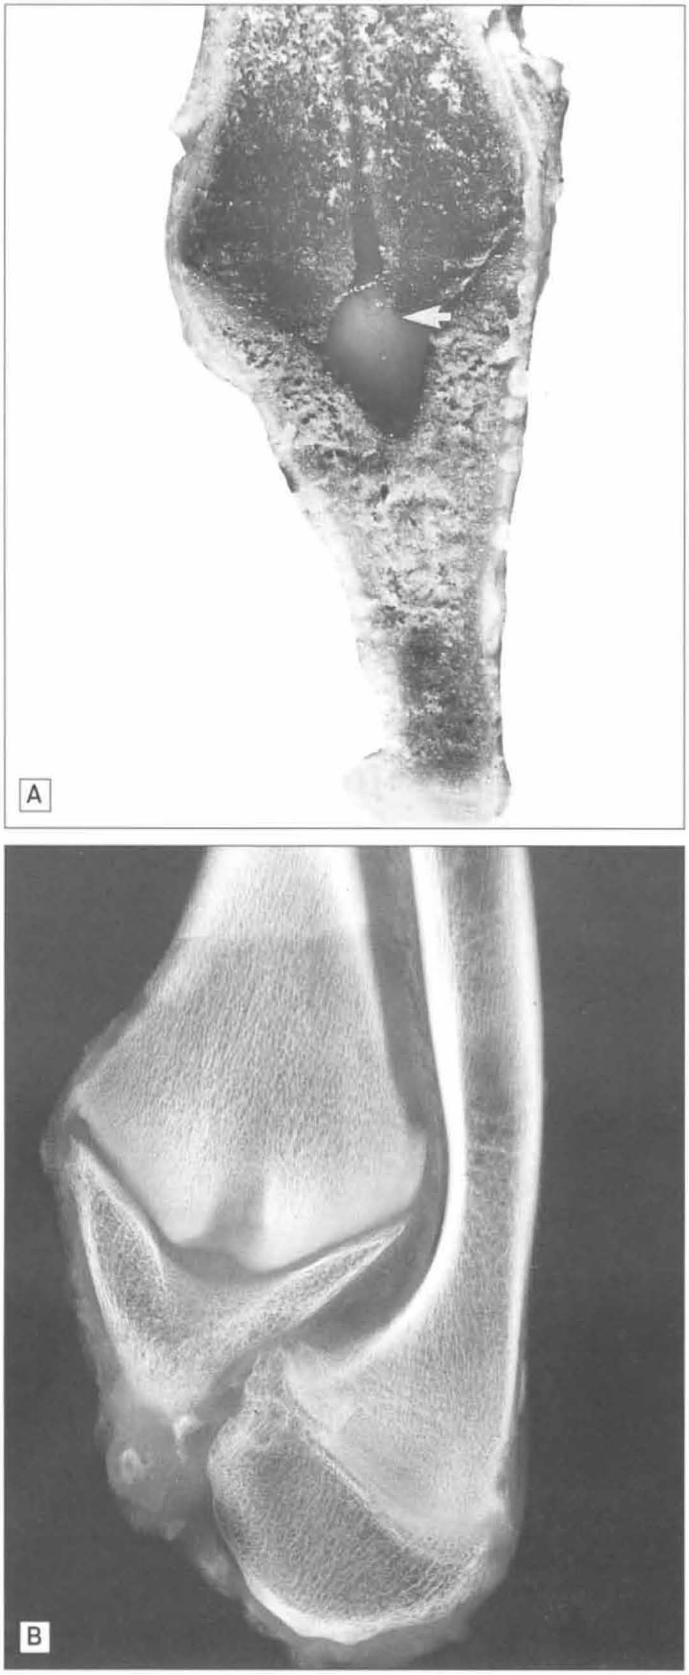

Figure 1.55 Retained cartilage core in the distal ulna of a dog. **A.** A mass of unresorbed physeal cartilage (arrow) projects into the metaphysis. **B.** Slab radiograph showing retained cartilage core in distal ulna of a dog with angular limb deformity secondary to reduced growth from the ulna physis.

Note the focal duplication of the physeal cartilage (arrow) in the right leg (R) and focal thickening of the physis (arrow) in the left leg (L). In both legs, the physeal abnormalities are on the side that has grown more.

are due to premature closure of the distal ulnar physis, as occurs in dogs. In one report describing several cases of limb deformity in an inbred group of llamas, a genetic etiology was suggested, but not proven. A high incidence of limb deformity was recorded in fallow deer from a large deer park in the United Kingdom. In these animals, the lesion was usually centered on the distal metacarpal or metatarsal physes. Thickening of the physes was seen radiographically and grossly only in deer less than 1 year of age, while deformities were detected only in older deer whose growth plates had fused. In addition to the physeal lesions, some affected deer had widened metaphyses. Also, young deer in the park had previously been found with spontaneous fractures, suggesting the possibility of a metabolic bone disease, such as rickets. *The physeal lesions of rickets could predispose to angular limb deformity* and may have been involved on this property. Such physeal lesions could also be involved in angular limb deformities in llamas as camelids appear to be more susceptible to rickets than other grazing ruminants, especially when farmed at low altitudes (see p. 76).

Effect of infectious agents on skeletal development and remodeling

Various infectious agents, in particular viruses, have been shown to infect bone cells and induce abnormalities in the developing skeleton. Infectious agents causing inflammatory changes in bones are discussed in a later section (see Inflammatory diseases of bones). Discussion here is confined to those infectious agents that influence skeletal development *by directly influencing the activity of bone cells.*

The ***Bovine viral diarrhea virus*** (BVDV) has been associated with the formation of zones of metaphyseal sclerosis parallel to the growth plate, referred to as **growth retardation lattices**, in aborted calves following maternal infection (Fig. 1.57A, B). These lattices consist of zones of persistent primary spongiosa with increased cross-connections between cartilage spicules (Fig. 1.57C), presumably reflecting transient periods of impaired osteoclastic activity. Similar zonal **osteopetrosis-like lesions** have also been linked to type 2 BVDV infection in older calves, up to 4 months of age. In these calves, a dense lattice of persistent primary spongiosa adjacent to growth plates contrasted sharply with the apparently normal trabecular arrangement deeper in the metaphysis. The paucity of osteoclasts detected histologically in affected calves, and reduced cellularity of marrow spaces, suggests that *viral destruction of osteoclasts*, or osteoclast precursors, is a likely mechanism for the lesion. It is possible that some cases of osteopetrosis in calves where there is widespread persistence of the secondary spongiosa might be caused by intrauterine viral infection but no specific agent has been incriminated.

Classical swine fever virus, which is closely related to BVDV, causes similar lesions in pigs that survive the acute phase of the disease.

Growth retardation lattices similar to those described in calves have been observed in association with natural and experimental infection by ***Canine distemper virus*** (Fig. 1.58), and in cats infected with ***Feline herpesvirus***. In experimental infections in weanling dogs, viral antigen was demonstrated by immunocytochemistry in osteoclasts, osteoblasts, and less often in osteocytes, from about day 5 to day 41 after infection. Viral antigen was most abundant in bone cells of the primary spongiosa and was strongly correlated with osseous changes, which were most prominent between days 26 and 32 post-infection. Impaired osteoclastic resorption of the primary spongiosa was considered the likely pathogenesis and was supported by the detection of necrotic osteoclasts. The lesions were transitory and resolved once viral antigen disappeared.

The term "growth retardation lattice" has become widely used for lesions of the type described here and in association with lead poisoning, but it creates a misleading impression of the nature of the lesion and *could easily be confused with "growth arrest lines."* The lattice of persistent primary or secondary spongiosa that comprises the former lesion is the result of reduced osteoclastic activity, not reduced growth of the bone. Physeal cartilage is not necessarily affected and growth in length of the bones may be continuing normally. In contrast, growth arrest lines, as discussed earlier in this section, occur when physeal growth ceases then commences again later. *The two lesions differ both in pathogenesis and in microscopic appearance, and should not be confused.*

Toxigenic strains of ***Pasteurella multocida*** cause osteoblast necrosis and are associated with the development of atrophic rhinitis in pigs.

METABOLIC BONE DISEASES

Metabolic bone diseases, also referred to as **osteodystrophies**, *are the result of disturbed bone growth, modeling, or remodeling due to either nutritional or hormonal imbalances.* Because of the complexity of the processes involved in bone development, errors may occur at many stages, the consequences varying with the nature and severity of the imbalance. Genetic defects involving specific enzymes or receptors critical to the activity of hormones or cells participating in bone formation are also reported as causing metabolic bone disease in man and animals, but these are rare. The manifestations of metabolic bone diseases are generally most severe in young animals where the skeleton is undergoing rapid turnover, but lesions also occur in adults due to an effect on the quality or quantity of bone formed during remodeling. In addition to variations with age, there are variations between species in the manifestations of dietary mineral imbalances.

Metabolic bone diseases are traditionally classified as **rickets, osteomalacia, fibrous osteodystrophy**, or **osteoporosis**. Although these are distinct morphological entities with characteristic pathogenesis and lesions, *they can occur in combination in the same individual*. This may create confusion diagnostically. Furthermore, *their etiology can vary between species*. For example, calcium deficiency in sheep is likely to result in osteoporosis, but in a rapidly growing pig, fibrous osteodystrophy is a more likely result. Also, each of these disorders can be caused by more than one dietary or endocrine imbalance. The distinguishing features of each entity, together with their etiology, pathogenesis, and occurrence in different species are discussed in detail below. The term **osteopenia** is often used to describe syndromes associated with increased radiolucency of bone, but makes no inference as to its quality. As such, it includes osteoporosis, where only the quantity of bone is abnormal, as well as osteomalacia, fibrous osteodystrophy, and osteogenesis imperfecta, where the bone is not only reduced, it is abnormal in quality.

Since bone matrix is composed largely of calcium and phosphate ions in the form of hydroxyapatite crystals, any dietary or physiological factors affecting the metabolism of calcium and/or phosphorus can interfere with the formation of bone tissue and cause an osteodystrophy. Because of the importance of these two elements in bone formation, and hence in the etiology of metabolic bone diseases, a brief review of their homeostasis is presented below. Vitamin D and parathyroid hormone are integral components of homeostatic control mechanisms for calcium and phosphorus and their role also is discussed.

Metabolic bone diseases can usually be treated successfully, providing the problem is recognized early enough and there are no lasting effects caused by pathologic fractures or disruption of growth plates in young, growing animals. However, in cases where severe generalized osteoporosis has developed, insufficient bone surfaces may remain to allow appositional bone deposition to proceed and affected animals remain susceptible to hypocalcemic crises and the deleterious effects of chronically weakened bones. In production animals, an early and accurate diagnosis is important if significant economic loss is to be avoided. This requires a good history, recognition of species differences and an ability to accurately interpret radiographic and/or pathologic alterations. Whenever possible, more than one affected animal should be examined as the lesions may vary in severity between animals even if they are being fed the same ration. *It is important to examine and sample bones from several sites, particularly those that are showing obvious abnormalities and those from sites of rapid growth or movement. This includes the physes of the distal radius, proximal humerus, proximal tibia, distal femur, and costochondral junctions of the largest ribs.*

In reality, metabolic bone diseases seldom result from a deficiency of a single dietary nutrient. *More often, there is either a deficiency of several nutrients or a dietary imbalance in the ratio of calcium and phosphorus.* Diseases of other organ systems, especially gastrointestinal disorders that cause malabsorption, can affect the skeleton by reducing the absorption of essential minerals or vitamins. Metabolic bone disease also occurs in humans and animals in association with renal failure, due to interference with mineral metabolism and reduced synthesis of 1,25-dihydroxyvitamin D. This will be discussed in more detail below. Hepatobiliary and pancreatic disorders can, at least potentially, predispose to osteodystrophy through impaired absorption of vitamin D and other nutrients, but this is seldom recognized in domestic animals.

Calcium and phosphorus homeostasis

Calcium and phosphorus are required for a variety of essential bodily functions in addition to those involving skeletal development. *Approximately 99% of the calcium in the body is present in the skeleton as hydroxyapatite, the remaining 1% being contained in extracellular fluids and soft tissues.* The concentration of calcium in extracellular fluids and in the cytosol must be kept within narrow limits in order to maintain critical functions such as muscle contraction, neuromuscular irritability, blood coagulation, and mineralization of bone matrix. A small fraction of the calcium in bone (about 1%) is freely exchangeable with the extracellular fluid compartment. The skeleton is therefore an important storage site for calcium, providing a readily available source should dietary levels become temporarily deficient. Phosphorus is also a component of hydroxyapatite in bone matrix but, like calcium, has other essential functions; in particular the generation and transfer of cellular energy. *Approximately 85% of the phosphorus in the body is included in the skeleton.*

There are *three distinct fractions of calcium* in extracellular fluids (including plasma); an ionized fraction (about 50%), a protein-bound fraction (about 40%), and calcium complexed to other ions such as citrate and phosphate (about 10%). The *ionized fraction of calcium* (Ca^{2+}) *is the physiologically active form* and is tightly controlled by the actions of parathyroid hormone, 1,25-dihydroxyvitamin D and calcitonin on the intestinal tract, skeleton and, to a lesser extent, the kidney. Most of the protein-bound calcium is bound to albumin and plasma concentrations vary with the concentrations of plasma albumin. The binding of calcium to albumin is highly pH-dependent. Acute acidosis decreases binding and increases ionized calcium concentrations, while acute alkalosis increases binding and reduces the concentration of ionized calcium in plasma and extracellular fluids. Such alterations in ionized calcium are seldom reflected in the total serum calcium concentrations routinely measured by diagnostic laboratories.

Inorganic phosphate also exists in ionized, protein-bound, and complexed forms in plasma. The protein-bound fraction is relatively small (about 10%), but 35% of plasma phosphate is complexed to sodium, calcium, and magnesium, the remaining 55% being ionized. The predominant form of ionized phosphate in plasma is the divalent anion HPO_4^{2+}. Plasma phosphorus concentration is controlled by the action of parathyroid hormone and 1,25-dihydroxyvitamin D on the kidney and intestinal tract, but the control mechanisms are not as precise as for calcium. Consequently, plasma phosphorus concentration varies more widely than calcium, and is more easily influenced by diet, age, sex, pH, and various hormones. An inverse relationship exists between plasma ionized phosphate and plasma ionized calcium concentrations, *an increase in phosphate resulting in a reduction in ionized calcium.*

Parathyroid hormone (PTH) is intimately involved in the regulation of ionized calcium and phosphate concentrations in plasma through its action on specific cells in bone and kidneys, and indirectly on the intestine:

- stimulates the release of calcium and phosphate from bone by osteoclastic resorption,
- stimulates reabsorption of calcium and inhibits reabsorption of phosphate from renal glomerular filtrate,
- stimulates renal synthesis of 1,25-dihydroxyvitamin D from 25-dihydroxyvitamin D, thereby increasing intestinal absorption of calcium and phosphate.

The parathyroid gland responds to any decrease in the concentration of plasma-ionized calcium by releasing PTH. *The net effect of PTH is to increase plasma-ionized calcium and reduce plasma phosphate concentrations.* Once the ionized calcium has been restored to an acceptable level, PTH secretion is halted. Although PTH releases phosphate from bone, together with calcium, the increased loss of phosphate in the urine under the influence of PTH results in a net decrease in plasma phosphate. Osteoclasts do not possess receptors for PTH but are stimulated indirectly through increased expression of RANK-L by osteoblasts under the influence of PTH. This functional linkage between osteoblasts and osteoclasts may account for the concurrent increase in osteoblastic and osteoclastic activity in the bones of animals with hyperparathyroidism. PTH also reduces expression of osteoprotegerin, an inhibitor of osteoclast maturation and activation, and is closely involved in regulating the formation of the active form of vitamin D through its action on renal 1α-hydroxylase. Interestingly, intermittent, low doses of PTH have been shown to have a powerful anabolic effect on bone, creating new opportunities for treating osteoporosis in human patients.

Vitamin D is biologically inert, but undergoes two successive hydroxylations, in the liver and kidney, to form the *active hormone 1,25-dihydroxyvitamin D*, which acts in concert with PTH in maintaining plasma ionized calcium concentrations. 1,25-dihydroxyvitamin D has various actions on target organs:

- enhances absorption of calcium and phosphate from the small intestine,
- stimulates release of calcium and phosphate from bone by osteoclastic resorption,
- enhances phosphate reabsorption from glomerular filtrate.

In the intestine, 1,25-dihydroxyvitamin D increases the efficiency of calcium absorption from about 10% to 70%, probably by stimulating the local production of calcium-binding protein, although several mechanisms may be involved. Phosphorus absorption in the intestine is also increased by 1,25-dihydroxyvitamin D. *The principal action of 1,25-dihydroxyvitamin D on bone is to enhance calcium mobilization when the dietary levels are inadequate to maintain normal plasma-ionized calcium concentrations.* This requires the presence of both 1,25-dihydroxyvitamin D and PTH and is achieved by inducing the differentiation of osteoclasts from monocytic stem cells in the bone marrow as well as stimulating osteocytic osteolysis. In the absence of vitamin D metabolites, osteoid is poorly mineralized and calcium cannot be efficiently mobilized by osteoclasts. Although vitamin D is considered essential for normal mineralization of bone matrix, there is uncertainty whether this is a direct effect or mediated through maintenance of adequate extracellular concentrations of calcium and phosphorus. In addition to its effects on bone, 1,25-dihydroxyvitamin D has other biological effects, including inhibiting the synthesis of PTH and interleukin 2, and enhancing the secretion of insulin and thyroid-stimulating hormone. In vitro, 1,25-dihydroxyvitamin D has been shown to induce monocytes to differentiate into osteoclast-like multinucleated giant cells.

Vitamin D exists in two forms, *vitamin D_2 and vitamin D_3*, both of which have similar potency in humans and domestic animals. Some species however, such as New World primates (Cebus monkeys, tamarins (*Saguinus* spp.)), can utilize only vitamin D_3, while in chickens vitamin D_3 has about ten times greater potency than vitamin D_2. *Vitamin D_2 (ergocalciferol)* is of dietary origin, being present predominantly in yeasts and plants. *Vitamin D_3 (cholecalciferol)* may also be derived from dietary sources, especially fatty fish and cod liver oil, but most is formed in the skin following photochemical conversion of 7-dehydrocholesterol by energy derived from solar ultraviolet light with wavelengths from 290–315 nm (ultraviolet B). The previtamin D_3 formed by this process is then transformed into vitamin D_3 over a period of a few hours by heat-induced isomerization. Latitude, time of day, and season can all have a dramatic effect on vitamin D_3 production in the skin due to lessening of the intensity of ultraviolet light when the sun is at lower angles. At higher latitudes, sunlight is incapable of stimulating vitamin D_3 synthesis in the skin during the winter months. Furthermore, dark-skinned people require longer exposure to sunlight than people with light skin to manufacture the same amount of vitamin D_3. The same most likely applies to animals, and a dense hair coat is likely to reduce cutaneous vitamin D_3 synthesis even further. In fact, there is doubt that vitamin D is synthesized at all in the skin of dogs and cats. The need for carnivores to manufacture their own vitamin D is perhaps obviated by the ample supply of this fat-soluble vitamin in their usual diet.

Once formed in the skin, vitamin D_3 is transported to the circulation where it is bound to an α-1-globulin. Vitamin D_2 or D_3 absorbed from the intestine is transported in chylomicrons, reflecting its lipid solubility. Vitamin D from either source is transported to the liver where it is converted to 25-hydroxyvitamin D by the addition of a hydroxyl group. This is the major form of vitamin D in circulation. Since the reaction of the hepatic enzyme vitamin D-25-hydroxylase is not closely regulated, the concentration of 25-hydroxyvitamin D in circulation reflects the level of cutaneous vitamin D_3 formation and/or dietary levels of vitamin D. Measurements of 25-hydroxyvitamin D in plasma are therefore used to determine whether an individual has adequate or deficient vitamin D status.

The most active form of vitamin D is 1,25-dihydroxyvitamin D, which is formed by the addition of a second hydroxyl group to 25-hydroxyvitamin D under the direction of 25-hydroxyvitamin D-1α-hydroxylase. This reaction occurs predominantly in mitochondria of renal proximal tubular epithelial cells and is closely regulated by circulating concentrations of PTH and inorganic phosphorus. In pregnant animals, 1,25-dihydroxyvitamin D is also formed in the placenta, from where it may become involved in fetal bone and mineral metabolism. Synthesis of 1,25-dihydroxyvitamin D is stimulated directly by high PTH and low phosphorus, and indirectly by low ionized calcium, which acts through PTH. Once formed, 1,25-dihydroxyvitamin D also induces negative feedback on its own synthesis. When plasma phosphorus and ionized calcium concentrations are adequate, and PTH levels are low, 25-hydroxyvitamin D is converted to either 24,25-dihydroxyvitamin D or 1,24,25-trihydroxyvitamin D. These biologically inert metabolites are considered to represent the initial steps in biodegradation pathways.

Calcitonin also plays an important role in calcium and phosphorus homeostasis, and in bone metabolism. Produced by thyroidal C-cells, and secreted in response to increased concentrations of plasma-ionized calcium, *the main biological function of calcitonin is to inhibit osteoclastic bone resorption.* Within minutes of calcitonin administration, osteoclasts shrink and reduce their bone-resorbing activity. As a result, the release of calcium from bone is inhibited and plasma calcium returns to normal.

Osteoporosis

Osteoporosis is easily the most common of the metabolic bone diseases, both in man and animals. Rather than being a specific disease, *osteoporosis is a lesion characterized by a reduction in the quantity of bone, the quality of which is normal.* In effect, osteoporosis represents an imbalance between bone formation and resorption in favor of the latter, resulting in bone that is structurally normal but with reduced breaking strength. Strictly speaking, all osteoporoses should be

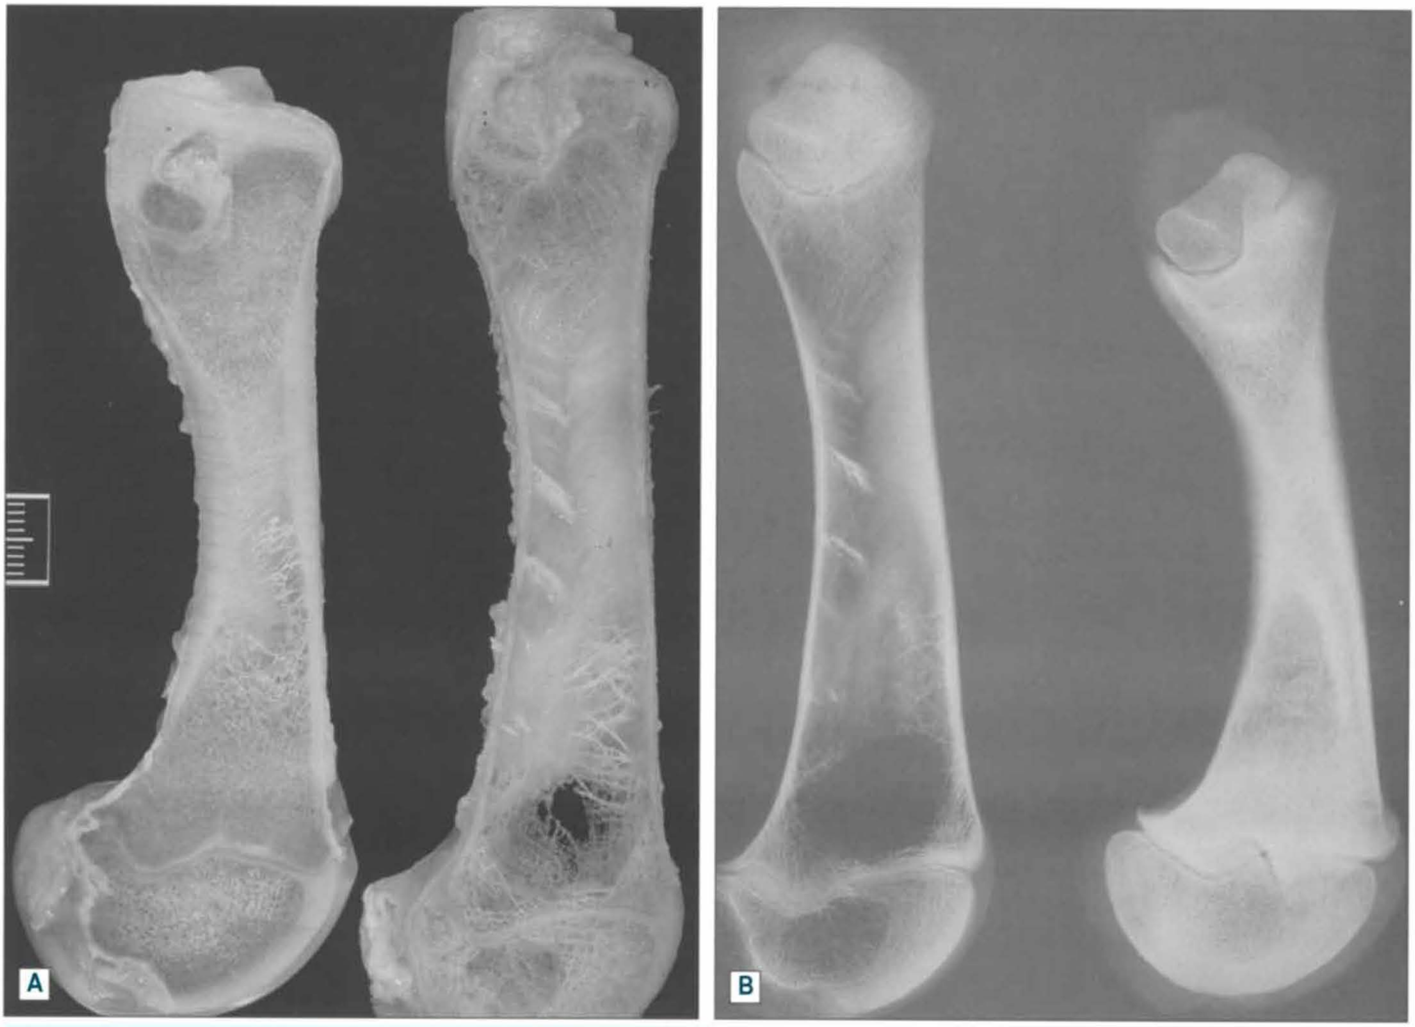

Figure 1.59 Osteoporosis in a pig. (Courtesy of RA Fairley.) **A.** Femur from a pig with severe osteoporosis (right) compared to that of a normal pig. Note the marked depletion of cancellous bone in the metaphyses and epiphyses and the very thin cortices in the affected pig. **B.** Radiograph of the same two bones (positions reversed) showing marked differences in the quantity of cancellous and cortical bone.

called osteopenias pending qualitative assessment of the bone tissue but, for practical purposes, this seldom occurs. Some diseases, for example osteogenesis imperfecta, are characterized by a reduction in bone quality as well as an alteration in bone mass and should not therefore be referred to as osteoporosis, even though the skeleton may appear porotic radiographically and show marked fragility.

The development of a negative balance between bone formation and resorption is recognized as a *normal part of the aging process* in man and animals. Osteoporosis could therefore be considered a natural phenomenon, but there are several physiological situations and disease states that either accelerate bone loss or increase bone resorption, leading to premature depletion of the skeleton. Those of most importance in animals are discussed in detail below.

Many mild cases of osteoporosis in animals remain undetected, even at postmortem examination, as the shape of individual bones is not altered and unless there have been pathological fractures, lameness is not likely to have been observed clinically. The *occurrence of a bone fracture without evidence of excessive trauma may be the first indication that an animal, or human, is suffering from osteoporosis.* In farmed livestock, there may be an unusually high incidence of fractures in the herd or flock, suggesting increased bone fragility.

Confirmation of osteoporosis can be difficult, especially when the degree of bone depletion is relatively mild. Routine radiographic procedures are insensitive in the early stages of osteoporosis as approximately 30–50% of skeletal calcium must be lost before the change can be reliably detected by this method. For this reason, and because of the importance of osteoporosis in human patients, *new diagnostic techniques* have been developed for its early recognition and quantitation. These techniques, which include photon absorptiometry, dual-energy X-ray absorptiometry, ultrasonography, magnetic resonance imaging, and computed tomography, are not widely used for the diagnosis of osteoporosis in animals. *Subjective assessment of the cut surface of bones at necropsy will allow diagnosis of advanced cases of osteoporosis,* but knowledge of what is normal for an animal of the age and species in question is essential, especially when the changes are equivocal. Radiography of isolated bones can detect much smaller alterations in bone density than whole-body radiographs, but comparison with an age-matched control may still be necessary before osteoporosis can be diagnosed with confidence. When it is important to be sure of the diagnosis, objective measurement of radiographs, or use of one of the more precise imaging techniques mentioned above, is recommended. Objective measurement of histological parameters such as bone volume, trabecular thickness, osteoid volume, osteoblastic and osteoclastic activity and bone mineral apposition rate is commonly used by medical pathologists (see review by Bullough et al.), but *histomorphometry* remains largely a research tool in veterinary pathology. *Bone ash measurements* have been traditionally used for the diagnosis of osteoporosis in animals and although they may provide information on the matrix–mineral relationship, reliable reference ranges are seldom available and interpretation of results is difficult. Because the ratio of calcium to phosphorus is fixed in deposits of hydroxyapatite within bone, bone ash samples do not identify low calcium or low phosphorus as causes for osteopenic bone disease, merely that the matrix to mineral ratio is abnormal.

Osteoporosis in human subjects is defined as bone mass 2.5 standard deviations below the young adult mean. In animals, such precise data are not available and the cut-off point between a normal and osteoporotic skeleton is somewhat arbitrary. For this reason, the diagnosis tends to be restricted to cases where there is an obvious reduction in bone mass.

Gross lesions of osteoporosis are generally most marked in bones, or areas of bones, which consist predominantly of *cancellous bone*, presumably because trabecular bone has a greater surface area to volume ratio than cortical bone and is resorbed more rapidly. Vertebral bodies in particular are affected early in the disease in human patients and animals with osteoporosis and may contain pathological fractures. Flat bones of the skull, scapula, ilium, and the ribs may also be severely affected and the breaking strength of the ribs, as assessed during necropsy, may be noticeably reduced. Cancellous bone in the metaphyses and epiphyses of long bones may be reduced in amount and more porous than normal (Fig. 1.59A, B). Trabeculae that are most concerned with transmission of weight-bearing stress are relatively spared and may become more prominent. Thickened trabeculae extending partially or completely across the medullary cavity may be present in the metaphysis or diaphysis of human patients and animals with chronic osteoporosis (Fig. 1.60). The pathogenesis of these *so-called reinforcement lines or bone bars* is uncertain but they may represent an attempt to reinforce weakened bones at locations of particular biomechanical stress. In most forms of osteoporosis, an exception being disuse osteoporosis (see below), cortical bone is resorbed most rapidly from the endosteal surface and along vascular channels. In advanced stages, the medullary cavities of affected long bones are enlarged and the cortices thin (Fig. 1.59A, B). Osteoporotic bones are usually light and fragile, but an accompanying reduction in soft tissue mass and muscular power in many cases tends to preserve the skeleton against stress fractures.

Histological examination of severely osteoporotic bones will not necessarily yield information of diagnostic value, as the depletion of bone tissue is likely to have been clearly established on the basis of either radiography or gross examination. However, it may allow assessment of bone quality, thus allowing differentiation from other metabolic bone diseases and certain other forms of osteopenia. Furthermore, *although it is not likely to allow an etiologic diagnosis, histology may provide an indication of the pathogenesis of bone loss*. For example, there is evidence that osteoporosis evolving from increased resorption is characterized by a decline in trabecular numbers, while in osteoporosis caused by decreased formation there are normal numbers of thin trabeculae. Quantitative histomorphometry may be of value in the diagnosis of osteoporosis in equivocal cases, but this is essentially a research tool rather than one to be used in routine diagnosis.

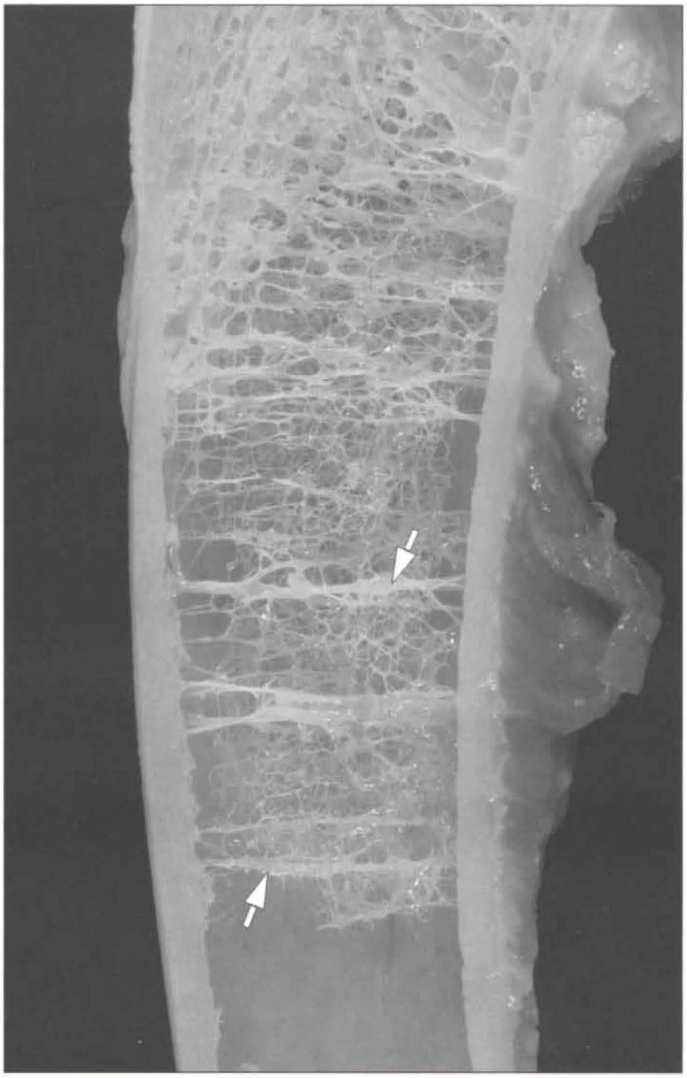

Figure 1.60 Osteoporosis in a dog. Narrow cortices, depletion of cancellous bone and formation of transverse reinforcement trabeculae (arrows), in a dog with chronic osteoporosis. (Courtesy of RA Fairley.)

In severely osteoporotic young animals, the hypertrophic zone of the growth cartilages may be narrowed or absent and when growth ceases, the physis is sealed by a plate of bone (Fig. 1.61A, B). Microscopically, trabeculae are reduced in number and/or size and often are fractured. Depending on the cause of the osteoporosis, evidence of abnormal activity of osteoblasts and/or osteoclasts is present. Intracortical resorption in long bones occurs along vascular channels and is produced by teams of osteoclasts working parallel to the long axes of the bones, the so-called *cutting cones*. Intracortical resorption is functionally important because a small loss of compact bone has a greater effect on bone stiffness than a comparable loss of cancellous bone.

Postmenopausal osteoporosis is the most important form of osteoporosis in human patients and, although the etiology is multifactorial, estrogen deficiency around the time of menopause is believed to play a significant role. Estrogen indirectly inhibits osteoclastic bone resorption through inhibition of interleukin-1 synthesis by peripheral blood monocytes. After estrogen withdrawal, interleukin-1 enhances the production of interleukin-6, a potent stimulator of

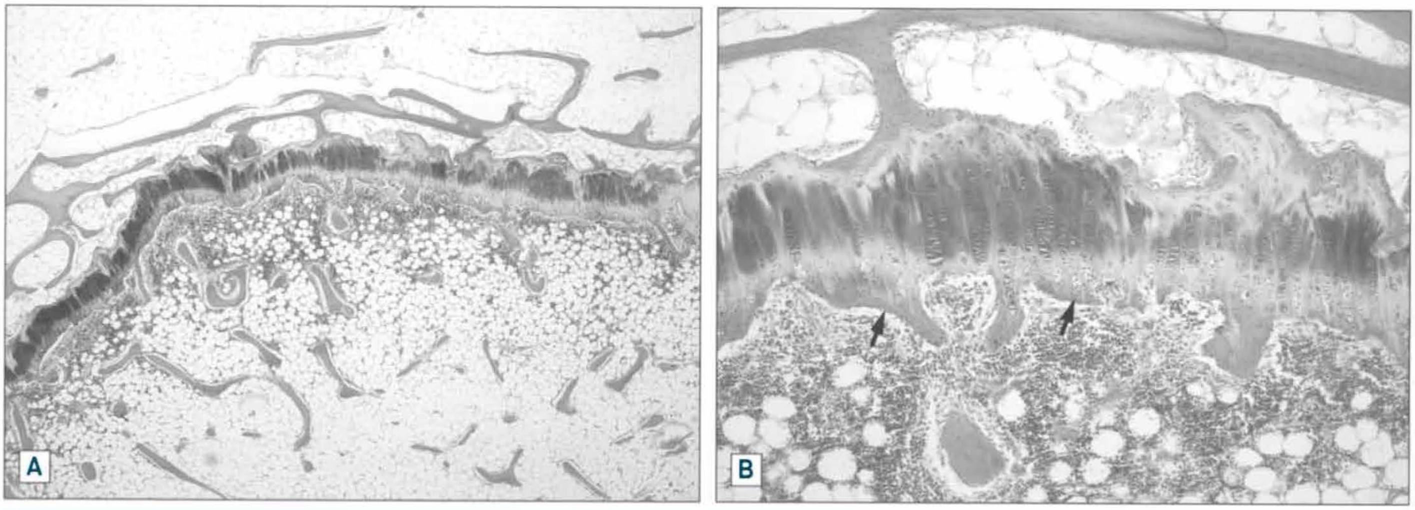

Figure 1.61 Osteoporosis: physeal closure. **A.** Narrowing of the physis and marked deficiency of trabecular bone in the epiphysis and metaphysis of a young pig with severe osteoporosis. **B.** Closer view of the physis in the same animal, showing almost complete absence of hypertrophic chondrocytes and sealing of the metaphyseal side of the physis with narrow plates of bone (arrows). Occasional plump trabeculae extend for a sort distance into the metaphysis.

osteoclastic activity. The inhibitory effect of estrogen on bone resorption may also involve promotion of osteoclast apoptosis by this hormone. This has been demonstrated both in vitro and in vivo and appears to be mediated by TGF-β. An equivalent form of osteoporosis is not currently recognized in animals but there are several other possible causes, many of which are discussed below.

Senile osteoporosis is common in humans and occurs in other animals, but *seldom appears as a clinical problem in veterinary medicine.* This may reflect the considerably shorter lifespan of most domestic animals when compared with humans, although in reality, it is often difficult for the veterinary pathologist to distinguish between the effects of age and other factors that might contribute to reduced skeletal mass in old animals. Beagle dogs aged 7–8 years have approximately 8% less bone tissue in their forelimbs than do young adults, but this reduction is not clinically significant.

Most cases of osteoporosis in animals, especially farm animals, are **nutritional** in origin and may be due to deficiency of a specific nutrient, such as calcium, phosphorus, or copper, or to **starvation**, where there is restricted intake of an otherwise balanced ration. Starvation is relatively common in grazing animals in areas prone to drought or due to overstocking in seasons when pasture growth is below expectations. Poor-quality milk replacers fed to young calves or other young animals may also result in starvation due to inadequate digestibility and absorption of nutrients. In starved animals, the mechanism of osteoporosis is complex, but the lack of dietary protein and energy most likely contribute, either directly or indirectly.

The *effects of starvation* on the skeleton are greater in young growing animals than in adults. Growth of the skeleton is retarded and may cease during periods of starvation due to reduced production of bone matrix. The physes are narrower than normal and the chondrocytes are small, with a relative increase in the amount of cartilage matrix. Thin, widely spaced bone trabeculae are present on the epiphyseal side of the physis, and the metaphyseal side may be sealed by a narrow, horizontal plate of bone (Fig. 1.61B), indicating cessation of growth. As a result, the epiphyseal and metaphyseal sides of the growth plate may appear similar. The cortical and trabecular bone of the diaphyses is reduced in amount. In some cases, characteristic transverse trabeculae may be evident grossly and microscopically in the metaphysis (see Fig. 1.44A, B). These **growth arrest lines**, which differ from the reinforcement lines referred to above, result from intermittent cessation and reactivation of physeal growth and represent a succession of sealing layers from the physis. Transverse radiodense striations also develop in limb bones of fetuses from ewes on a low plane of nutrition. In these lambs, there may be considerable variation in the number of arrest lines between littermates, the number of lines being correlated positively with retardation of fetal size and skeletal maturity. Serous atrophy of medullary adipose tissue is a common feature of starvation-induced osteoporosis in animals (Fig. 1.62).

The *pathogenesis of starvation osteoporosis* in terms of remodeling imbalance is not completely defined. The histologic appearance of inactive osteoblasts, and *a priori* reasoning, both *suggest that deficient bone formation is responsible.* Support for this hypothesis is derived from findings in dogs with malabsorption syndrome, in which tetracycline-labeled sites of bone formation are sparse or absent. The level of bone resorption during starvation is not known.

Severe undernutrition also has a profound effect on tooth development. Delayed formation and eruption of the whole dentition, with a relatively greater delay in the growth of the jaws, leads to overcrowding of the teeth, especially the permanent molars. This causes malocclusion and malalignment of teeth, and there is partial or complete elimination of the diastemata between incisors and canines, and between canines and deciduous molars. Nutritional rehabilitation allows rapid growth of jaws and teeth but malocclusion of permanent dentition persists and often there is abnormal development of parts of some teeth.

Uncomplicated **calcium deficiency**, in the presence of optimum dietary levels of phosphorus and vitamin D, causes osteoporosis experimentally in mature and immature animals, but rarely if ever occurs as a natural disease. In gilts, **lactational osteoporosis** occurs when rations marginally deficient in calcium, and with normal or excess phosphorus, are fed over extended periods during gestation and/or lactation. Generalized osteoporosis, and a tendency to fracture vertebrae, femurs, and phalanges, characterizes the condition.

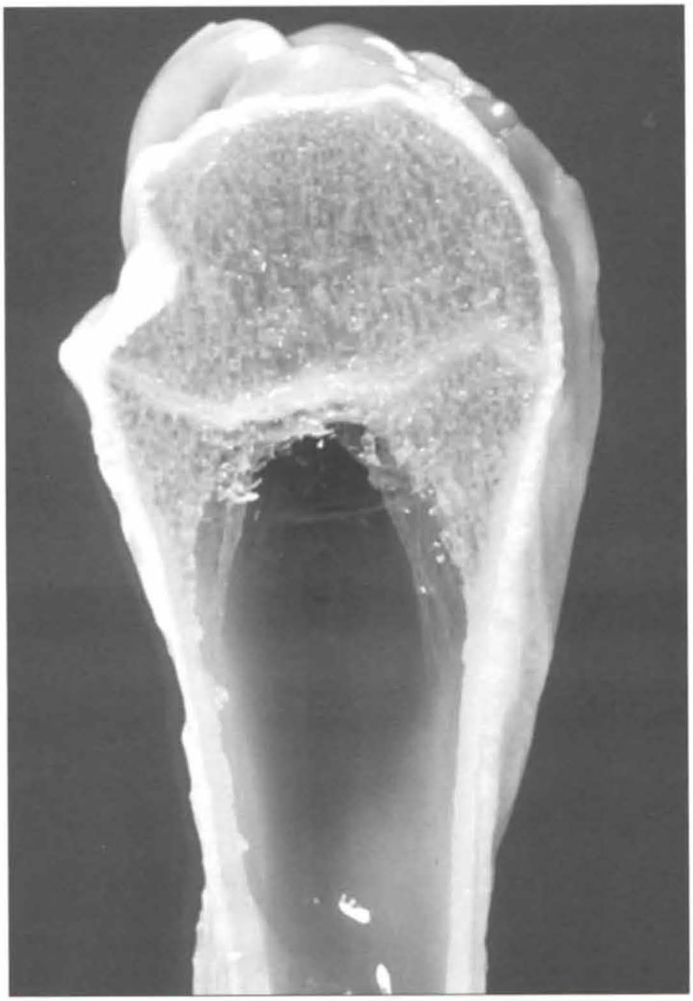

Figure 1.62 Starvation-induced osteoporosis in a lamb. Marked depletion of metaphyseal cancellous bone, thin cortices, and serous atrophy of medullary adipose tissue.

Significant losses associated with lactational osteoporosis occur in some swine herds. The condition may be complicated by disuse osteoporosis caused by confinement in farrowing crates, or by other dietary deficiencies and affected animals may have microscopic evidence of concurrent fibrous osteodystrophy.

The *osteoporosis induced by calcium deficiency is due to excess bone resorption* as a result of increased activity of parathyroid hormone following a reduction in plasma-ionized calcium concentration. In adult animals, the bone loss probably results from an increase in the activation of new remodeling sites. Cortical bone is lost through increased endosteal resorption and, in severe calcium deficiency, intracortical resorption as well. In both adult and growing animals, there is severe loss of cancellous bone, especially in bones with a high trabecular component such as vertebrae. In immature metaphyses, the primary spongiosa may be removed completely, so that there is no framework remaining for the production of secondary spongiosa.

Unless the deficiency is extremely severe, physeal growth and mineralization of cartilage are normal. Osteoid seams are of normal width and frequency, and mineralization occurs normally. *Rickets is not a feature of uncomplicated calcium deficiency* because calcium resorption from bone ensures that this mineral is not a limiting factor at sites of mineralization. In mature animals, calcium deficiency is usually asymptomatic, but in the young, trabecular microfractures, infractions, and complete fractures of bones may occur in both the axial and appendicular skeleton, and animals may die suddenly from hypocalcemic crises when stressed. Parathyroid glands are slightly enlarged due to hyperplasia, and fibrous osteodystrophy sometimes develops, but is less florid than in the osteodystrophy of calcium deficiency induced by phosphorus excess or vitamin D deficiency.

Prolonged calcium deficiency causes dental abnormalities in sheep, including delayed eruption, and increased susceptibility to wear due to mild enamel hypoplasia. When adequate calcium becomes available, superior brachygnathia develops because of inadequate repair of the upper skull compared to the mandible.

Classically, **phosphorus deficiency** *produces osteomalacia in adults and rickets in growing animals, both under natural and experimental conditions. However, under some circumstances it causes osteoporosis.* The reasons for this are not clear, but it may be related to the anorexia that often accompanies phosphorus deficiency, the age and growth rate of the animals, and the severity and duration of phosphorus deficiency. It is not clear whether osteoporosis and osteomalacia are interconvertible or whether osteoporosis is a stage in the development of osteomalacia.

Osteoporosis is recognized as a feature of naturally occurring and experimental **copper deficiency** in lambs, calves, foals, pigs, and dogs. As a component of the enzyme lysyl oxidase, *copper is required for the cross-linkage of collagen and elastin.* Deficiency of this enzyme is probably responsible for the reduced osteoblastic activity observed in swine and dogs with copper deficiency, while the impaired cross linkage of collagen in bone matrix most likely accounts for the increased bone fragility in copper-deficient animals when compared to animals with osteoporosis of other causes.

The bone lesions associated with primary and secondary copper deficiency are discussed earlier in this chapter in the section Mineral imbalances and will not be repeated here. It should be mentioned however that *the gross and microscopic bone lesions of copper deficiency may resemble the lesions of rickets and osteochondrosis*. In fact, there is increasing evidence, at least in some species, that copper deficiency is a cause of, or predisposing factor in, osteochondrosis.

Osteoporosis is often present in animals with severe **gastrointestinal parasitism**, most likely *secondary to malabsorption*. However, there is convincing evidence that subclinical parasitism may also cause osteoporosis, probably by a different mechanism. In one study, continuous dosing of lambs with *Trichostrongylus colubriformis* between 4 and 7 months of age produced a mineral osteoporosis characterized by a reduction in cortical and trabecular bone. This was accompanied by a reduction in the length and volume of bones, and in their degree of mineralization. Some animals showed widened osteoid seams on trabeculae and physeal changes suggestive of concurrent rickets. The lambs had low plasma phosphorus concentrations and normal plasma calcium, suggesting that the bone lesions were due to an induced phosphorus deficiency, although the possible effect of increased corticosteroid production on bone formation was also considered. In goats infused with a subclinical dose of *Trichostrongylus colubriformis* in another study, concurrent subclinical coccidial infection was shown to have an additive effect. Recently, trichostrongyle infections have been shown to lower the concentration of phosphorus carrier proteins in the intestinal mucosa, leading to phosphorus malabsorption in parasitized animals.

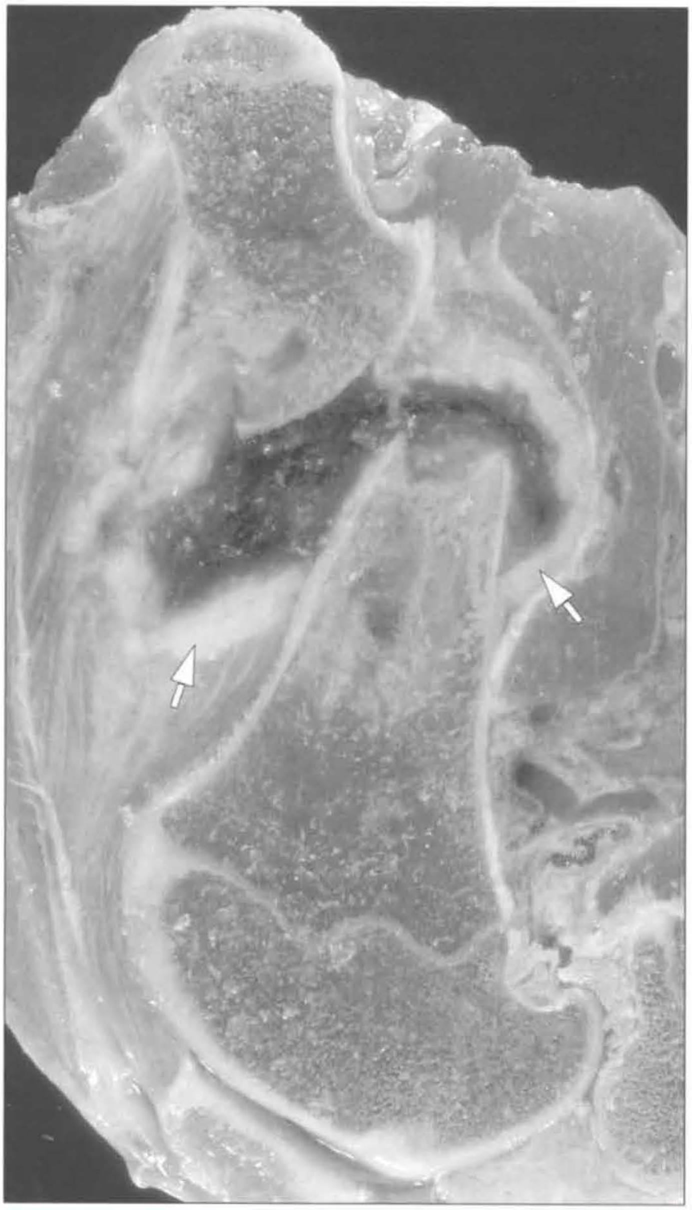

Figure 1.63 Spontaneous femoral fracture (approximately 1 week duration) in a heavily parasitized young sheep with **severe osteoporosis**. Note the thin cortices and porous cancellous bone. There is hemorrhage and early callus formation (arrows) between the malaligned bone ends.

Subclinical infection of lambs with *Ostertagia circumcincta* has also been shown to produce osteoporosis. This was a *matrix osteoporosis*, mediated apparently through restrictions in the availability of protein and energy for matrix deposition. Reduced bone volume was a consistent finding, but there was no effect on growth plates and the length of bones was normal. In calves infected experimentally with *Ostertagia* spp., the utilization of phosphorus is adversely affected.

The *importance of parasite-induced osteoporosis in grazing animals is unknown* but it is undoubtedly much more common than is recognized and may be responsible for some of the unexplained cases of spontaneous bone fractures encountered in cattle and sheep (Fig. 1.63).

Osteoporosis is a complication of **inflammatory bowel disease** in humans and has been described in dogs with **malabsorption syndrome**, but the mechanism is unknown. Reduced intake and/or absorption of vitamin D and calcium have been suggested as a possible mechanism for the osteoporosis in human patients with ulcerative colitis or Crohn's disease. So too has corticosteroid therapy, which is often used in such patients and is well known as a cause of osteoporosis, but recent human studies have failed to demonstrate a link between corticosteroid therapy and inflammatory bowel disease. The generation of proinflammatory cytokines such as interleukin-1 and interleukin-6, both of which induce bone resorption and inhibit its formation, may play an important role in the osteoporosis associated with inflammatory bowel diseases of humans, and may also be important in various parasitic and other enteric diseases of animals. Recent evidence that activated T lymphocytes may play a role in local or systemic bone loss through the production of RANK-L has provided an alternative hypothesis for the osteoporosis of inflammatory bowel disease.

Corticosteroid-induced osteoporosis is common in humans and its occurrence in animals may be underestimated. Moderate doses of corticosteroids inhibit both the synthesis of collagen by pre-existing osteoblasts and the differentiation of osteoblasts from their precursor cells, resulting in *decreased apposition rate*. In addition to their effect on bone formation, corticosteroids have been shown to *stimulate osteoclastic bone resorption*, resulting in a generalized loss of skeletal mass. Indirect effects of corticosteroids on the skeleton are mediated through reduced calcium absorption in the intestine and reduced calcium reabsorption in renal tubules, both of which would be expected to enhance bone resorption through secondary hyperparathyroidism. Interference with vitamin D metabolism has also been implicated in the development of corticosteroid-induced osteoporosis but the evidence from various studies is conflicting.

The clinical importance of osteoporosis in dogs and other animal species with *spontaneous and iatrogenic hyperadrenocorticism* is not clear as few studies have been reported, but hyperadrenocorticism is considered one of the most common causes of generalized osteopenia observed radiographically in dogs. In one study, a 25% reduction in mean trabecular bone volume was detected in Beagle dogs with clinical hyperadrenocorticism. In addition, a significant reduction in osteoblast number and the amount of osteoid lining trabecular surfaces was also demonstrated in Beagles with subclinical hyperadrenocorticism. Reduced bone formation in these dogs did not appear to be accompanied by increased osteoclastic activity.

Other causes of *generalized osteoporosis* in humans and domestic animals include **vitamin A toxicity**, **hyperthyroidism,** and chronic **metabolic acidosis**. The immunosuppressive agent **cyclosporin** and certain **anticonvulsant drugs** (e.g., phenobarbital, diphenylhydantoin, and carbamazepine) have also been associated with osteoporosis in human patients.

Disuse osteoporosis is a loss of bone mass due to muscular inactivity and reduced weight bearing. It may be localized, following paralysis or fracture of a limb, or more generalized in association with prolonged recumbency or inactivity. *Bones that normally carry the greatest loads suffer the greatest proportional loss in mass from disuse.* Measurable loss of mineral occurs in horses that have a limb cast for prolonged periods. The mechanism of disuse osteoporosis is not clear but it does occur in immobilized parathyroidectomized animals, indicating that it is *not PTH-dependent,* and is seen in human fetuses with neuromuscular disease.

In experimental long-term disuse osteoporosis of the forelimb in young adult Beagle dogs, the lesion develops in several stages. The first is marked by rapid loss of tissue, which reduces the bone mass by about 16% in 6 weeks. This results from imbalanced resorption on endosteal, periosteal, and intracortical surfaces, and may be due to nonspecific activation of numerous remodeling sites. This is followed by an increase in bone mass from 8–12 weeks after immobilization, presumably as a result of net bone formation at activated remodeling sites, and the bone mass approaches normal. In the period between 8–12 and 24–32 weeks following immobilization, there is slower bone loss, 80–90% of which is subperiosteal bone. The reduction in bone mass may reach 30–50% of normal and be maintained at this level. The distal bones of the limb lose more bone than the proximal, but in all cases the subperiosteal bone is diminished.

The effects of remobilization on disuse osteoporosis are not clearly defined. Recovery from relatively short periods of immobilization does occur but the age of the patient influences the response. The effect of weightlessness associated with prolonged space travel is well documented and the loss of bone strength remains for a prolonged period after returning to normal gravity.

Rickets and osteomalacia

It is convenient to consider these two diseases together as they have *a similar etiology and pathogenesis, differing only in the age at which they occur.* **Rickets** is a disease of the developing skeleton in young animals and is accompanied *by abnormal endochondral ossification at growth plates, in addition to defective bone formation.* Its expression is greatly influenced by the level of physical activity undertaken; sedentary animals are less likely to suffer from fractures, infractions, and joint collapse. **Osteomalacia** occurs only in adults and although there are no lesions associated with growth cartilages, *the bone changes are the same as those that occur in rickets.* Both diseases occur in all domestic animal species and wildlife, but there are differences between species in the circumstances under which they occur, and in the most likely cause.

The pathogenesis of both rickets and osteomalacia involves **defective mineralization.** In young animals with rickets, this includes cartilage matrix at sites of endochondral ossification, as well as newly formed osteoid. In adults, where skeletal growth by endochondral ossification is no longer occurring, the defective mineralization affects only the osteoid formed during skeletal remodeling. The nature of the lesions varies, depending on the etiology, the age and growth rate of the animal, and the duration of the disease process. Furthermore, the dietary abnormality may involve a deficiency of more than one nutrient. As a result, the macroscopic and microscopic changes are not always classical, and the lesions may overlap with those of the other metabolic bone diseases. Accurate diagnosis on the basis of morphology alone may therefore be difficult.

Anything that interferes with the mineralization of cartilage or bone matrix may cause rickets or osteomalacia, but *most cases in animals result from dietary deficiencies of either vitamin D or phosphorus.* It is still uncertain whether the protective effect of 1,25-dihydroxyvitamin D against rickets is mediated by a direct effect on matrix mineralization or whether it is based on maintenance of adequate extracellular ionized calcium concentrations. The role of 1,25-dihydroxyvitamin D in matrix mineralization may involve its action in stimulating the synthesis of noncollagenous proteins such as osteocalcin, which is thought to be required for normal mineralization.

Vitamin D deficiency may occur in grazing animals where the combination of relatively high latitudes and temperate climates allows them to be pastured for much of the year. Such conditions occur in parts of the United Kingdom, South America, New Zealand, and southern Australia. Photobiosynthesis is a more important source of vitamin D than diet in grazing animals, but may be inadequate during the winter months in some regions. When the winter sun is at an angle of less than 30 degrees to the horizontal, the short-wavelength ultraviolet rays required for the activation of 7-dehydrocholesterol in the skin are reflected by the atmosphere and dermal synthesis of previtamin D_3 is impaired. Mature grass and sun-cured hay are relatively good alternative sources of vitamin

D_2, but the levels present in immature pasture are likely to be inadequate. This may be further compounded by the anti-vitamin D activity of carotenes present in lush pasture and green cereal crops. The extra demands of pregnancy and lactation during winter and early spring may also contribute significantly to the development of clinical osteomalacia. *It is likely that many grazing animals are vitamin D deficient for a period during the winter*, but clinical rickets or osteomalacia are only likely to develop if the deficiency is marked or persists for longer than usual. Problems may also occur if vitamin D deficiency is combined with deficiencies of other essential nutrients, such as phosphorus or copper.

Sheep appear to be more susceptible to vitamin D deficiency than **cattle**, possibly because a dense fleece covers much of their skin. Not surprisingly, the concentration of vitamin D in blood increases following shearing. **Alpacas** and **llamas** *may be even more susceptible to vitamin D deficiency than sheep*. Rickets has been diagnosed in young camelids in New Zealand, South Australia, and northern regions of the USA. The disease occurs during winter months and is accompanied by low blood concentrations of both 25-hydroxyvitamin D and phosphorus. In the New Zealand report, lambs grazing the same pasture had normal serum phosphorus concentrations and the phosphorus content of the pasture was normal. Vitamin D deficiency was considered the most likely etiology, the low serum phosphorus concentrations being secondary to reduced absorption of phosphorus from the intestine. The natural environment for alpacas and llamas is at high altitude near the equator, where solar irradiation is intense. Their dense fiber and pigmented skin may have evolved as a protective mechanism to prevent excessive solar irradiation reaching the skin. This could prove to be a disadvantage in animals moved to lower altitudes, especially at latitudes with limited solar irradiation during the winter.

Dietary deficiency of vitamin D also occurs in housed animals, particularly **piglets** and **calves** (at higher latitudes), due to lack of sunlight and errors in the formulation of rations. Piglets grow rapidly and are weaned early. If exposed to rachitogenic diets while the cartilages are still growing rapidly, the lesions tend to be florid. Vitamin D deficiency rickets occurs only rarely in **pups** and **kittens**, even though neither species seems capable of manufacturing vitamin D in their skin. The widespread availability of balanced commercial diets has reduced the likelihood of deficient rations being fed to dogs and cats, although inadequate rations are occasionally incriminated in the etiology of osteodystrophies in pups, as indicated in a report of rickets in a litter of Greyhounds. In the presence of adequate dietary levels of calcium and phosphorus, the vitamin D requirements of dogs appear to be very low. The vitamin D concentration of canine milk is very low, but deficiency in neonatal pups is unlikely, providing sufficient vitamin D has been stored in the liver of the pups during pregnancy.

Phosphorus deficiency *is well established as a cause of rickets and osteomalacia*, although the exact mechanism is uncertain. Presumably, the delayed mineralization in phosphorus-deficient animals reflects inadequate extracellular concentrations of the phosphate ions essential for the formation of hydroxyapatite. *Rickets and osteomalacia due to phosphorus deficiency are uncommon, but do occur in animals grazing pastures low in phosphorus*. There are many areas of the world, including South America, South Africa, northern Australia, and New Zealand, where soil phosphorus levels are very low and successful livestock production requires application of phosphorus either to the soil or the animals. Supplementation of individual animals is often not practical, but the problem can be prevented by regular applications of phosphorus-containing fertilizers. Reduced fertilizer use in an effort to cut production costs has led to an increased incidence of rickets, osteomalacia, and other diseases associated with phosphorus deficiency in some countries. **Cattle** appear to be more susceptible than **sheep** to phosphorus deficiency, while **horses** seem to be remarkably resistant. Rickets has also been diagnosed in farmed red **deer** grazing phosphorus deficient pastures in New Zealand. Phosphorus-deficiency rickets is not recognized in piglets but hypophosphatemia may be a complication of vitamin D deficiency.

Signs of phosphorus deficiency develop slowly, especially in the mature skeleton, and many animals with subclinical osteomalacia no doubt remain undiagnosed. Clinical disease is most likely to occur in cows where the deficiency is exacerbated by the extra demands of pregnancy or lactation. Such animals lose condition, develop transient, shifting lameness, and show an increased susceptibility to fractures. They may crave phosphorus-rich materials, and *osteophagia and pica are characteristic signs of the deficiency*. Fertility can be severely reduced and estrum may be irregular, inapparent, or absent. Newborn calves are of normal size and development (at the expense of their dams) but while suckling, their growth is subnormal, and this is accentuated after weaning. Growth is also aberrant in that maturity is delayed and deficient animals appear long and lean, and have a rough hair coat. Hypophosphatemia develops early but also returns to normal rapidly if the animals are supplemented. Serum calcium concentrations are usually normal or increased. The presence of normal serum phosphorus concentration in an animal with osteodystrophy does not therefore exclude phosphorus deficiency as the cause. The poorly mineralized bone is removed only slowly and will persist until well after the underlying dietary deficiency has been corrected.

Dietary phosphorus deficiency is virtually impossible in carnivores because of the high levels of phosphorus normally present in their rations. In fact, excess dietary phosphorus resulting in nutritional secondary hyperparathyroidism and fibrous osteodystrophy is relatively common in pups and kittens.

Calcium is also required for mineralization but there is doubt that uncomplicated calcium deficiency is capable of inducing rickets. Since any decrease in extracellular concentrations of ionized calcium is rapidly corrected by the actions of PTH and 1,25-dihydroxyvitamin D on bone and small intestine, *calcium is unlikely to be a limiting factor at sites of mineralization. Persistent dietary deficiency or unavailability of calcium is more likely to lead to fibrous osteodystrophy or osteoporosis* (depending on age and species) due to hyperparathyroidism and excessive bone resorption. Hypocalcemia does not occur until the advanced stages of calcium deficiency, by which time skeletal growth will be retarded and any effect on growth plates reduced. It is important to recognize however, that vitamin D deficiency will be accompanied by hypocalcemia due to impaired resorption of calcium from bone and absorption from the small intestine. The skeletal lesions of vitamin D deficiency in young animals would therefore be expected to include changes characteristic of both rickets and fibrous osteodystrophy. In contrast, lesions attributable to hyperparathyroidism should not complicate phosphorus-deficiency rickets or osteomalacia. More likely, chronic phosphorus deficiency will be accompanied by anorexia, and the skeletal changes may therefore reflect a combination of osteomalacia and osteoporosis.

Interestingly, calcium deficiency has been shown to induce a deficiency of vitamin D in rats. The mechanism is not certain, but evidence suggests that increased secretion of PTH in calcium deficiency stimulates increased production of 1,25-dihydroxyvitamin D, which acts directly or indirectly to enhance inactivation of 25-hydroxyvitamin D in the liver. This may explain the concurrent development of vitamin D deficiency in certain human disorders characterized by hyperparathyroidism, including gastrointestinal disease, chronic liver disease, and anticonvulsant therapy.

Several other, less common, causes of rickets and osteomalacia are recognized in man and animals. These include two types of **vitamin D-dependent rickets** (types I and II) caused by inborn errors in vitamin D metabolism. **Type I** is caused by a defect in the renal enzyme 1α-hydroxylase, which converts 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D in proximal tubules. The disease is inherited as an *autosomal recessive trait* in people and pigs, and sporadic cases have been suspected in dogs and cats. The disease is characterized by high levels of serum parathyroid hormone and 25-hydroxyvitamin D but low or undetectable levels of 1,25-dihydroxyvitamin D. Affected pigs are clinically normal until 4–6 weeks of age, but then plasma calcium and phosphate levels fall and alkaline phosphatase activity rises. Florid rickets develops over the next 3–4 weeks and the pigs die unless treated. **Type II** vitamin D-dependent rickets, which is also more appropriately called **hereditary vitamin D-resistant rickets**, is due to a defect in 1,25-dihydroxyvitamin D receptor-effector systems in the cells of target organs. The disease occurs in people, and possibly in the common marmoset, *Callithrix jacchus*. These animals, like other New World monkeys, cannot utilize vitamin D_2 but, in addition, require unusually large amounts of vitamin D_3 and have very high levels of plasma 1,25-dihydroxyvitamin D without hypercalcemia. Despite the elevated 1,25-dihydroxyvitamin D, some marmosets develop a bone disease with features of rickets.

Hypophosphatemic vitamin D-resistant rickets (renal hypophosphatemic rickets) is characterized by hypophosphatemia, normocalcemia, decreased renal tubular reabsorption of phosphate, and skeletal deformities. Plasma 1,25-dihydroxyvitamin D levels are inappropriately low. Hypophosphatemia results from impaired renal reabsorption and intestinal absorption of phosphorus. Combined treatment with 1,25-dihydroxyvitamin D to depress parathyroid hormone and thus phosphaturia, and phosphate has beneficial effects on bone lesions. The disease is inherited as an X-linked dominant trait in children and in mice. Hypophosphatemic vitamin D-resistant rickets and osteomalacia have also been associated with various neoplasms in human patients. The mechanism is unknown but is thought to involve production by the tumor of a humoral substance that interferes with phosphate absorption in renal proximal tubules. This syndrome has yet to be reported in animals but could easily be missed both clinically and at necropsy.

Rickets and osteomalacia are recognized in human patients with **gastrointestinal malabsorption** resulting from chronic disorders of the small bowel, hepatobiliary system, or pancreas. Since vitamin D is fat soluble, any interference with the digestion or absorption of fat would be expected to reduce dietary vitamin D absorption and predispose to deficiency. Reduced absorption of calcium in malabsorption syndromes may enhance the efficiency of vitamin D, as outlined above. Although the same would be expected to occur in animals, there are no reports. This may reflect less complete radiographic and pathologic evaluation of the skeleton in animals with such diseases or the fact that affected animals do not live long enough for the skeletal lesions to become manifest clinically.

Rickets has been reproduced experimentally in rats by the addition of **iron** to a normal, nonrachitogenic diet. *Iron interferes with the absorption of phosphorus* and high dietary levels may induce phosphorus deficiency. High dietary levels of other phosphorus antagonists, such as **calcium** and **aluminum**, might also be expected to induce phosphorus-deficiency rickets. Lesions resembling osteomalacia have been observed in cattle ingesting high concentrations of **fluoride**, which *interferes with mineralization* when incorporated into bone matrix.

Animals with *rickets* are generally stiff or lame, and in severe cases are reluctant to stand. The limbs, especially the forelimbs, may be bowed. Swelling of the carpals and other joints, due to enlarged ends of long bones, may lead to an initial suspicion of arthritis. Varus or valgus deformity may be present, reflecting asymmetric involvement of growth plates. Affected pigs may stand with a hunched back, walk on the tips of their toes, or adopt a dog-sitting position. Knuckling of the carpus is also described in pigs with rickets. In many animals however, the clinical signs are mild and nonspecific.

Macroscopic lesions of rickets are most prominent at sites of rapid growth, including metaphyseal and epiphyseal regions of long bones and costochondral junctions of the large middle ribs. Enlargement of costochondral junctions is a classic feature of the human disease and is referred to as the "*rachitic rosary*." Costochondral junctions are normally prominent in fast-growing young animals and any enlargement must be interpreted with caution. In rickets, the metaphysis of the rib is often wider than the cartilaginous portion and on sagittal section, the chondro–osseous junction is irregular, with tongues of unresorbed cartilage extending into the metaphysis (Fig. 1.64A). The normal architecture of the metaphysis is replaced by a mixture of disorganized trabeculae, irregular tongues and islands of cartilage, fibrous tissue, and sometimes hemorrhage (Fig. 1.64B). Loss of the normal trabecular arrangement in the metaphysis is best appreciated radiographically, at least in severe cases (Fig. 1.65). Similar changes may be evident in sagittal sections of long bones (Figs 1.66A, B; 1.67A, B), especially at sites of most rapid growth, such as distal radius, proximal humerus, distal femur, and both ends of the tibia. Metacarpal and metatarsal physes are also likely to show gross changes (Fig. 1.68). The severity of lesions between different physes may vary considerably, even within the same animal, and although the disease is systemic, the physeal lesions are often multifocal rather than diffuse. This emphasizes the importance of examining sagittal sections of several bones during postmortem examination. The enlargement of the ends of long bones is due partly to flaring of the metaphysis and partly to compression caused by weight bearing on metaphyseal bone of reduced strength. Also, there is accumulation of poorly mineralized osteoid, which is not removed efficiently by osteoclasts.

Focal thickening of physeal cartilage, similar to that observed in rickets is also described in osteochondrosis in various species, and in the inherited dwarfism of Alaskan Malamute dogs. In rickets however, the physeal lesions are generally accompanied by evidence of bone fragility, including trabecular disruption, hemorrhage, and infractions. Pathological fractures may be present in the limbs, ribs, or vertebrae in severe cases. When the deficiency is relatively recent but severe, a distinct zone where abnormal bone formation commenced may be present in the metaphysis (Fig. 1.64A). This reflects a change from adequate to inadequate dietary phosphorus or vitamin D and

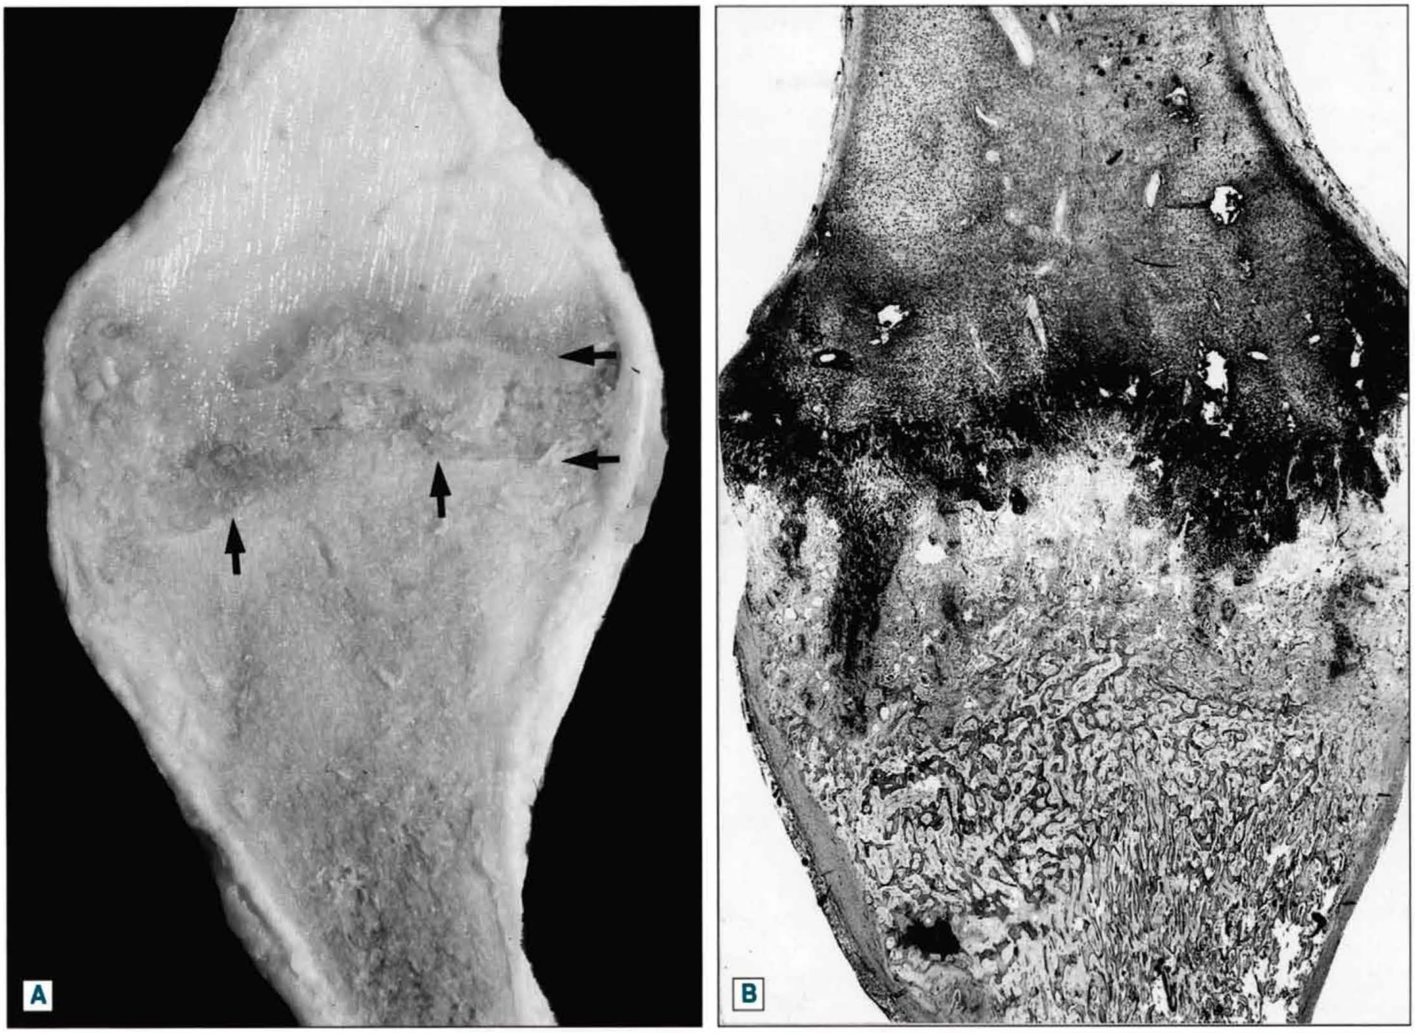

Figure 1.64 Rickets, bovine. **A.** Phosphorus deficiency rickets in a 1-year-old steer. Swelling of metaphysis at the costochondral junction and disruption of normal architecture in the zone between the horizontal arrows. Broad tongues of cartilage extend into the metaphysis from the physeal cartilage. The stage at which defective bone formation commenced is indicated by the vertical arrows. **B.** Subgross preparation of costochondral junction from a calf with rickets showing irregular tongues of cartilage remaining in the metaphysis and disorganization of metaphyseal bone.

may be of value in relating the disease to a particular change in diet or environment.

Endochondral ossification occurring beneath articular cartilage is also abnormal in animals with rickets, but since the rate of epiphyseal bone formation is slower than that of the metaphysis, the lesions are milder. The articular cartilage may be irregularly thickened and in severe cases, there may be infolding and irregularity of the articular surface due to collapse of weakened subchondral bone. These articular lesions of rickets occur most often in pigs, but also occur in association with fibrous osteodystrophy, and tend to involve large, weight-bearing joints such as the shoulder and hip. Similar macroscopic lesions occur in the articular cartilage of pigs with osteochondrosis, but since this disease is not associated with defective bone formation, the subchondral bone does not collapse.

In mild rickets, the lesions may not be apparent grossly or radiographically. Furthermore, reduced growth rate in animals with phosphorus-deficiency rickets may reduce the severity of lesions. In such cases, histology is essential for confirmation.

The microscopic lesions of rickets reflect the failure of mineralization of cartilage at sites of endochondral ossification, and of osteoid deposited during bone growth and remodeling. Mineralization of cartilage matrix is a critical event in the process of endochondral ossification at physes and appears to be functionally coupled with vascular invasion from the metaphyseal side. As the physeal cartilage becomes mineralized, the hypertrophic chondrocytes degenerate, the narrow septa between adjacent cells are broken down and capillary sprouts derived from metaphyseal vessels invade their vacant lacunar spaces. These invading capillaries are accompanied by osteoprogenitor cells, which differentiate into osteoblasts and deposit osteoid on the spicules of mineralized cartilage, which previously separated the columns of chondrocytes. Experiments in vitamin D-deficient rachitic rats demonstrated that metaphyseal angiogenesis and invasion of physeal cartilage is halted or impaired. Within 96 hours of vitamin D repletion, the metaphyseal vasculature returns to normal and capillary sprouts recommence invasion of the physeal cartilage.

Persistence of hypertrophic chondrocytes at sites of endochondral ossification, both at physes and beneath articular cartilage, is the hallmark of rickets in histological preparations. The lesions are often irregular and are usually accompanied by disruption of the underlying trabecular bone. As the cartilage continues to accumulate, its growth rate slows, possibly

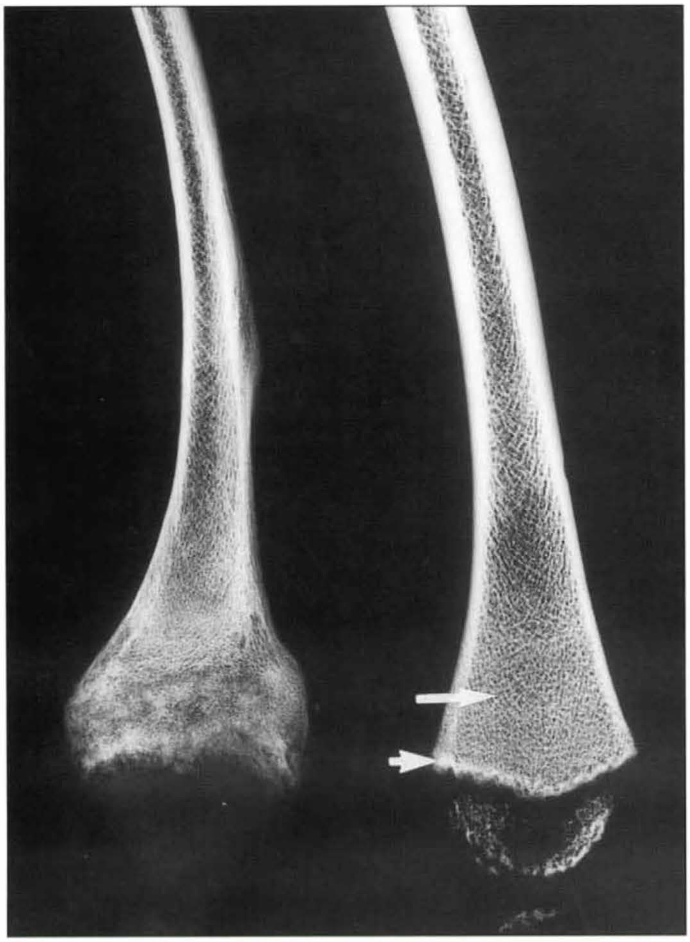

Figure 1.65 Rickets, calf. Normal rib on right. There is metaphyseal swelling and disorganization of trabecular bone in the rachitic bone. Note the regular trabecular pattern in the primary (short arrow) and secondary spongiosa (long arrow) in the normal rib.

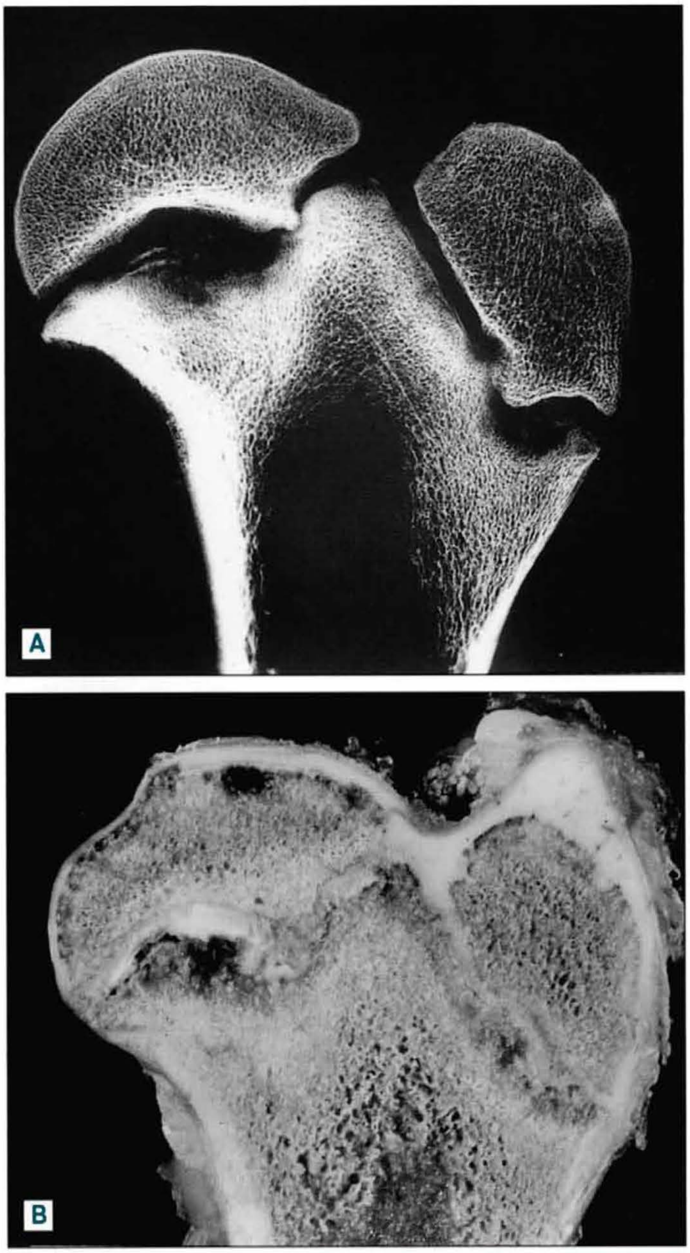

Figure 1.66 Rickets, pig. **A.** Slab radiograph of proximal femur showing increased depth of physeal cartilage. **B.** Proximal femur showing irregular thickening of the physes in addition to hemorrhage and disruption of trabeculae in metaphyses. because of inadequate diffusible nutrient, and the hypertrophic cells form irregular clumps instead of the characteristic columns. Some of these clumps are bypassed by the irregular ingrowth of vascular and osteogenic tissue and ultimately come to lie in the metaphysis as unmineralized clusters of hypertrophic chondrocytes surrounded by osteoid (Fig. 1.69A, B). Occasionally, the persistent tongues of cartilage degenerate and are replaced by connective tissue, in which metaplastic osteoid forms. Degenerate cartilage, which loses its basophilia and stains like osteoid, is sometimes referred to as pseudo- or cartilaginous osteoid. If the dietary deficiency is corrected, plates of rachitic cartilage may become undermined by invading vessels and stranded in the metaphysis, forming a grossly visible, translucent band parallel to the growth plate.

Metaphyseal trabeculae are thicker than normal, irregular in shape and may be partly covered by seams of unmineralized osteoid (Fig. 1.70A). Trabecular microfractures are common. Infractions (incomplete fractures) in various stages of repair are also relatively common and reflect the fragility of the trabeculae (Fig. 1.70B). *In vitamin D deficiency, the histologic lesions may have features of fibrous osteodystrophy in addition to rickets*, because of the hypocalcemia and secondary hyperparathyroidism. In such cases, osteoblastic and osteoclastic activity are prominent and trabeculae are separated by loose fibrous connective tissue, even in areas distant from repairing infractions. A combination of rickets and fibrous osteodystrophy can, at least in theory, also occur in association with chronic renal disease (see Fibrous osteodystrophy section below) due to renal secondary hyperparathyroidism and impaired renal synthesis of 1,25-dihydroxyvitamin D. However, in animals with renal disease the lesions of fibrous osteodystrophy generally predominate.

Cortical bone is also affected in rickets, but the lesions are generally overshadowed by those involving growth plates. Grossly, the diaphyses of long bones may appear shorter and thicker than normal with a narrow medullary cavity. In spite of their increased thickness, the cortices are more susceptible to weight-bearing trauma and, in severe cases may be soft, bent, or contain pathological fractures.

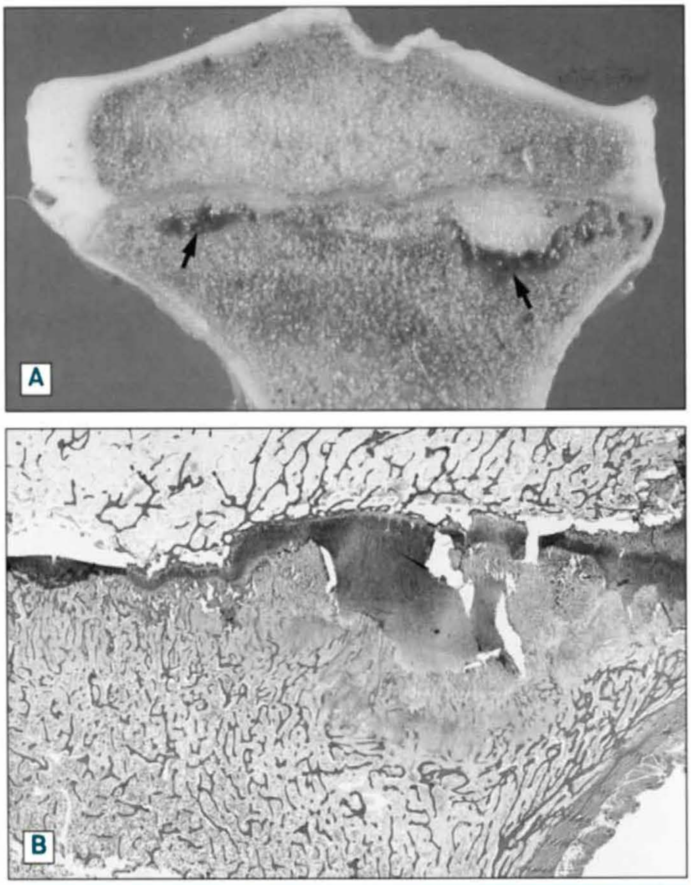

Figure 1.67 Rickets, pig. **A.** Massive, focal thickening of the physis in the proximal tibia. The dark areas, which appear gelatinous grossly (arrows), indicate trabecular disruption and replacement with highly vascular fibrous connective tissue. **B.** Subgross photograph of the same specimen showing the thickened physeal cartilage and replacement of trabecular bone in the underlying metaphysis with repair tissue.

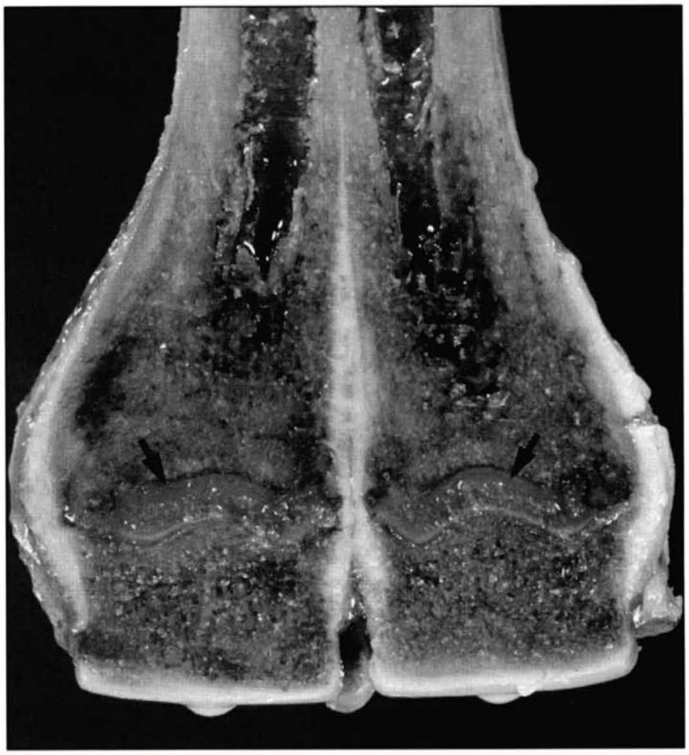

Figure 1.68 Rickets, alpaca. The physes of the distal metacarpal bone (arrows) are diffusely thickened and bulging from the cut surface.

Histologically, a layer of poorly mineralized osteoid may accumulate within partly filled Haversian systems and on the periosteal surface.

Osteoid seams are best illustrated in undemineralized sections, but can be appreciated in demineralized sections stained with hematoxylin and eosin as pale, eosinophilic matrix against the darker staining bone tissue that was previously mineralized (Fig. 1.70A). Special stains for demonstrating unmineralized osteoid in demineralized sections (see page 18) can be of value but are not used routinely and sections may be difficult to interpret in the absence of controls. *It is important to recognize that osteoid seams are not pathognomonic for rickets and osteomalacia.* Nor are they invariably present. They also may occur in other syndromes at sites of rapid bone formation rather than due to delayed mineralization.

The **lesions of osteomalacia** *are similar to those of rickets but since they occur in adult animals, growth plates are not involved.* Osteomalacic bones have reduced resistance to pressure and tension, and increased susceptibility to the stress and strain of ordinary activity. As a result, there is *excessive deposition of matrix where mechanical stimuli are strongest*, such as at insertions of tendons and fascia, places of angulation and curvature, and on stress-oriented epiphyseal trabeculae. When the disease is advanced, the *bones fracture readily*, the marrow cavity is expanded and may extend into the epiphysis, and the cortex is thin, spongy and soft. In affected cattle, fractures are most common in the ribs, pelvis, and long bones, while in pigs they occur most often in the vertebral column. *Deformities* are often present, including kyphosis or lordosis, medial displacement of the acetabula with compression of pubic bones, twisting of the ilia, and narrowing of the pelvis. The ribs and transverse processes of the lumbar vertebrae droop so that the thorax is narrowed and flattened and the sternum prominent. Collapse of articular surfaces and degeneration of cartilages is sometimes observed and tendons may separate from their attachments. In long-standing cases of osteomalacia, cachexia and anemia are often present.

The *histological changes of osteomalacia reflect the inadequate mineralization of osteoid formed during remodeling*, the lesions resembling those in the cortex of animals with rickets. In many cases, particularly those caused by phosphorus deficiency, osteoporosis associated with concurrent deficiency of protein and other nutrients is superimposed. The lesions develop slowly but in advanced cases, trabeculae are reduced in size and number, and the cortices are thin and porous. Osteoid covers the trabeculae and lines the expanded Haversian canals. Localized accumulations of osteoid occur at sites of mechanical stress.

Fibrous osteodystrophy

Fibrous osteodystrophy (osteodystrophia fibrosa, osteitis fibrosa cystica) is a relatively common metabolic bone disease characterized by extensive bone resorption accompanied by proliferation of fibrous tissue and poorly mineralized, immature bone. The pathogenesis involves persistent elevation of plasma PTH and the lesion can be considered to represent the skeletal manifestation of primary or secondary hyperparathyroidism. Different animal species vary in their susceptibility to fibrous osteodystrophy and, to some degree, in the distribution of lesions. Horses, pigs, dogs, cats, ferrets, and goats are often affected, as are reptiles and New World nonhuman primates, but the disease is rare in sheep and cattle.

Primary hyperparathyroidism *is usually the result of a functional parathyroid gland adenoma* (see Vol. 3, Endocrine glands). This occurs rarely in adult dogs and there are isolated reports in horses and cattle. Hereditary primary hyperparathyroidism associated with diffuse parathyroid hyperplasia was also reported in a litter of German Shepherd puppies with fibrous osteodystrophy. *In primary hyperparathyroidism, autonomous secretion of PTH results in persistent hypercalcemia and hypophosphatemia*, the latter reflecting increased urinary clearance of phosphate. This differs from secondary hyperparathyroidism where plasma total calcium concentrations are usually either normal or slightly decreased and, depending on the cause, plasma phosphorus concentrations are either normal or increased. The persistent hypercalcemia in primary hyperparathyroidism is generally accompanied by *polydipsia/polyuria, muscular weakness, and widespread mineralization of soft tissues*. Affected animals may succumb to the effects of *nephrocalcinosis* before the skeletal changes are severe enough to become clinically apparent. The skeletal changes in the German Shepherd pups with primary hyperparathyroidism (discussed below) were more severe than those described in adult dogs with functional parathyroid adenomas. This probably reflects the more rapid turnover of bone in young animals. Generalized bone resorption also occurs in **pseudohyperparathyroidism** or **hypercalcemia of malignancy** caused by the production of parathyroid-related hormone by tumors such as malignant lymphoma and apocrine gland adenocarcinoma of the anal sac. However, although increased osteoclastic activity and reduced trabecular bone volume have been demonstrated by histomorphometric techniques, the bone lesions are usually mild and are not apparent clinically or even radiographically.

Secondary hyperparathyroidism is a much more common cause of fibrous osteodystrophy in animals than primary hyperparathyroidism and *may be due to either chronic renal disease or a dietary imbalance of calcium and phosphorus*. PTH secretion is stimulated by a reduction in plasma-ionized calcium, whatever the cause, and if the stimulus persists then generalized bone resorption results. **Renal secondary hyperparathyroidism** occurs most often in dogs, and occasionally in cats, as a complication of chronic renal failure. Impaired glomerular filtration in animals with renal failure leads to progressive hyperphosphatemia due to reduced renal clearance of phosphate. Hypocalcemia develops as a result of the inverse relationship between plasma-ionized phosphate and calcium concentrations, and stimulates the release of PTH. In addition, chronic renal disease may result in impaired formation of 1,25-dihydroxyvitamin D, thereby reducing calcium absorption from the intestine and contributing further to the hypocalcemia. This combination of secondary hyperparathyroidism and deficient synthesis of 1,25-dihydroxyvitamin D in animals and humans with renal failure may give rise to a bone disease with features of both fibrous osteodystrophy and osteomalacia. For this reason, the disorder is often referred to by the more general term, **renal osteodystrophy**.

Nutritional secondary hyperparathyroidism *may be due to a simple dietary deficiency of calcium, excess dietary phosphorus, or to a deficiency of vitamin D.* As discussed previously in this chapter, vitamin D deficiency alone is also a cause of rickets or osteomalacia, but reduced calcium absorption from the intestine in animals with vitamin D deficiency often results in concurrent fibrous osteodystrophy. Excess dietary phosphorus may cause fibrous osteodystrophy even in animals receiving adequate dietary calcium. Increased plasma phosphate concentration, resulting from increased intestinal absorption of phosphorus, depresses plasma-ionized calcium and indirectly stimulates the release of PTH.

In practice, *nutritional secondary hyperparathyroidism is most often caused by diets containing low calcium and a relatively high concentration of phosphorus* and, with the exception of horses, affects young, rapidly growing animals. Horses seem to be remarkably sensitive to the effects of high-phosphorus diets and relatively resistant to the effects of rations low in phosphorus. In all species, there are several factors that influence the development and the severity of lesions in secondary hyperparathyroidism. These include the degree to which dietary calcium is deficient and, perhaps more importantly, the degree to which dietary phosphorus is in excess. Although the efficiency of calcium absorption decreases markedly at high intakes, that of phosphorus seems to be unchanged. Furthermore, over a wide range of intakes, plasma calcium concentration is more sensitive to dietary phosphorus than to dietary calcium.

Differences between species in the susceptibility, likely etiology, and distribution of lesions in fibrous osteodystrophy are discussed below in some detail.

In the **horse**, the disease occurs at any time after weaning but the prevalence, and possibly the susceptibility, declines after about the seventh year. Horses require a calcium:phosphorus ratio of approximately 1:1. Diets in which the calcium:phosphorus ratio is 1:3 or wider, can result in osteodystrophia fibrosa depending to some extent on individual and familial susceptibility, and on alternative sources of calcium, such as drinking water. The condition usually occurs after maintenance for some months on diets consisting largely of grain, corn, and grain by-products such as bran, hence the term "bran-disease." Fibrous osteodystrophy also occurs in horses grazing tropical grasses high in oxalate, even though dietary calcium and phosphorus are normal. Prevalences of 10–15% occur in Sri Lanka and the Philippines. The problem is also reported in northern Australia and southern states of the USA. Lush pastures are most hazardous, some containing as much as 7.8% oxalate on a dry weight basis. Those with total oxalate over 0.5% and calcium:oxalate ratios below 0.5 are potentially dangerous because oxalate binds the calcium and makes it unavailable for absorption. Several grasses, including *Setaria sphacelata*, *Cenchrus ciliaris* (buffel grass), *Brachiaria mutica* (para grass), *Digitaria decumbens* (pangola grass), and *Panicum* spp., contain sufficient oxalate to produce clinical disease. Renal secondary hyperparathyroidism is not reported in horses as renal failure in this species typically results in hypercalcemia rather than hypocalcemia.

The *clinical signs and gross lesions* of fibrous osteodystrophy generally develop more rapidly in young, growing horses due to their increased rate of bone formation and remodeling. Early signs consist of minor changes in gait, stiffness, transient and shifting lameness, and lassitude. Loss of appetite with progressive cachexia and anemia develop later. The anemia may be due to depression of erythropoiesis by parathyroid hormone or its metabolites. *The most characteristic feature is bilateral swelling of the bones of the skull* (Fig. 1.71A), including both the maxillae and mandibles, hence the term "*bighead*." The bony swelling begins along the alveolar margins of the mandibles, producing cylindrical thickenings and reducing the intermandibular space. The molar margins of the maxillae then begin to swell and the enlargement spreads to involve the palate, the remainder of the maxillae, and the lacrimal and zygomatic bones. In severe cases (Fig. 1.71B), the nasal and frontal bones are also swollen. Initially, the swellings are soft but later they harden. Involvement of the palate reduces the nasal passages and may cause dyspnea. Palatine and mandibular thickening causes reduction of the buccal cavity and mastication is impaired. The teeth loosen and are partially buried or may exfoliate, and the softened bone yields to pressure, further impairing prehension and mastication. The food may be swallowed unchewed or allowed to drop out of the mouth. The face may be continually wet from occlusion of the lacrimal canals. In advanced cases, the enlargement of the head may be extreme and although the swelling is invariably bilateral, it is not always symmetrical.

Gross lesions in the remainder of the skeleton indicate advanced disease. In such cases, the scapulae may be thickened and curved so that the shoulder joint is displaced forward and the trunk droops in the pectoral girdle, giving undue prominence to the sternum. The vertebral column curves downwards, sometimes upwards, and the arch of the ribs is reduced. There is an increased susceptibility to *fractures* and to avulsion of ligaments. *Detachment of ligaments and tendons* occurs chiefly in the lower limbs. Some animals escape the fractures and ligamentous detachments and pass into *cachectic recumbency* but multiple fractures may occur if such animals are forced to rise. Radiography of affected bones may show generalized osteopenia, but not until the relatively advanced stages of the disease. Macerated bones from severely affected animals are finely cancellous or pumice-like and may be brittle and crumbly. The weight of the macerated bones may be less than 50% of normal.

Severe cases of fibrous osteodystrophy in horses are now rare and animals with facial swelling due to nutritional secondary hyperparathyroidism are seldom seen. Milder forms of the disease, however, may still be a cause of poorly defined lameness and could perhaps predispose to spontaneous fractures of sesamoid bones or phalanges in racehorses in training, which are fed rations high in grain.

Serum concentrations of calcium and phosphate are of limited value in the diagnosis of nutritional secondary hyperparathyroidism in horses, although a slight increase in serum phosphate is reported as a common finding in affected horses. Serum concentrations of PTH are likely to be of more diagnostic value and the test has been validated for use in horses. Increased urinary fractional clearance of phosphorus is also considered a sensitive indicator of secondary hyperparathyroidism. In one survey, abnormally high phosphorus clearance ratios were detected in 87.5% of racehorses in Hong Kong, suggesting that subclinical hyperparathyroidism is relatively common.

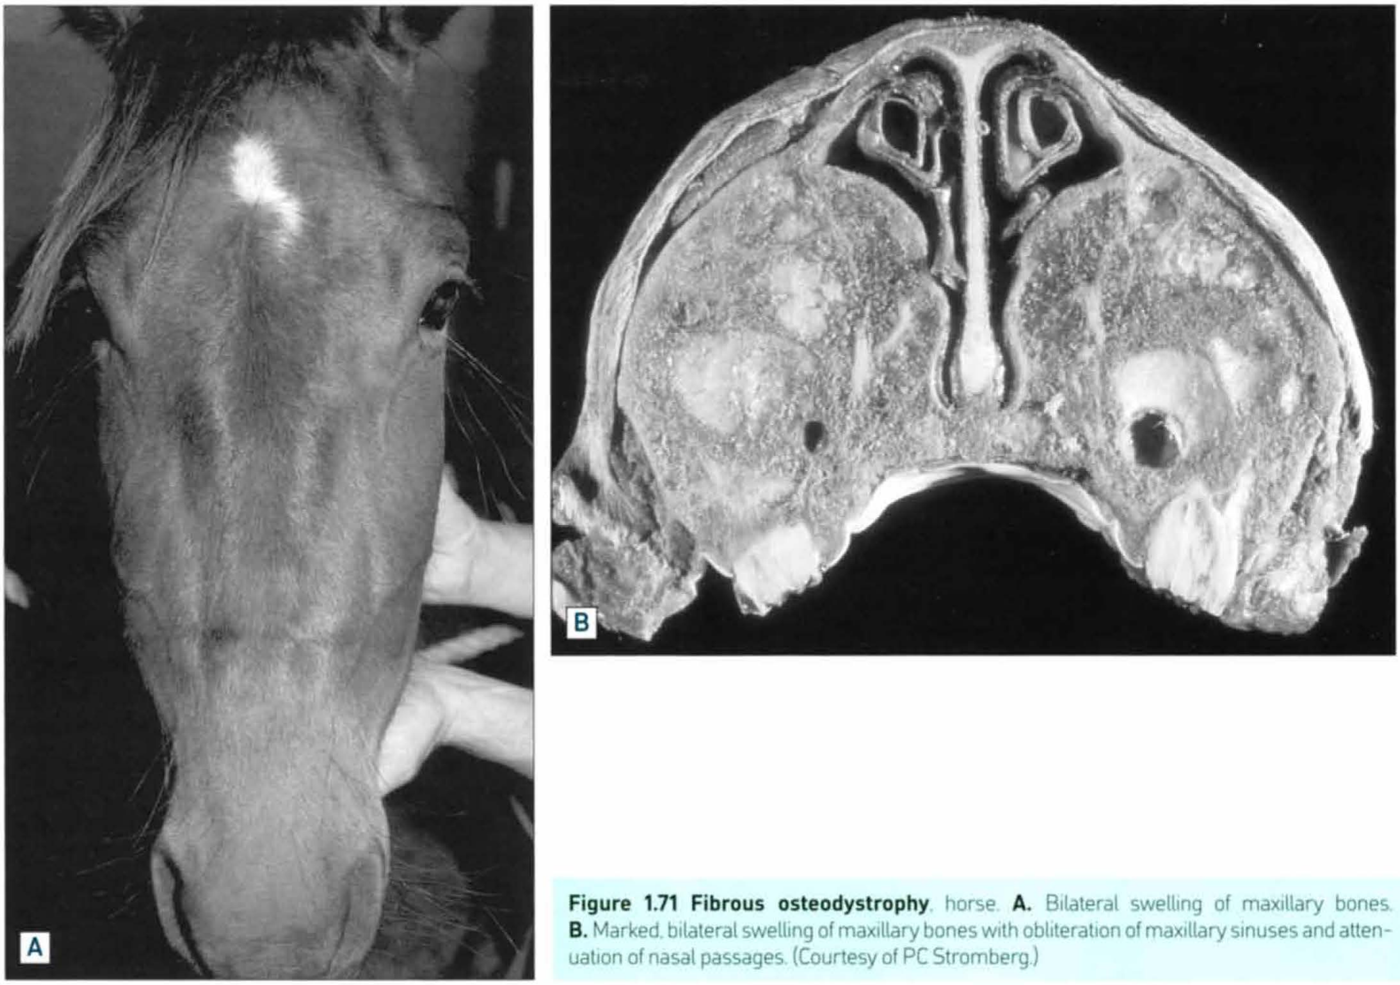

Figure 1.71 Fibrous osteodystrophy, horse. **A.** Bilateral swelling of maxillary bones. **B.** Marked, bilateral swelling of maxillary bones with obliteration of maxillary sinuses and attenuation of nasal passages. (Courtesy of PC Stromberg.)

In **swine**, *fibrous osteodystrophy usually occurs in young growing animals fed unsupplemented grain rations.* The disease also accompanies rickets in association with vitamin D deficiency. Clinical signs include stiffness, reluctance to rise and, in severe cases, lameness. Some affected animals may develop enlargement of the skull similar to that seen in horses. The mandibles may be affected first, and sometimes are the only site of gross lesions, but in other cases, the basocranium is also enlarged. Sometimes, the mouth cannot be closed and the tongue protrudes because of the swelling of the jaws and the shortness of the mandibular rami. The teeth are mobile and often deeply and obliquely embedded in the fibro-osseous connective tissue. Radiographically, there is a generalized reduction in bone density.

At necropsy, the ribs may bend or snap with little effort. Recent or healing pathological fractures are often present. Articular surfaces of major joints may be irregular and focally depressed due to collapse of subchondral bone (Fig. 1.72). Growth plates are of normal thickness, except in cases caused by vitamin D deficiency where rickets and fibrous osteodystrophy occur concurrently.

Severe fibrous osteodystrophy is relatively common in **goats** fed rations high in concentrates, but there are no convincing reports of the disease in either **sheep** or **cattle**, suggesting species variation in susceptibility. In goats, fibro-osseous enlargement of the mandibles and maxillae is a characteristic clinical feature (Fig. 1.73). Respiratory distress may be present due to encroachment by swollen maxillary bones on the nasal cavity. The relative severity of lesions in bones of the skull in goats and certain other species may be related to the mechanical stimulus associated with chewing. The bones of the limbs are also affected in goats with fibrous osteodystrophy and may be markedly bowed.

In **dogs** and **cats**, nutritional secondary hyperparathyroidism is usually caused by *diets consisting largely or entirely of meat or offal.* The calcium content of such diets is low and the calcium:phosphorus ratio very wide. For example, the calcium content of cardiac and skeletal muscle is approximately 10 mg/100 g and the ratio of calcium to phosphorus approximately 1:20. The calcium:phosphorus ratio of liver is approximately 1:50. The ideal ratio is about 1:1, and skeletal abnormalities develop when ratios are 1:2 or greater. Supplementation of all-meat diets with appropriate levels of calcium corrects the imbalance and prevents fibrous osteodystrophy.

Clinical signs of nutritional secondary hyperparathyroidism usually begin a few weeks after weaning. Kittens fed exclusively on beef heart develop signs of fibrous osteodystrophy within 4 weeks. In both kittens and puppies, signs of the disease are progressive and include reluctance to move, hindlimb lameness and incoordination. Enlargement of facial bones is uncommon. Affected animals become depressed and may develop sudden lameness due to infractions of long bones or vertebrae, the latter resulting in paralysis. Callus formation at fracture sites does occur but consists primarily of fibrous tissue with little evidence of mineralization. Radiographically there is generalized, often marked, osteopenia (Fig. 1.74). Fibrous osteodystrophy in cats has been inappropriately referred to as osteogenesis imperfecta in the early veterinary literature because of the osteopenia and

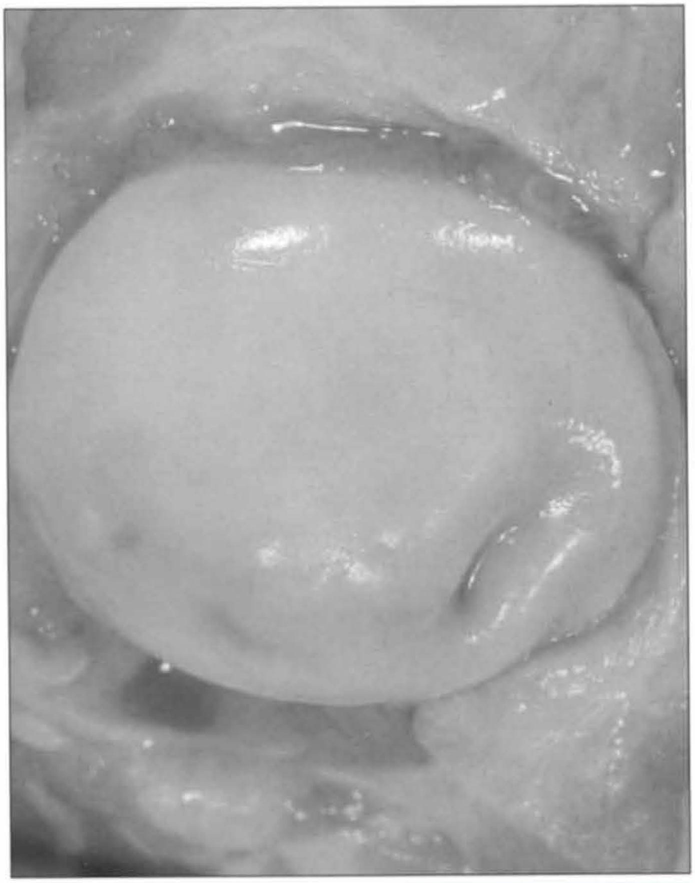

Figure 1.72 Fibrous osteodystrophy, pig. Irregular articular surface of humeral head due to collapse of subchondral bone. (Courtesy of RA Fairley.)

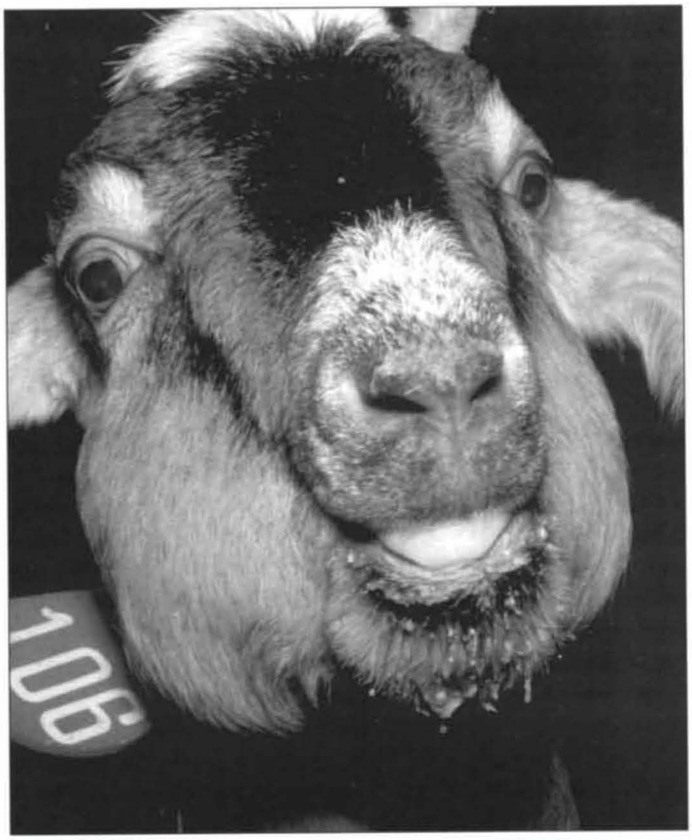

Figure 1.73 Fibrous osteodystrophy, goat. Bilateral swelling of maxillary bones and mandibles.

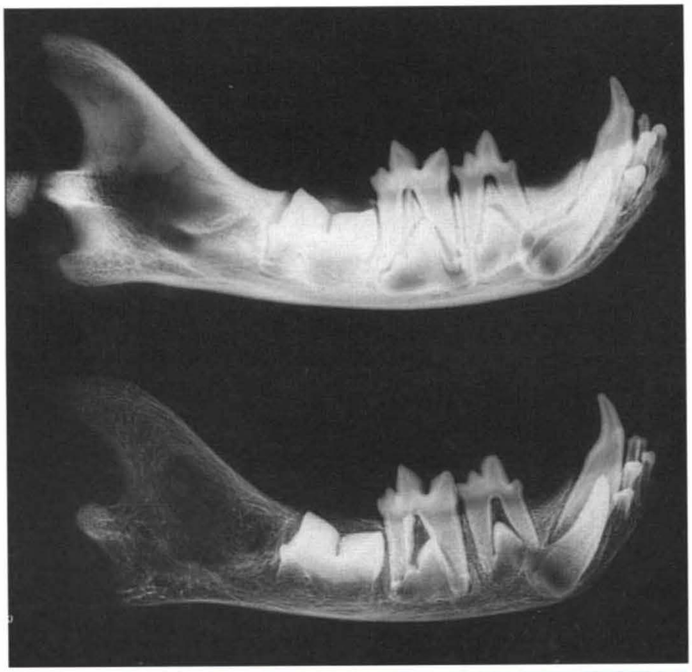

Figure 1.74 Fibrous osteodystrophy, kitten. Mandible from a normal kitten (top) and a kitten with fibrous osteodystrophy. Note the marked, diffuse rarefaction in the affected kitten and the loss of alveolar bone.

bone fragility. Osteogenesis imperfecta has however been diagnosed in the cat and remains a differential for fibrous osteodystrophy.

Renal secondary hyperparathyroidism may occur in adult dogs with renal failure, but the skeletal lesions are usually of secondary importance to the manifestations of uremia. Resorption of alveolar socket bone and loss of lamina dura dentes occurs early in the disease and may be evident radiographically. As the disease progresses, there is accelerated resorption of cancellous bones of the maxilla and mandibles, occasionally resulting in soft, pliable mandibles (so-called "*rubber jaw*"). Skull bones may have a moth-eaten appearance due to localized areas of accentuated resorption. Facial hyperostosis is a feature of some dogs with renal secondary hyperparathyroidism, but usually occurs in dogs with familial renal disease that develop slowly progressive renal failure from a young age. In such dogs, there is symmetrical enlargement of the head due to marked swelling of the maxillae and mandibles. The bones are firm rather than hard and can usually be cut with a knife. Focal red-brown areas of recent or old hemorrhage may be evident on cut surface. Young dogs with renal osteodystrophy may also have enlarged costochondral junctions and irregularly thickened physes, reflecting concurrent rickets due to impaired formation of 1,25-dihydroxyvitamin D.

In the German Shepherd pups with *hereditary primary hyperparathyroidism*, clinical signs were apparent by 2 weeks of age and included stunted growth, muscular weakness, and polydipsia/polyuria. Diffuse reduction in bone density was detected radiographically. At necropsy, the long bones were fragile and had narrow cortices. Facial bones were not enlarged but firm, pale yellow, swollen regions in the

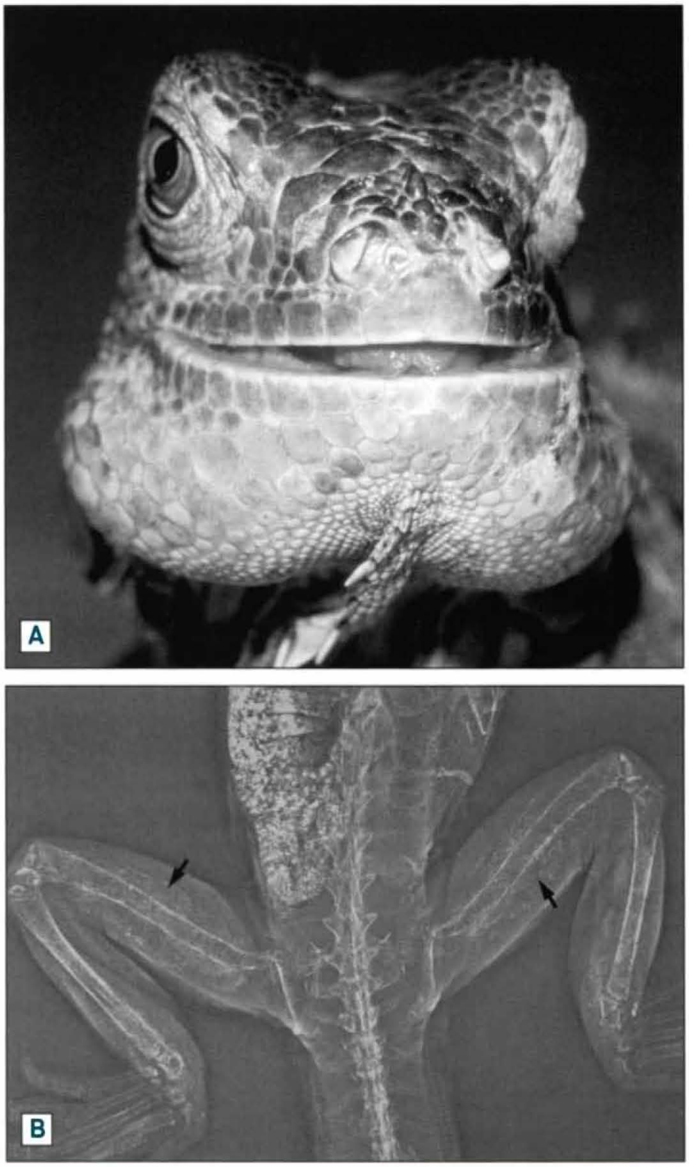

Figure 1.75 Fibrous osteodystrophy, iguana. **A.** Bilateral mandibular swelling. **B.** Xeroradiograph of the hindlegs and spine of the same iguana. The cortices of long bones are very thin and there is extensive periosteal new bone formation, particularly along the femurs (arrows).

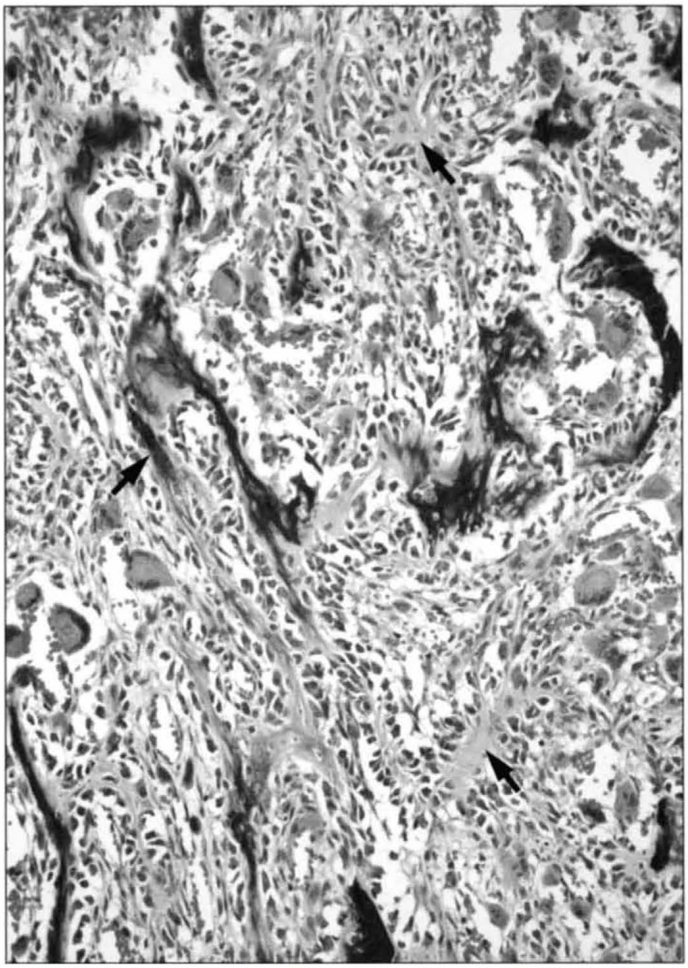

Figure 1.76 Fibrous osteodystrophy, ferret. Undemineralized section stained by the Von Kossa method and counterstained with hematoxylin and eosin. Highly reactive osteoblasts are forming delicate spicules of poorly mineralized or unmineralized bone (arrows). Many large osteoclasts are also present.

metaphyses of the ribs extended 2–3 cm along the shaft from close to costochondral junctions. Similar swollen segments were also present in the diaphyses of some ribs.

Fibrous osteodystrophy was reported in a strain of German Shepherd pups in Japan and although the possibility of a familial increase in susceptibility was suggested, the syndrome was apparently due to nutritional secondary hyperparathyroidism and was not analogous to the hereditary primary hyperparathyroidism referred to above.

Nutritional secondary hyperparathyroidism is relatively common in **reptiles** fed on diets that are either high in phosphorus (e.g., meat) or low in calcium (e.g., fruits, vegetables). Typically, there is thickening and softening of the bones of the skull and limbs, and a reduction in radiographic bone density (Fig. 1.75A, B).

The **microscopic features** *of fibrous osteodystrophy are similar in all domestic animal species and are characterized by increased osteoclastic bone resorption, marked fibroplasia, and increased osteoblastic activity with formation of immature woven bone.* These are also features of normal bone during development, and can be found in other disease processes. For example, longitudinal growth of long bones in rapidly growing young animals is accompanied by prominent osteoclastic and osteoblastic activity and intertrabecular fibrosis in the peripheral metaphyses as part of the normal modeling process. Such areas must be avoided when examining bone for histological evidence of fibrous osteodystrophy. Repairing fractures at certain stages of maturity, and diseases associated with hyperostosis (discussed elsewhere in this chapter), may also be confused with fibrous osteodystrophy if histological sections are examined without an awareness of their exact location and an adequate clinical and/or radiographic knowledge of the case.

The lesions of fibrous osteodystrophy vary between different bones, depending on their rate of turnover, and with the stage of the disease process. It is important therefore to examine several sections from different parts of the skeleton, particularly those areas that are growing most rapidly. In early lesions, the increase in bone resorption is reflected by increased numbers of plump, active osteoclasts, often within Howship's lacunae along the surface of bone trabeculae. Osteoblastic activity is also prominent (Fig. 1.76) and it is not unusual to find

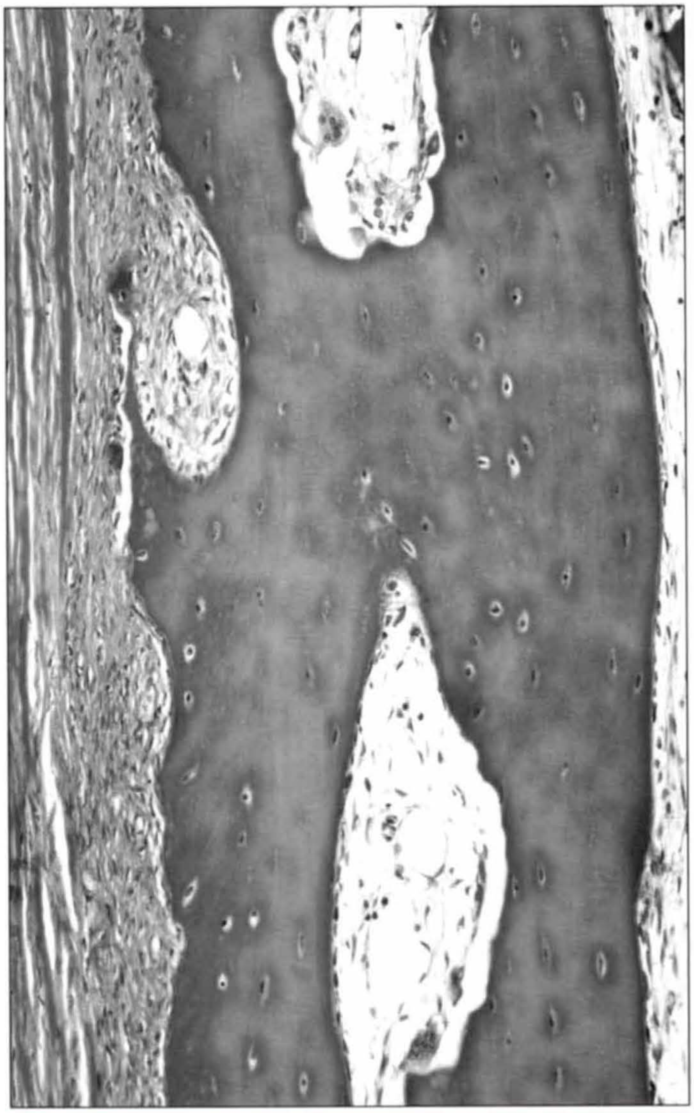

Figure 1.77 Fibrous osteodystrophy, kitten. Large resorption cavities in the cortex. Osteoclasts and Howship's lacunae indicate active resorption.

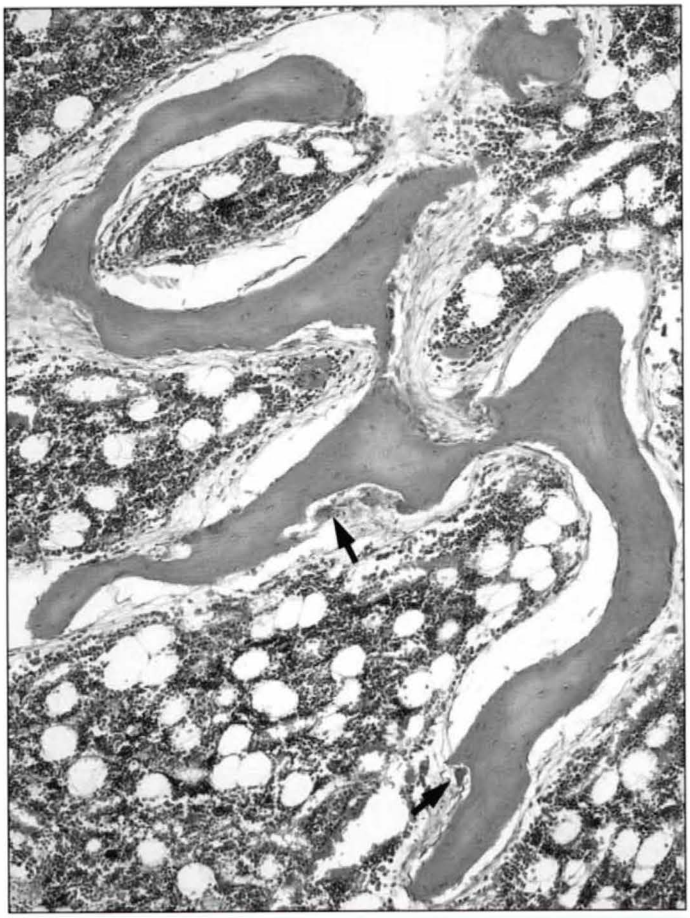

Figure 1.78 Fibrous osteodystrophy, pig. Early lesion with peritrabecular fibrosis and osteoclastic resorption (arrows).

bone trabeculae being resorbed on one side while new bone is being added to the other. Wide osteoid seams may be present at sites of rapid bone formation, especially in renal osteodystrophy where there may be concurrent rickets or osteomalacia due to deficient renal synthesis of 1,25-dihydroxyvitamin D. Resorption cavities lined by osteoclasts may be present in cortical bone (Fig. 1.77), and even within trabeculae, providing convincing evidence for exaggerated bone resorption. Lightly fibrillar connective tissue initially surrounds trabeculae undergoing resorption (Fig. 1.78), but later progresses to fill the intertrabecular spaces. As the disease progresses, *mature trabecular and cortical bone are extensively replaced by a combination of loose fibrous connective tissue and irregular trabeculae of poorly mineralized or unmineralized woven bone*, which may encroach on the medullary cavity and expand peripherally to elevate the periosteum (Fig. 1.79). The compact bone of the cortex is resorbed from endosteal and periosteal surfaces, and from within. In advanced lesions, only porous remnants of the original cortex may remain (Fig. 1.79). The soft, swollen mandibles and maxillae in animals with facial hyperostosis consist of highly cellular fibrous connective tissue surrounding delicate trabeculae of poorly mineralized woven bone (Fig. 1.80A, B). Osteoclastic activity may be largely absent in such advanced lesions, or remain in isolated pockets where remnants of the original bone are still being resorbed. In the absence of an adequate history or gross description, such lesions could be confused with benign or malignant bone tumors, or perhaps a fracture callus. Cyst-like cavities are sometimes present, possibly secondary to localized hemorrhage, and there may be sufficient hemosiderin in some areas to cause brown discoloration grossly.

Growth plates are histologically normal in fibrous osteodystrophy unless there is concurrent rickets or interference with vascular invasion due to trabecular fractures in the adjacent metaphysis. Premature resorption of the primary spongiosa is a feature of fibrous osteodystrophy in young, growing animals. The primary spongiosa normally consists of delicate trabeculae extending into the metaphysis at right angles to the growth plate and containing a central core of mineralized cartilage. In fibrous osteodystrophy, the newly formed trabeculae are resorbed almost as rapidly as they form and are replaced by disorganized spicules of woven bone lacking the cartilage core (Fig. 1.81). The spicules are often lined by osteoclasts and/or active osteoblasts, two to three cells deep, and are separated by a moderate amount of fibrous connective tissue.

In severe cases, articular cartilage of weight-bearing joints is often herniated into the epiphysis, causing an irregular articular surface. This is the result of osteoclastic resorption of the calcified zone of

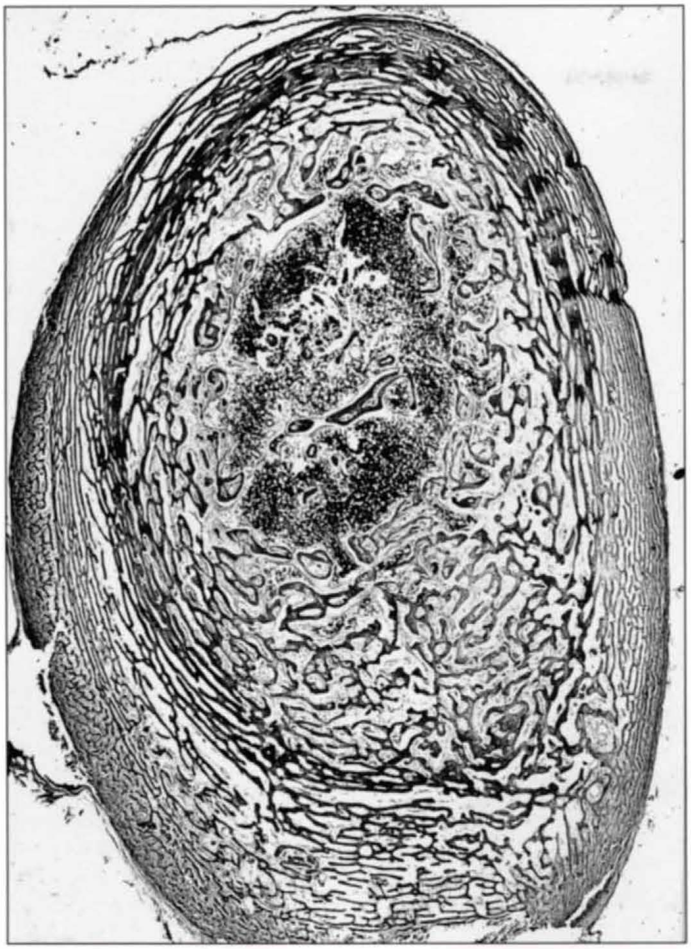

Figure 1.79 Fibrous osteodystrophy, pig. Transverse, subgross section of humeral diaphysis in an advanced lesion. Rarefaction of original and proliferation of new bone on medullary and periosteal surfaces.

articular cartilage, as well as resorption and collapse of subchondral epiphyseal bone.

In humans with renal failure, histologic lesions of osteomalacia are a prominent feature, but in dogs with renal secondary hyperparathyroidism, fibrous osteodystrophy predominates. An inherited disease known as Albright's syndrome appears as fibrous osteodystrophy in children, and in some children a phosphorus-losing nephropathy has been identified. Even in relatively young pups, histologic evidence of rickets is unlikely because the characteristic physeal lesions of rickets require relatively rapid growth and pups with renal failure generally grow poorly. *The lesions of renal osteodystrophy in dogs are usually most severe in the bones of the skull.* Histologic evidence of bone resorption by numerous large osteoclasts is prominent, particularly around teeth where the alveolar bone may be removed completely (Fig. 1.80A). Although facial hyperostosis occurs in some cases, osteopenia is more common in dogs with renal failure. Increased bone resorption on endosteal and periosteal surfaces is not balanced by formation, resulting in reduced cortical thickness.

OSTEONECROSIS

Like any living tissue, *bone will die when deprived of its blood supply.* This is referred to as **osteonecrosis**, or the synonymous term **osteosis**. In animals, bone ischemia is most often associated with trauma, particularly fractures, where vascular disruption to part of the fractured bone is inevitable. Osteonecrosis also occurs in many acute inflammatory diseases of bones, where the periosteal or myeloid vascular supplies may be disrupted by exudate accumulating either beneath the periosteum or between trabecular bone in marrow spaces. In such cases, the presence of a *large fragment of necrotic bone,* or **sequestrum**, often proves to be a major hindrance to successful repair. This is discussed in more detail in the following section Inflammatory diseases of bones. Other causes of ischemic necrosis of bone, or **bone infarction**, include infiltrating neoplasms, thromboembolism and peripheral vasoconstriction in association with ergotism, fescue foot, or chronic anemia. Severely dehydrated animals in cold climates may also develop peripheral vasoconstriction and necrosis of bone, together with ischemic necrosis of other tissues in peripheral regions. As a rule, regions of bone that are served by end-arteries and have poor collateral circulation, such as the femoral head, are most prone to nonseptic osteonecrosis.

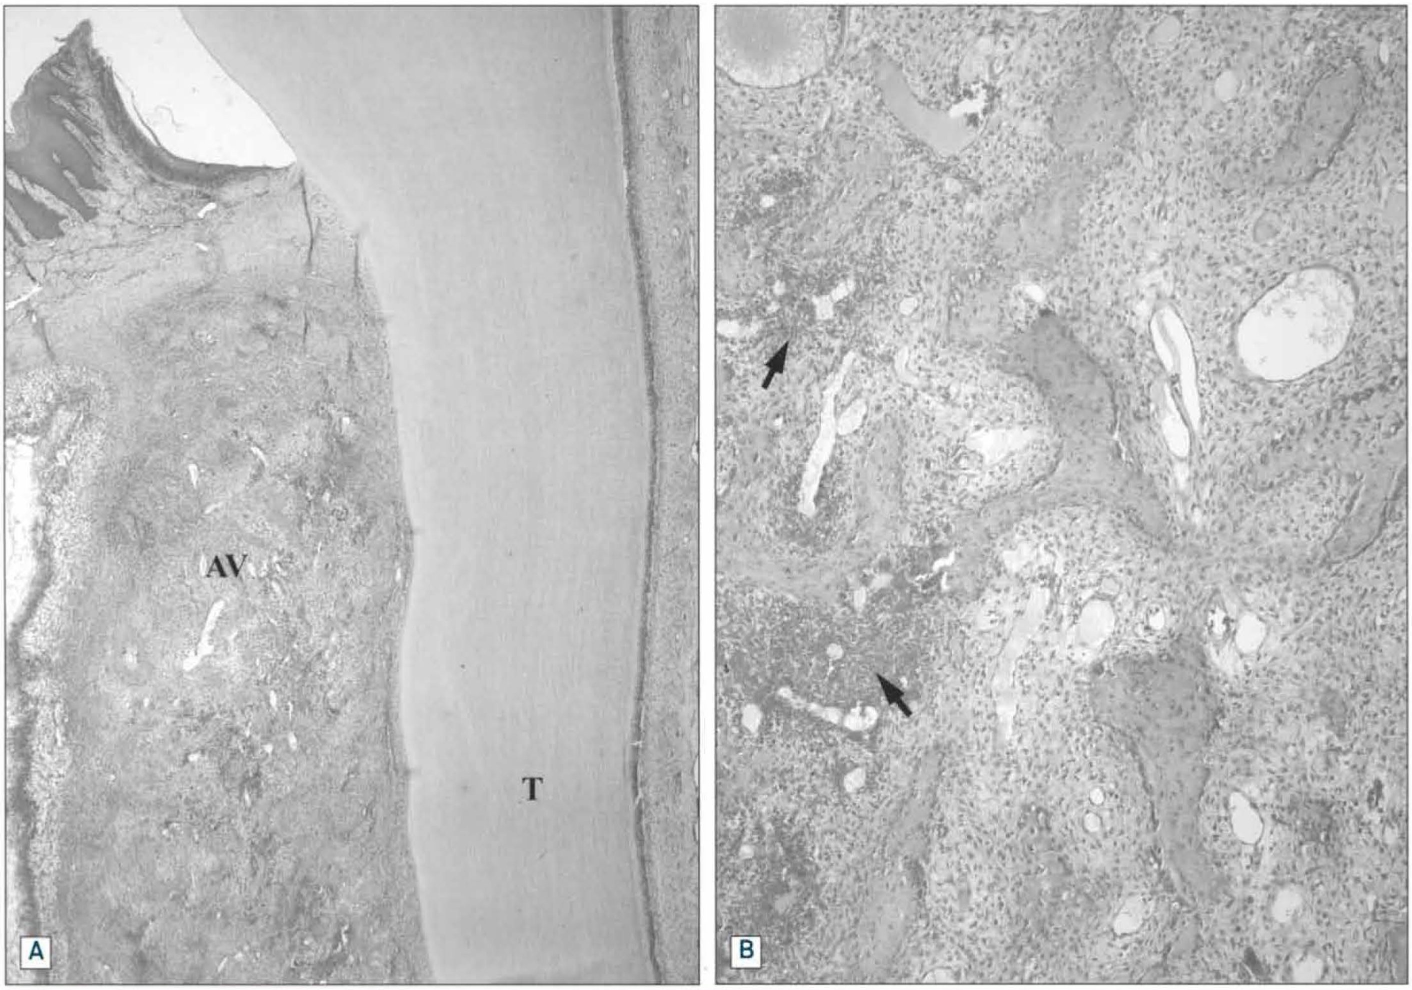

Figure 1.80 Fibrous osteodystrophy, dog. **A.** Section of tooth (T) and alveolar bone (AV) from a young dog with renal secondary hyperparathyroidism. The normally dense alveolar bone has been completely replaced by disorganized trabecular bone and fibrous connective tissue. **B.** Higher-power view showing the irregular trabeculae of woven bone surrounded by highly cellular fibrous connective tissue. The trabeculae are surrounded by active osteoblasts and occasional osteoclasts. Foci of hemorrhage (arrows) are also present.

In humans, bone infarction occurs in association with steroid therapy, alcoholism, hyperviscosity, hemoglobinopathies, and in divers or tunnel workers who work in dysbaric conditions. **Steroid-induced bone necrosis** is believed to be secondary to fat embolism of small blood vessels and although it can occur in many locations, lesions are found most often in the femoral head, distal femur, and proximal humerus. In animals, bone necrosis has been induced experimentally in rabbits and horses, but its prevalence in association with routine steroid therapy is unknown. The availability of sensitive imaging tools such as MRI now provides an opportunity to investigate the occurrence of bone infarcts in animals on long-term steroid therapy. Fat embolism is also believed to be involved in the pathogenesis of alcohol-induced osteonecrosis in humans. Although alcoholism is not a problem in animals, other causes of impaired lipid metabolism that do occur in animals might be expected to predispose to bone infarction. Dysbaric osteonecrosis is caused by the lodgment of nitrogen gas emboli in subarticular bone and medullary cavities following rapid decompression.

Necrosis of bone and bone marrow is described in calves with the juvenile form of sporadic lymphosarcoma. Infarcts of various sizes are found both in vertebral bodies and long bones (see Fig. 1.124A). The pathogenesis of the lesion is not known but may involve vascular obstruction due to increased intra-osseous pressure associated with neoplastic infiltration of the bone marrow.

A possible sequel to bone infarction is the *development of osteosarcoma.* Multiple bone infarcts have been associated with the formation of osteosarcoma in breeds of dog not usually susceptible to this tumor (e.g., Miniature Schnauzer). The reparative process triggered by the infarcts may be responsible for initiating the malignancy, similar to the proposed mechanism of tumor induction at sites of fracture repair and osteomyelitis in dogs and cats (see below).

Morphology and fate of necrotic bone

In the early stages, necrotic bone is often impossible to recognize on gross examination. Furthermore, its mineral composition will be unaltered and its radiographic appearance will therefore resemble that of normal healthy bone. *The earliest recognizable alteration is usually a change in the periosteum to a dull, dry, parchment-like sheath, which can be detached easily.* This contrasts with the normal periosteum and cortical surface, which is smooth, white, glistening, and firmly adherent, except where muscles and fascia are inserted. The sharp contrast in

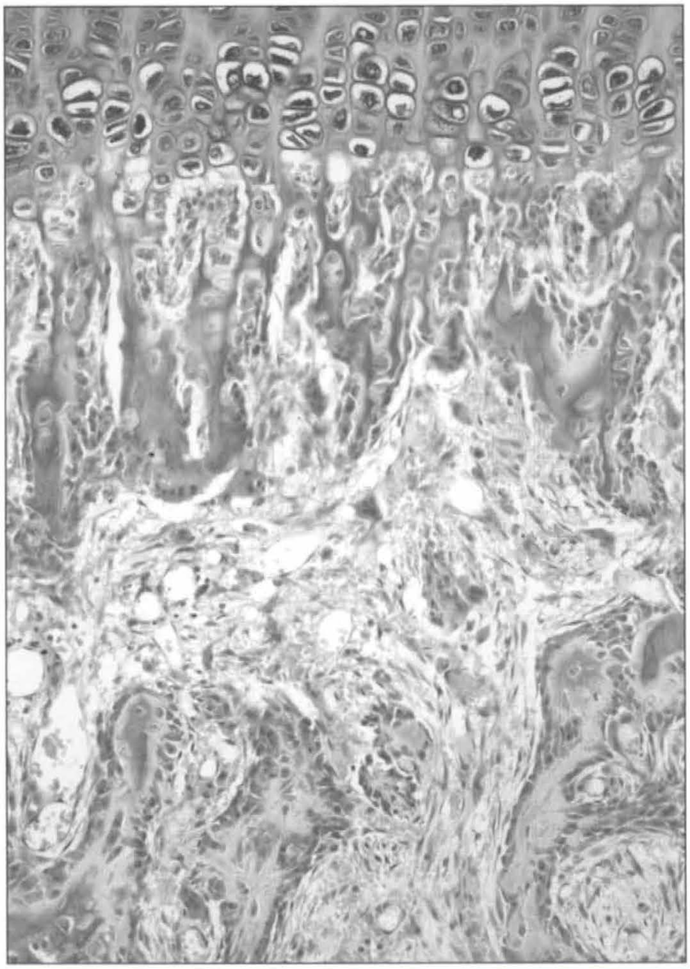

Figure 1.81 Fibrous osteodystrophy, kitten. Physis is normal, but there is premature osteoclastic resorption of trabeculae in the primary spongiosa and replacement with disorganized spicules of woven bone.

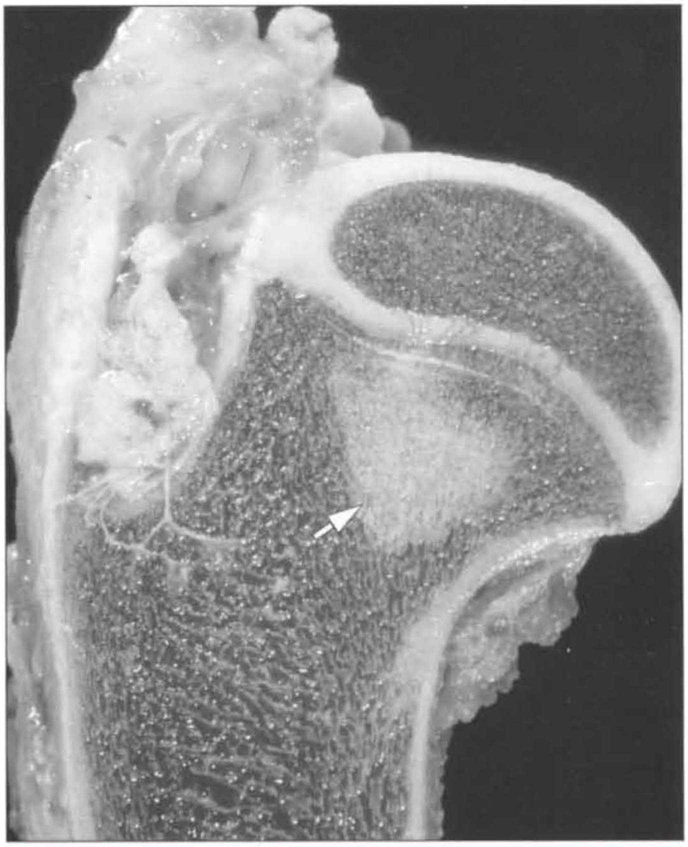

Figure 1.82 Necrosis of bone in the metaphysis of a young foal with **acute osteomyelitis**. The necrotic bone (arrow) is much paler than the surrounding hematopoietic bone marrow.

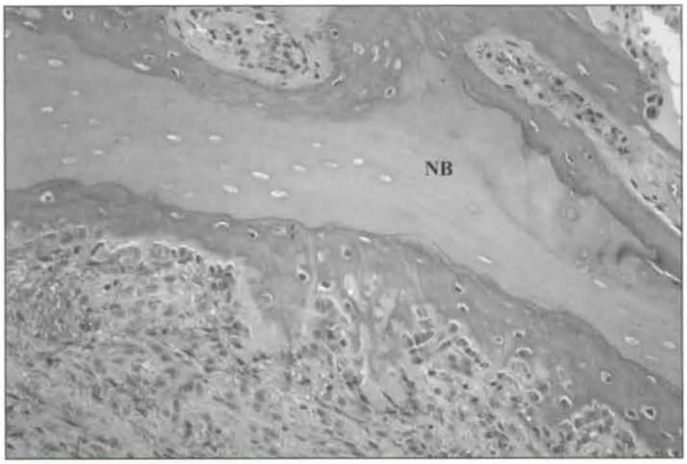

Figure 1.83 Necrotic bone surrounded by new, woven bone at a **fracture site** in a cat. Note the empty lacunae in the necrotic bone (NB) and the more basophilic matrix of the new bone. The necrotic bone has a scalloped margin, reflecting a period of osteoclastic resorption before the new bone was deposited on its surface.

color between a pale tan area of ischemia and the adjacent areas of normal marrow is an early indication of necrosis during gross examination, especially in young animals where the marrow is red due to active hematopoiesis (Fig. 1.82). Necrotic bone is slowly but progressively resorbed by osteoclasts, but these cells can only gain access to areas where the blood supply is intact and oxygen tension is maintained. Within a few weeks, evidence of the resorptive process will be apparent grossly as a margin of fibrous connective tissue separates the necrotic bone from adjacent viable bone. The necrotic bone may remain chalky white or become light brown.

Microscopically, zones of empty lacunae due to loss of osteocytes characterize necrotic bone (Fig. 1.83), but pyknotic nuclei from dead osteocytes may take anywhere from 2 days to 4 weeks to disappear. Hematopoietic tissue in the marrow cavity will show evidence of necrosis within 2 to 3 days after ischemia and can therefore provide an early indication, but adipose tissue is more resistant to ischemia and will not show evidence of necrosis for about 5 days. If an ischemic event is only transient, then there may be death of hematopoietic cells and perhaps osteocytes, but not adipocytes. Gas gangrene occasionally develops in the necrotic bones of livestock, but is rare in companion animals. The discovery of scattered empty lacunae in a section of bone does not justify a diagnosis of osteonecrosis as this may reflect normal turnover or even be an artifact of preparation. Prolonged immersion in acidic demineralizing solutions can also mimic osteocyte death. In osteonecrosis, all the lacunae in an area of bone should be empty, and the contents of the marrow cavity should be necrotic. Sometimes, focal dystrophic calcification occurs in the necrotic medullary fat.

The fate of necrotic bone depends on several factors, the most important being its volume, whether it is accompanied by sepsis, and whether it is in contact with viable tissue. In pyogenic infections of bone, sequestration is a common problem and usually has serious implications. The prognosis is more favorable if the necrotic bone is at a site that is both sterile and has good collateral circulation, and the volume of necrotic bone is small. In such cases, a zone of granulation tissue develops at the interface between the necrotic and viable tissue. This encroaches on the dead tissue and over a period of several weeks, the necrotic fat is replaced with collagenous connective tissue. *Osteoblasts derived from local progenitor cells begin to deposit seams of new woven bone on the remnants of necrotic bone* (Fig. 1.83). This new bone is sharply demarcated from the necrotic bone, which will usually be lamellar, and can be easily distinguished by its increased basophilia and the presence of viable osteocytes. Meanwhile, osteoclasts are recruited to the site and commence removal of the necrotic bone that is being used as a framework for deposition of new bone. This repair process, sometimes referred to as "*creeping substitution*," therefore involves the gradual resorption of dead bone at the same time that it is being replaced by new bone. Eventually, the new woven bone will be replaced with lamellar bone, but until such remodeling is complete, the combination of woven bone and partly resorbed dead bone may not be strong enough to withstand the forces of weight bearing, and the fragile, repairing trabeculae may collapse.

When the volume of necrotic bone is small, and is not in an area predisposed to further damage during the repair process, resolution is likely to be uncomplicated and complete. In fact, many such events probably occur throughout life but do not become clinically apparent. Repetitive injury at the same site may lead to an exaggerated response with formation of local exostoses.

The healing process is more complex when the necrotic bone is separated from viable connective tissue, as occurs frequently with necrosis or detachment of the periosteum. In such lesions, resorption of necrotic bone may still be complete if its volume is small, but if a relatively large volume of cortical bone is involved, sequestration may occur. Even when infection is not present, the sequestrum may interfere with the healing process by acting as a foreign body. *Attempts to wall off the sequestrum will lead to the formation of a layer of granulation tissue and reactive bone, the latter being referred to as an* **involucrum** (Fig. 1.84).

The efficacy of the collateral circulation is another important factor in the likely outcome of osteonecrosis. When the nutrient artery is occluded, large areas of the bone marrow become necrotic, along with the adjacent cancellous and compact bone. If the damage is restricted to the diaphyseal extremities, the prognosis is more favorable as this region has a dual blood supply of osseous origin – from the nutrient vessels on the diaphyseal side, and from the vessels of the joint capsule and ligaments on the epiphyseal side – as well as that from adjacent soft tissues.

As a rule, *the collateral circulation in cortical bone is inefficient* because, in spite of abundant anastomoses, the vessels are small and because they are confined within narrow canals, they are incapable of effective compensatory dilation. The resting and proliferative cartilage of the major growth plates depends on the epiphyseal circulation, while the sinusoidal circulation of the primary spongiosa is derived from metaphyseal vessels and is vulnerable to trauma. In contrast, the articular cartilages are relatively insensitive to regional ischemia since their nutrient supply is obtained by diffusion from the synovial fluid.

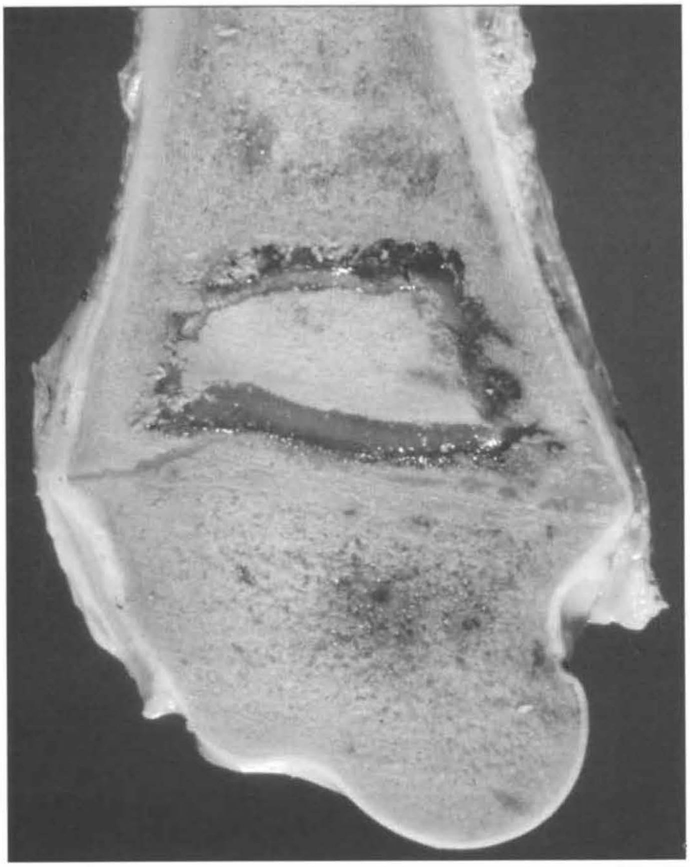

Figure 1.84 Large sequestrum surrounded by an involucrum of granulation tissue in the distal radius of a foal with salmonellosis.

Osseous sequestration is a relatively common sequel to distal limb wounds in horses, the most common sites being the proximal half of the third metatarsal bone and the third metacarpal bone. Although the initial event may be traumatic, it is likely that the introduction of infection to the site predisposes to sequestration, rather than reduced peripheral cortical circulation alone. Sequestra may be detected at about 14 days after injury, when there is some separation from adjacent viable bone and early formation of an involucrum.

Legg–Calvé–Perthes disease

This disease, characterized by *avascular necrosis of the femoral head*, is a well-recognized entity in children but also occurs with some frequency in dogs, especially smaller breeds. Miniature Poodles are particularly susceptible, as are West Highland white and Yorkshire Terriers, and there is evidence to suggest that the disease is inherited as an *autosomal recessive trait.* Avascular necrosis of the femoral head may also occur in other breeds of dog, and in other species, as a result of fractures of the femoral head, but such cases should not be confused with Legg–Calvé–Perthes disease which has a different pathogenesis. Clinically, the disease has an insidious onset, usually between 4 and 8 months of age, and is bilateral in approximately 15% of cases. There is no obvious sex or leg preference in dogs, unlike children where boys are affected five times more frequently than girls.

Anatomical and experimental evidence supports the theory that *the osteonecrosis in Legg–Calvé–Perthes disease is initiated by one or more episodes of ischemia.* As maturation takes place, the developing blood

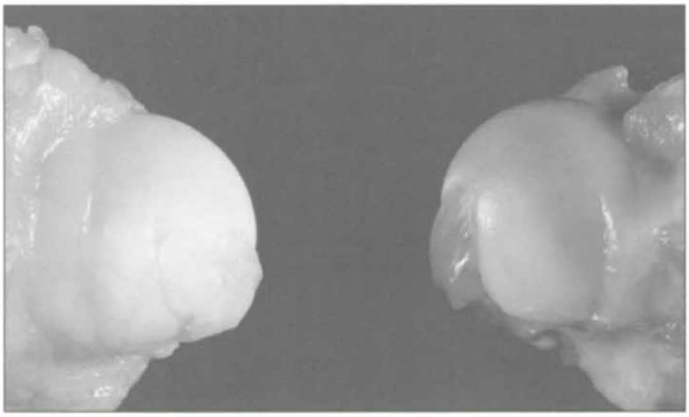

Figure 1.85 Legg–Calvé–Perthes disease in a dog. The articular surface of the femoral head on the left is irregular due to collapse of necrotic subchondral bone. The unaffected femoral head from the same dog is included for comparison. (Courtesy of MW Leach.)

vessels supplying the femoral head are progressively incorporated into fibro-osseous canals, which offer protection as they travel along the femoral neck. In highly susceptible Miniature Poodles, the incorporation of vessels into these canals is delayed, or is incomplete, in contrast to mongrels, where the vessels run mainly intra-osseously. In experimental studies, even a relatively slight degree of intracapsular tamponade produces lesions similar to those in the naturally occurring disease, probably by occluding the veins that drain the femoral head. A transient increase in intra-articular pressure caused by an effusion associated with synovitis or trauma would therefore be expected to interfere with venous drainage from the femoral head and produce the natural disease.

In the early stages of the disease, the shape of the femoral head, and the outlines of the articular cartilage and physis appear grossly and radiographically normal, even though the subchondral bone may be necrotic. If the area of necrosis is small, and the vascular supply is quickly re-established, healing may occur uneventfully. When the subchondral infarct is more extensive, *continued weight-bearing leads to fracture and collapse of the necrotic trabecular bone and flattening of the femoral head* (Fig. 1.85), predisposing to degenerative arthropathy. The physis of the femoral head is also disrupted in some cases, presumably due to interruption of its epiphyseal blood supply at the time of the initial insult.

The repair process involves initial revascularization and proliferation of mesenchymal cells from the margin of the necrotic area, followed by deposition of woven bone on the remnants of necrotic trabeculae. Gradually, the dead bone is removed by osteoclasts and eventually the woven bone is replaced by lamellar bone.

INFLAMMATORY DISEASES OF BONES

Inflammation of bones inevitably originates in vascular areas of either the medullary cavity or the periosteum and is referred to as either **osteomyelitis** or **periostitis** respectively. **Osteitis** is a more general term for inflammation of bones, but is used less frequently. Most inflammatory diseases of bones are caused by bacterial infections, although mycotic and viral agents can also infect bones. *Bacterial osteomyelitis is particularly common and important in domestic animals* and will be discussed in some detail below, as will other forms of infectious osteitis.

Noninfectious osteitis also occurs, usually in response to local periosteal injury, and typically results in the formation of **exostoses**. This may be due to a single insult if there is damage to the periosteum or to repeated minor trauma. Tearing of ligamentous insertions will often induce local periostitis and the development of exostoses or osteophytes. Small exostoses may be completely resorbed if the stimulus is removed, but larger ones may be converted from woven to lamellar bone and persist indefinitely. These often remain clinically inapparent but may interfere with the function of adjacent structures, such as tendons or ligaments, as occurs in some cases of "splints" on the second and fourth metacarpal bones of horses. There is evidence to suggest that traumatic injury to the periosteum may predispose to bacterial osteitis at the site, even if the overlying skin is intact. The mechanism is uncertain but damage to adjacent tissues may increase their susceptibility to infection. More extensive periostitis, particularly involving vertebrae, is reported in dogs in association with parasitic myositis caused by *Hepatozoon americanum* infection. Presumably, the periosteum is reacting to the release of inflammatory mediators or other factors in response to the presence of parasitic stages in muscle fibers.

Bacterial infections of bones

Bacterial infections of bones are very common in animals, especially young horses and ruminants. Since the route of infection is *usually hematogenous*, most are centered on the medullary cavity and are referred to as osteomyelitis. There is little doubt that bacterial osteomyelitis is far more common than is diagnosed, as affected animals often die of septicemia before the bone lesions become evident and the skeleton is generally not closely examined at necropsy unless clinical signs have suggested a skeletal disorder.

During bacteremia or septicemia, bacteria can become localized in many organs and at many sites. In bones, there is a strong predilection for sites of active endochondral ossification within the metaphyses and epiphyses of long bones and vertebral bodies. This reflects the unique nature of the vascular architecture at the physis, and at the equivalent site in expanding epiphyses. Capillaries invading the mineralized cartilage make sharp loops before opening into wider sinusoidal vessels that communicate with the medullary veins. The capillaries are fenestrated, thus permitting ready escape of bacteria into the bone marrow. Furthermore, sluggish circulation in the sinusoidal system, and the relative inefficiency of the phagocytic cells lining it, also tend to favor the development and persistence of infection. Experiments in rabbits have suggested that trauma, or some other factor that alters the metaphyseal environment, enhances the establishment of bone infection in animals with bacteremia. Thus, *a combination of physeal, metaphyseal, or epiphyseal injury and concurrent bacteremia or septicemia may be involved in the pathogenesis of hematogenous osteomyelitis.* Localization of bacteria in the vessels of cartilage canals is also common in hematogenous infections of young animals. As the skeleton matures, the vascular morphology at chondro–osseous junctions alters to make it less suitable for bacterial localization. In fact, there is probably only a narrow window during which bacteria, be they derived from umbilical infections in colostrum-deprived animals, or from infections in the respiratory or alimentary tracts, are able to establish in bones. The clinical manifestations of osteomyelitis may not develop until several months later when the bone lesion becomes extensive enough to cause pain, disfigurement of the bone, or perhaps result in a pathological fracture.

Some bacteria appear to have a predilection for localization within bone. This probably reflects the fact that *certain bacteria* (e.g., *Staphylococcus aureus*) *possess receptors to bone surface proteins,* such as sialoproteins and collagen. It is possible that trauma makes binding sites on these proteins more accessible to bacterial receptors. This might account for the frequent establishment of bone infection at sites of blunt trauma, even when the skin surface has remained intact. Once bound to bone proteins, *S. aureus* bacteria surround themselves with a thick mucopolysaccharide glycocalyx, which allows tighter adhesion to the bone surface and favors persistence of the infection by protecting the organisms from host defense mechanisms and inhibiting the penetration of antibiotics. Other bacteria that commonly establish in bones (e.g., *Salmonella* spp.) may possess similar mechanisms of survival.

At sites of bacterial infection, cytokines such as tumor necrosis factor, interleukin-1, and prostaglandin E_2 released from inflammatory cells activate *bone resorption by osteoclasts.* There is also evidence that inflammatory cells themselves may be able to resorb bone.

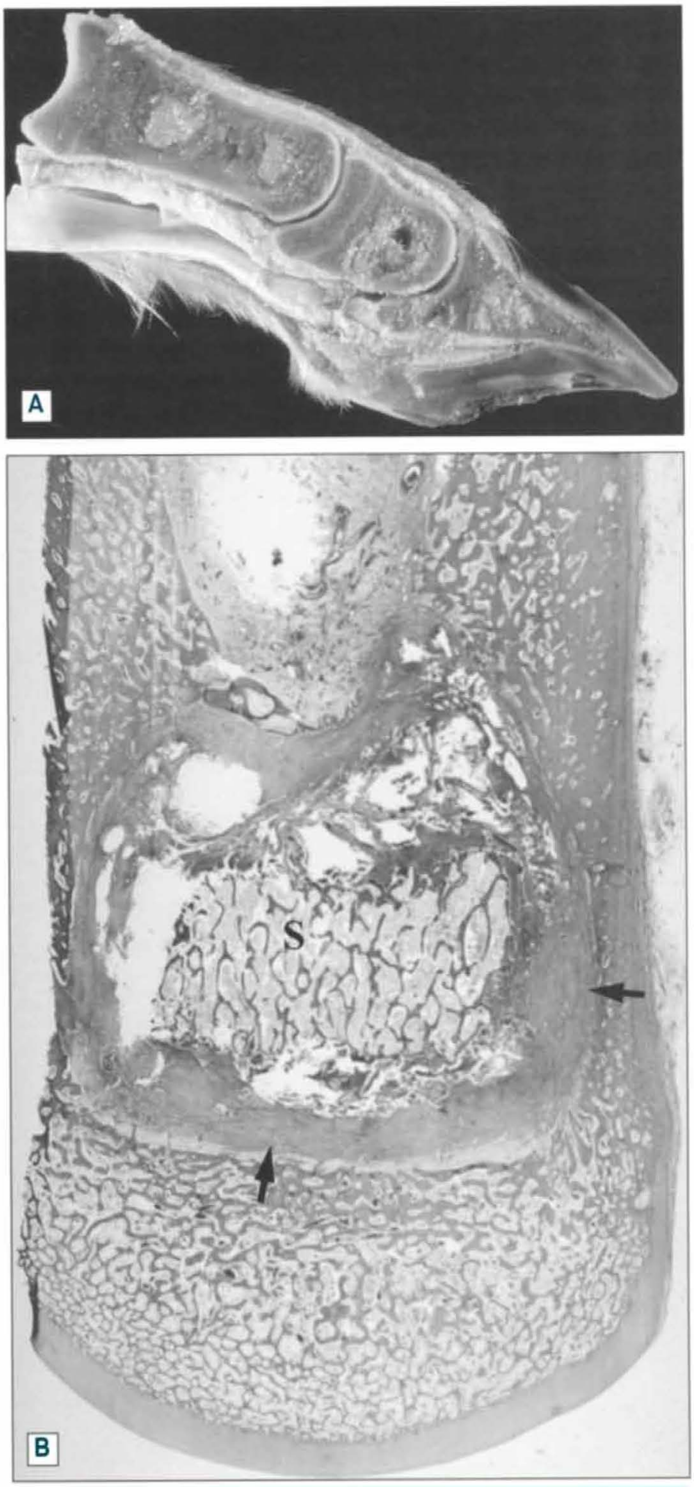

Figure 1.86 Osteomyelitis in a foal with salmonellosis. **A.** All three digits contain large sequestra. **B.** Sequestrum in the distal metaphysis of P-1 from the same foal. Note the thick involucrum of granulation tissue (arrows) surrounding the sequestrum of necrotic cancellous bone (S).

There are several possible sequelae to hematogenous bacterial infection of bone. The initial response is characterized by *edema and acute purulent inflammation.* Many infections are probably eliminated spontaneously by host defenses at this early stage, perhaps assisted by prompt and vigorous treatment with specific antibacterial agents. If the infection is not eliminated it may become segregated by fibrous inflammatory tissue and woven bone, with development of a *metaphyseal or epiphyseal abscess* (*Brodie's abscess*). Alternatively, the exudate may percolate through the adjacent marrow cavity causing necrosis of soft tissues and trabecular bone. These early lesions appear grossly as discrete areas of pallor, sharply demarcated from the normal red bone marrow (Fig. 1.82). *Resorption of necrotic trabecular bone* from the edge of the lesion, and *proliferation of granulation tissue*, results in separation of the necrotic, infected bone from adjacent viable tissues (Fig. 1.84). It is not unusual to find several foci of osteomyelitis in different bones within the same animal (Fig. 1.86A), or even within the same bone. Osteoclasts or inflammatory cells

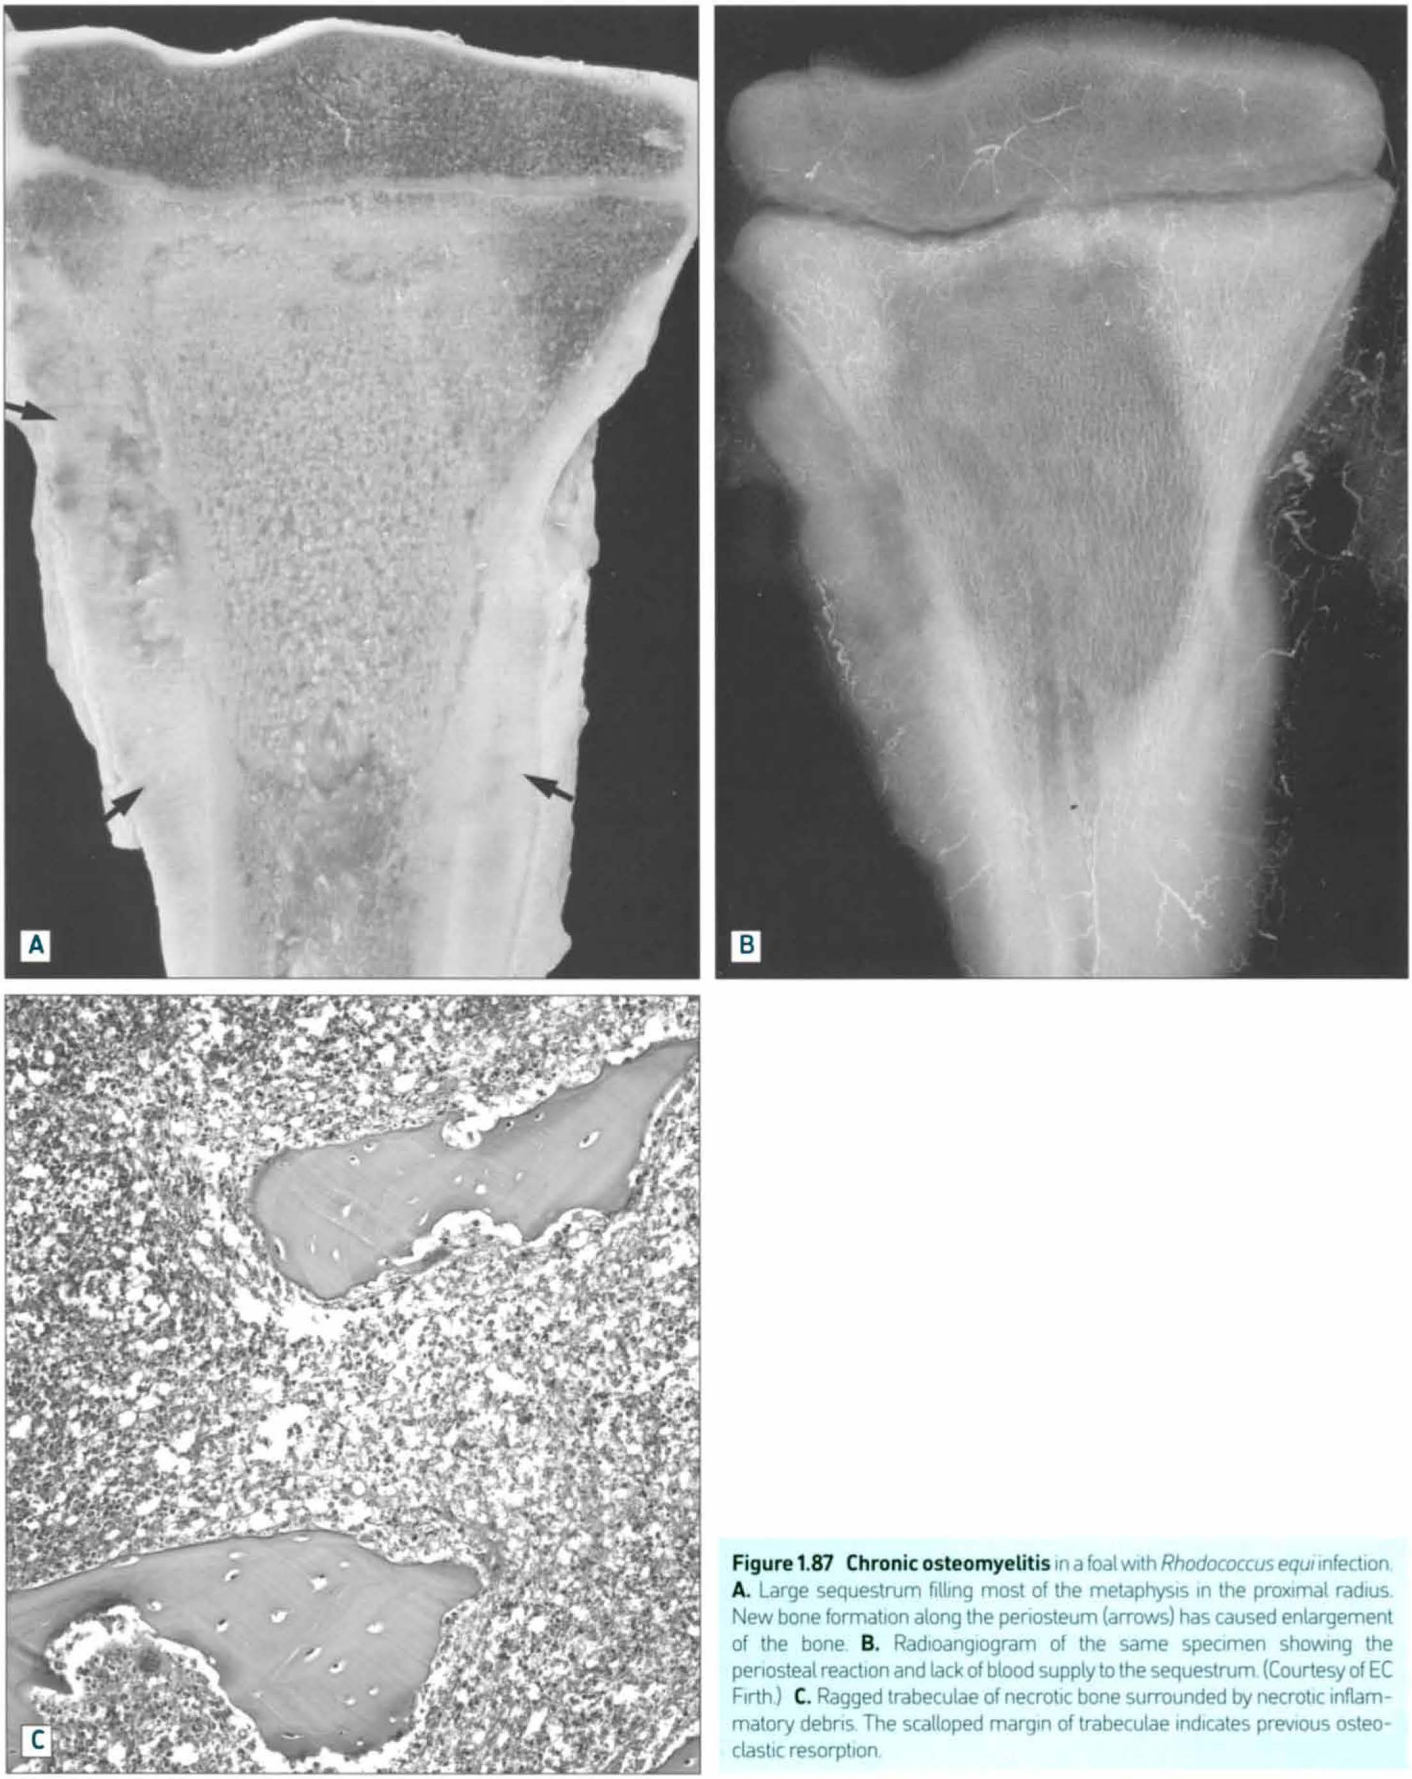

Figure 1.87 Chronic osteomyelitis in a foal with *Rhodococcus equi* infection. **A.** Large sequestrum filling most of the metaphysis in the proximal radius. New bone formation along the periosteum (arrows) has caused enlargement of the bone. **B.** Radioangiogram of the same specimen showing the periosteal reaction and lack of blood supply to the sequestrum. Figure 1.88 Osteomyelitis, foal. *Salmonella typhimurium* infection. **A.** Extensive destruction of subchondral bone in the distal femur. The infection has spread to involve much of the epiphysis, as well as the physis and part of the metaphysis. **B.** Same lesion prior to sectioning, showing communication with the stifle joint through a focal defect in the trochlear groove.

may resorb small foci of necrotic bone, but larger foci, which become separated from a viable vascular supply, persist as **sequestra**, harboring bacteria and interfering with the repair process. *Granulation tissue or reactive bone, which often forms a layer around sequestra* (Figs 1.84; 1.86A, B) is referred to as an **involucrum**.

The physis usually prevents the spread of infection from the metaphysis to the epiphysis, but transphyseal blood vessels in very young animals may transmit infection from one side to the other. In such cases, the physis is usually involved in the septic inflammatory process and is destroyed locally (see Fig. 1.53). The cortex is relatively porous in young animals and offers little resistance to the spread of infection, which penetrates through vascular canals to the periosteum. If cortical penetration occurs within the attachment of a joint capsule, then *septic arthritis* may result but, more commonly, a *subperiosteal abscess* develops. Disruption or thrombosis of the blood supply from the metaphysis to the inner portion of the cortex, together with periosteal elevation and interference with periosteal blood vessels, causes *segmental cortical necrosis and formation of sequestra*. In severe cases of bacterial osteomyelitis, there may be locally extensive necrosis and sequestration of metaphyseal and cortical bone, with an exuberant involucrum formed beneath an elevated periosteum, resulting in swelling and disfigurement of the bone (Fig. 1.87A, B).

The *predilection sites* for long bone lesions of osteomyelitis vary in distribution between species. There is also some variation in the bacteria involved and in the age distribution of affected animals. In **foals**, osteomyelitis seldom occurs after 4 months of age and the lesions occur more often in the secondary ossification centers of the epiphyses than the metaphysis. *Most infections establish immediately beneath the thickest part of the articular cartilage*, particularly in the caudal aspect of the lateral and medial femoral condyles, dorsal to the weight-bearing articular surface. Other common sites for epiphyseal localization of infection in foals include the distal intermediate ridge of the tibia, medial styloid process of the radius, and the proximal humerus, but many other sites also may be involved. The vascular arrangement at sites of thickened cartilage is characterized by an increased arterial supply and greater sinusoidal filling than in areas where the articular cartilage is thinner. If the infection becomes established, there may be extensive destruction of subchondral bone with underrunning of the articular cartilage (Fig. 1.88A, B). The inflammation may progress to involve much of the epiphysis and may communicate with the joint space through defects in the overlying cartilage.

Metaphyseal lesions in foals are most common at sites where the physis deviates greatest from a horizontal plane. Approximately 70% of foals with bacterial osteomyelitis, including virtually all of those with epiphyseal lesions, also have septic arthritis. This may reflect either concurrent establishment of infection in the synovium during bacteremia, or direct spread from bone. The bacteria most commonly involved in foals with osteomyelitis are *Escherichia coli*,

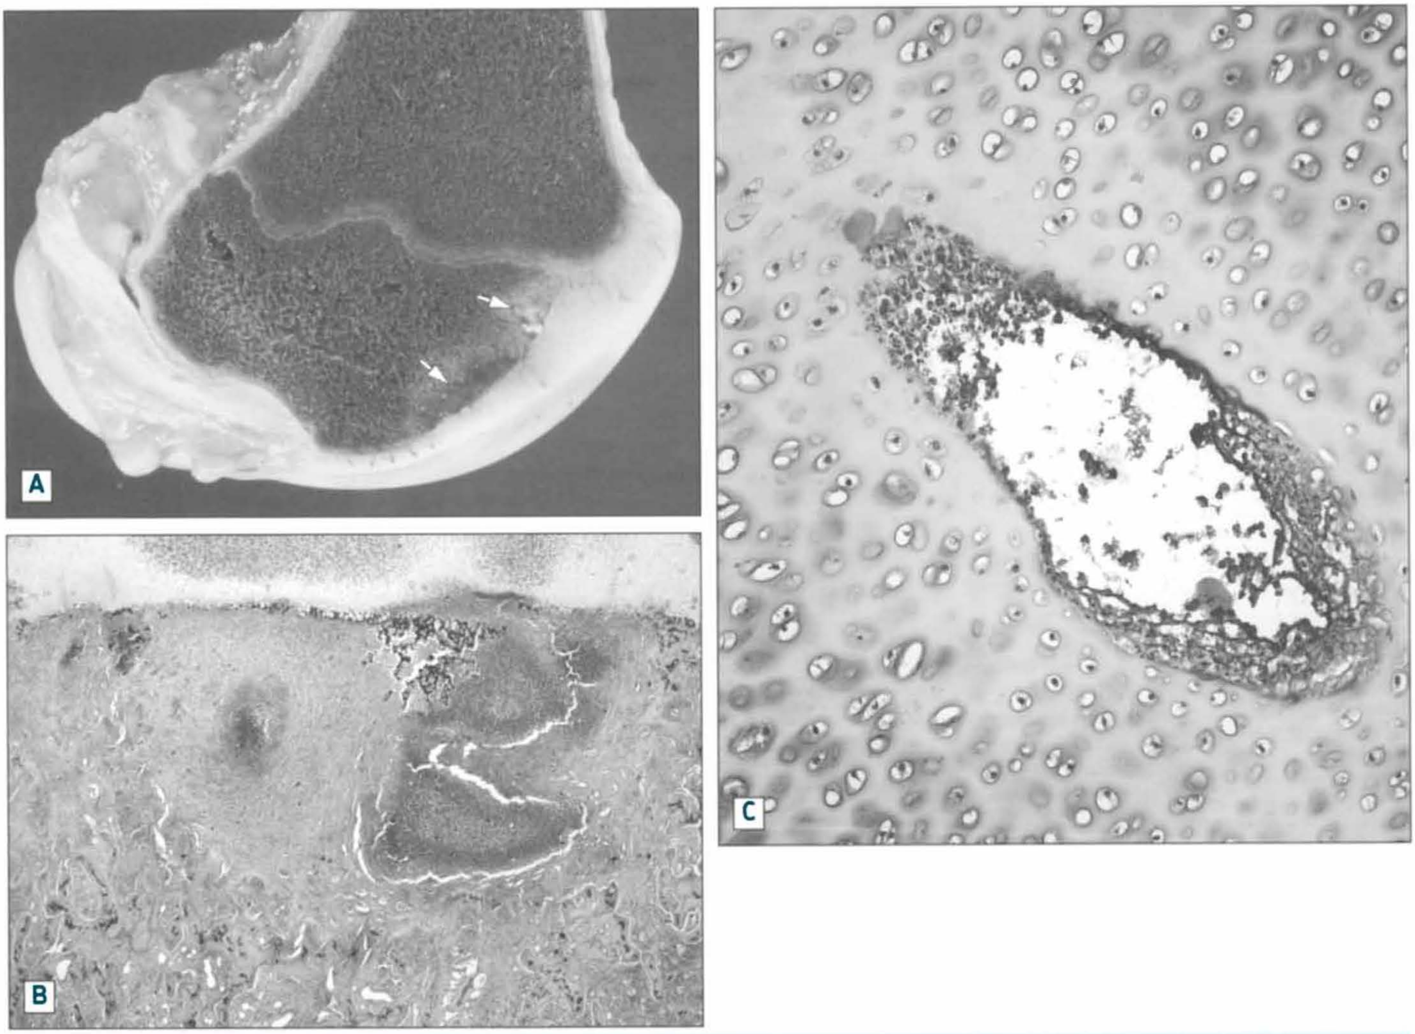

Figure 1.89 Subacute, suppurative osteomyelitis in the epiphysis of the distal femur in a calf. **A.** Foci of suppuration and trabecular destruction (arrows) immediately beneath the articular surface of the trochlear groove. The calf also had polyarthritis (see Fig. 1.154A, B) **B.** Low-power microscopic view showing foci of intense, suppurative inflammation and effacement of epiphyseal trabecular bone immediately beneath the articular cartilage. The pale areas of cartilage are degenerate. **C.** Cartilage canal in the same calf, showing destruction of vascular structures and replacement with necrotic debris.

Streptococcus spp., *Salmonella* spp., *Klebsiella* spp., and *Rhodococcus equi*. Hematogenous osteomyelitis of the tarsal bones, usually in association with infectious arthritis, is reported as an entity in young foals less than a month of age.

In **cattle**, hematogenous osteomyelitis is not confined to young animals, as it is in foals. In one study, the age range in cattle was 2 weeks to 5 years. *Metaphyseal osteomyelitis* in this study occurred at many sites in long bones, but particularly the distal metacarpus, metatarsus, radius, and tibia. *Epiphyseal osteomyelitis* occurred most often in the distal femoral condyle, distal radius and in the patella, and was usually associated with infection by *Salmonella* spp. In contrast, metaphyseal infections were most often caused by *Arcanobacterium pyogenes*. The *Salmonella* spp. infections were almost invariably in calves less than 3 months of age, while *Arcanobacterium pyogenes* usually affected cattle older than 6 months. As in foals, septic osteomyelitis generally accompanies bacterial arthritis in calves (Fig. 1.89A). Hematogenous osteomyelitis and arthritis also frequently occur together in young **lambs**, **goats**, and **deer**, and are associated with a range of organisms.

Histological changes in bacterial osteomyelitis are predictable, but depend on the causative agent and the stage of infection. *Acute osteomyelitis* in young animals may be distinguished from active myelopoiesis by the presence of fibrin, and a dense population of neutrophils and necrotic cells in the primary spongiosa, where hematopoietic tissue is usually absent. Inappropriate or excessive osteoclastic resorption of bone trabeculae is another characteristic microscopic feature and there may be necrosis of physeal or articular cartilage. In the epiphysis, inflammatory foci typically start immediately beneath the articular cartilage resulting in local destruction of subchondral trabecular bone (Fig. 1.89B). Degeneration or necrosis of the overlying articular cartilage is common in young animals with hematogenous bacterial osteomyelitis due to septic embolism or thrombosis of blood vessels in cartilage canals (Fig. 1.89C). In *chronic osteomyelitis*, marrow spaces between necrotic, partly resorbed bone trabeculae may be filled with necrotic debris (Fig. 1.87C), fibrous connective tissue, or a mixed population of inflammatory cells. A thick layer of granulation tissue infiltrated with neutrophils may surround larger areas of necrotic bone, with prominent osteoclastic activity at the margins. Proliferation of connective tissue and woven bone in chronic lesions may create difficulty in distinguishing the reaction from neoplasia, especially in biopsy specimens where the sample is small and perhaps not representative. The presence of neutrophils and plasma cells amongst the reactive bone and connective tissue supports a diagnosis of chronic osteomyelitis. Osteomyelitis secondary to a compound fracture may present a considerable diagnostic challenge, as the inflammatory changes will be superimposed on the proliferative components of fracture repair. In such cases, the history and radiographic changes are indispensable.

Hematogenous bacterial osteomyelitis is rare in **dogs** but may occur in pups that survive canine parvovirus infection, or other diseases associated with short-term or persistent neutropenia. A myelokathexis-like syndrome in Border Collie pups, characterized by persistent neutropenia, is typically accompanied by hematogenous osteomyelitis involving the metaphyses of several long bones. More often, bacterial osteomyelitis in dogs and **cats** is a *complication of compound fractures, wound contamination during open fracture repair, bite wounds, or gunshot injury*. Staphylococci, especially *Staphylococcus intermedius*, and streptococci are the most common organisms involved, although mixed infections including gram-negative bacteria, such as *Escherichia coli* and *Proteus* spp., also occur. Because of the association with fractures, osteomyelitis in dogs is most common in long bones of the appendicular skeleton, particularly the femur. Foreign material implanted traumatically beneath the skin, or surgical implants, may act as a nidus for infection. The surfaces of such implants are soon coated with matrix and serum proteins, fibronectin, and carbohydrates. Cell membrane receptors on staphylococci and some other gram-positive bacteria bind with fibronectin, while anaerobes and gram-negative bacteria attach less firmly via pili and fimbriae. In addition, the mucopolysaccharide glycocalyx produced by staphylococci and other gram-positive aerobes protects them from phagocytosis, antibodies, and may even alter the action of some antibiotics. Even after apparent resolution, bacterial infections of bone may recur as a result of proliferation of bacteria that have survived within the glycocalyx or in fragments of necrotic bone.

Vertebral osteomyelitis is a relatively common manifestation of bacterial osteomyelitis in horses and farmed livestock. Most cases probably result from hematogenous spread of infection to the bones during the neonatal period in animals with inadequate passive immunity. Bacteria may enter via the umbilicus, respiratory tract, digestive tract, or perhaps via the placenta immediately before parturition. In piglets and lambs, tail biting and tail docking respectively are believed to provide a portal of entry for bacteria in at least some cases of vertebral osteomyelitis. Following localization in the epiphysis or metaphysis of a vertebral body, or adjacent to a growth plate in a developing vertebral arch, the infection causes progressive destruction and weakening of the affected vertebral bone. As in long bones, sequestration and abscessation may occur. The *most common sequela is pathological fracture and collapse of affected vertebrae* with dorsal displacement of pus and necrotic bone fragments into the spinal canal (Fig. 1.90). Such an event is accompanied by the sudden onset of neurological signs caused by compression of the spinal cord. The severity and nature of the clinical signs will depend on the segment of cord involved and the degree of damage. In cases where vertebral fracture does not occur, the suppurative process may permeate the cortex in any direction, spreading to involve the pleura or peritoneum, the spinal muscles, or protrude as an encapsulated abscess into the spinal canal and cause partial compression of the cord. If the infection is contained or does not result in cord compression it may go undetected, or be found incidentally at slaughter.

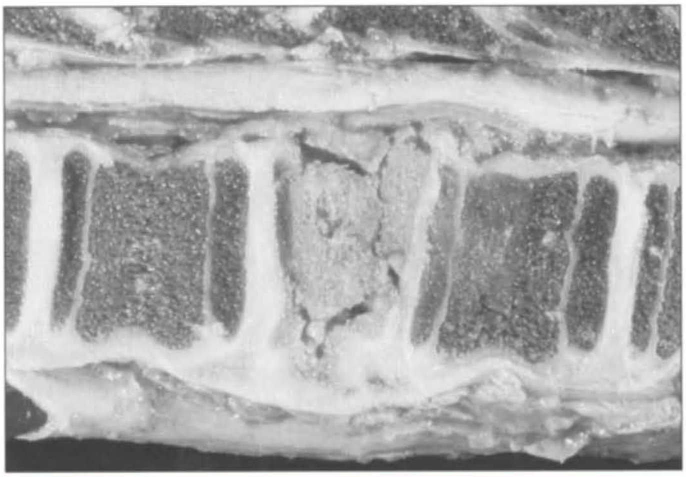

Figure 1.90 Vertebral osteomyelitis, calf. *Escherichia coli* infection. The vertebral body is completely necrotic and has collapsed. Several fragments have been forced into the spinal canal, compressing the cord. (Courtesy of PC Stromberg.)

Arcanobacterium pyogenes is the most common causative organism in vertebral osteomyelitis in most species, but a range of other bacteria may be involved. These include: *Escherichia coli, Salmonella typhimurium,* staphylococci, streptococci, and *R. equi* in foals; tuberculosis in older horses; *Fusobacterium necrophorum* in calves; *Mannheimia (Pasteurella) haemolytica, F. necrophorum,* and staphylococci in sheep; and *Erysipelothrix rhusiopathiae*, staphylococci, and streptococci in pigs. In one survey of cervico-thoracic vertebral osteomyelitis in calves, *Salmonella dublin* was isolated from eight of ten cases at postmortem. The lesions in this study all involved one or more of the vertebrae between C5 and T1. In regions where brucellosis is endemic in swine, *Brucella suis* may produce vertebral lesions as a sequel to diskospondylitis.

In dogs, bacterial osteomyelitis has been linked to penetration of grass seeds. Since the lesions are confined to the lumbar region, it is suggested that the grass seeds have most likely been ingested and penetrate the intestinal wall, perhaps at the caudal duodenal flexure, and ascend in the mesoduodenum to the lumbar vertebrae. Possible sequelae include sublumbar abscessation, osteomyelitis, and fistulation to the skin of the flank.

Localized bacterial periostitis is often associated with primary inflammatory conditions in adjacent tissues. Examples include infections of the feet of cattle with *F. necrophorum* ("footrot"), necrotic stomatitis of cattle caused by the same organism, infections of the paranasal sinuses as an extension from perforating injuries, bite wounds that produce cellulitis or abscesses, chronic paronychia and pressure sores over bony prominences. Penetrating wounds of the hoof in cattle or horses may also spread to involve the adjacent third phalanx.

Atrophic rhinitis of pigs, induced by exposure to toxins from certain strains of *Pasteurella multocida,* is associated with mixed bacterial infections and rhinitis. Absorption of the toxins leads to localized osteonecrosis of turbinate bones, and affected bones may lyse completely, leaving no substrate for repair (see Vol. 2, Respiratory system). A similar lytic condition may affect the turbinates of dogs.

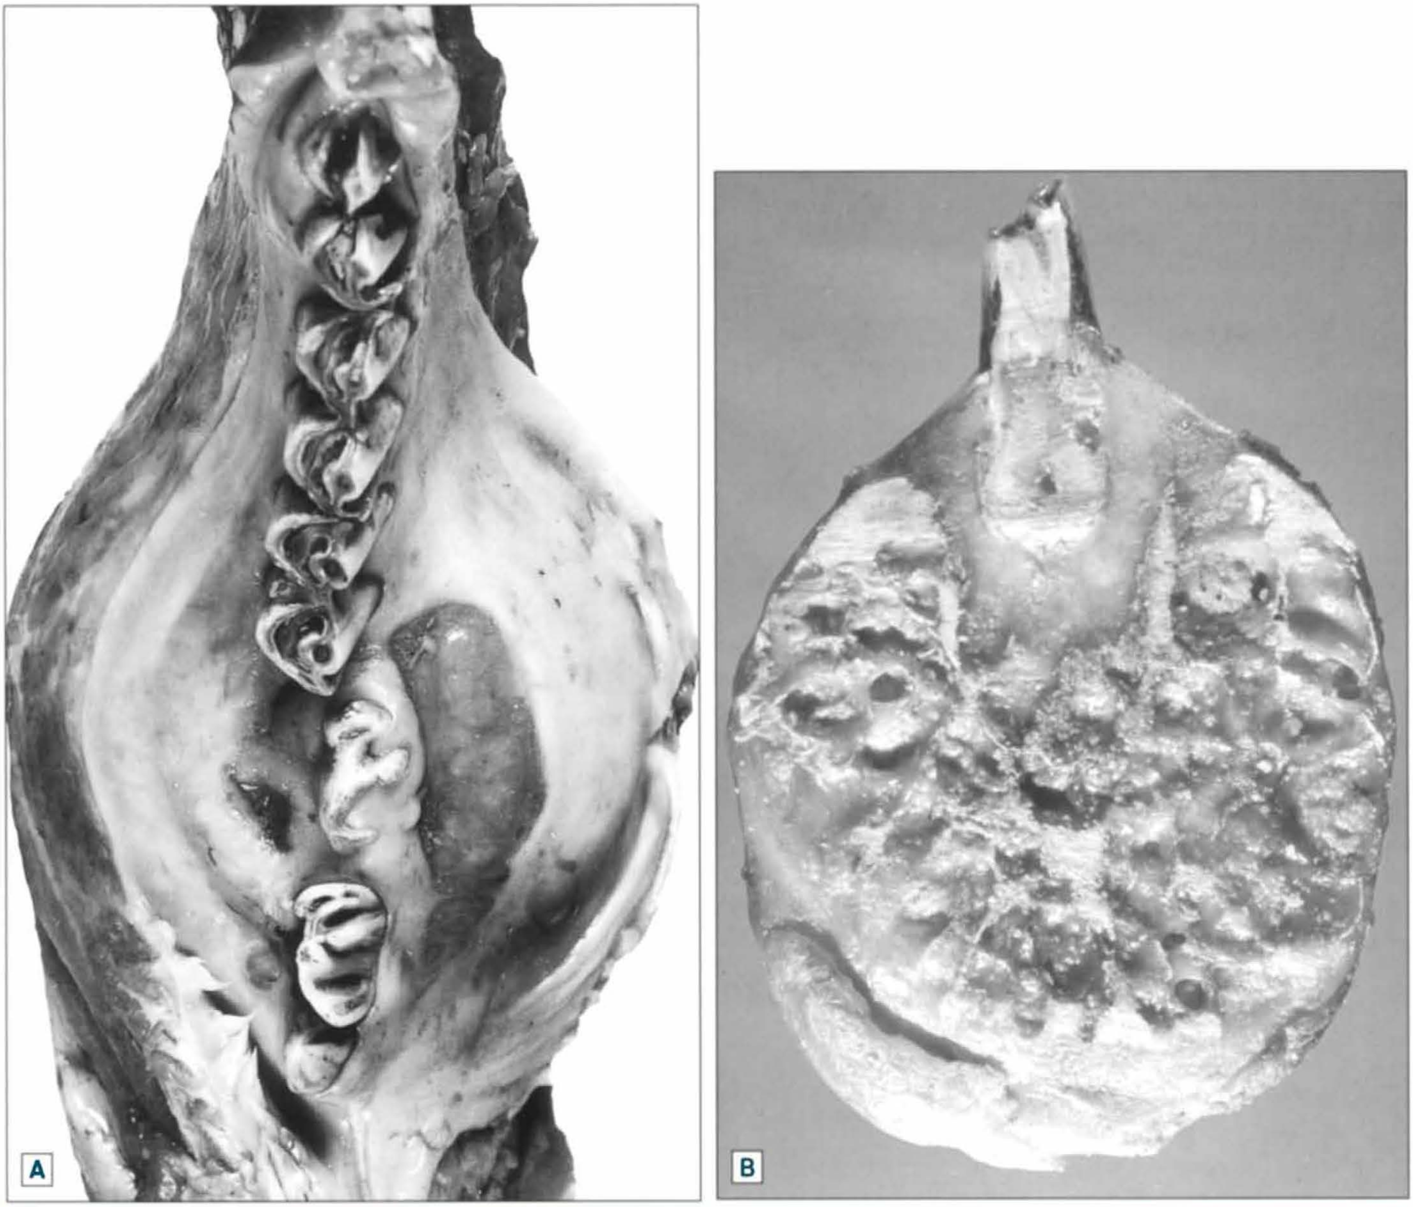

Figure 1.91 Mandibular osteomyelitis, cow. *Actinomyces bovis* infection. **A.** The mandible is markedly swollen. There is gingival ulceration and displacement of a tooth. **B.** Section through mandible showing "honeycomb" appearance caused by pockets of inflammatory tissue surrounded by reactive bone.

Mandibular osteomyelitis is primarily a disease of cattle caused by *Actinomyces bovis*, but occasionally occurs in horses, pigs, deer, sheep, and dogs. In cattle, the disease is known as **actinomycosis** or **"lumpy jaw,"** and *the classic lesion is confined to the mandible.* The maxilla is rarely involved and the organism rarely spreads even to regional lymph nodes, which, although large and indurated, are not infected. *A. bovis* is probably an obligate parasite of the oropharyngeal mucosa in a number of animal species, and most infections involve the buccal tissues. The organism is not particularly virulent, and in most, perhaps all cases, the surface tissues must be injured by some other agent or by a foreign body for invasion to occur. The osteomyelitis follows direct extension of the infection from the gums and periodontium. Extension to the periosteum causes actinomycotic periostitis, and the infection may not progress any further. Similar lesions may be produced by *A. pyogenes. Actinomyces bovis* may invade bone directly though the periosteum, but *osteomyelitis usually develops from periodontitis*, presumably via lymphatics, which drain into the mandibular bone. Once in the bone, *A. bovis* causes a chronic, pyogranulomatous inflammatory reaction. Suppurative tracts permeate the medullary spaces leading to multiple foci of bone resorption and proliferation. Large sequestra do not develop, even when the cortex is invaded, probably because of the slow, progressive nature of the disease. Fistulae often extend into the overlying soft tissue and may discharge through the skin or mucous membranes. Periosteal proliferation is excessive and the bone may become enormously enlarged (Fig. 1.91A), the normal architecture of the mandible being destroyed. The teeth in the affected portion of the jaw become loosened, lost, or buried in granulation tissue. On cut surface, the affected mandible has a "honeycomb" appearance with reactive bone surrounding pockets of inflammatory tissue (Fig. 1.91B). Fragments of necrotic trabecular bone accumulate in purulent exudate as "bone sand." The pus is also likely to contain many 1–2-mm diameter, soft,

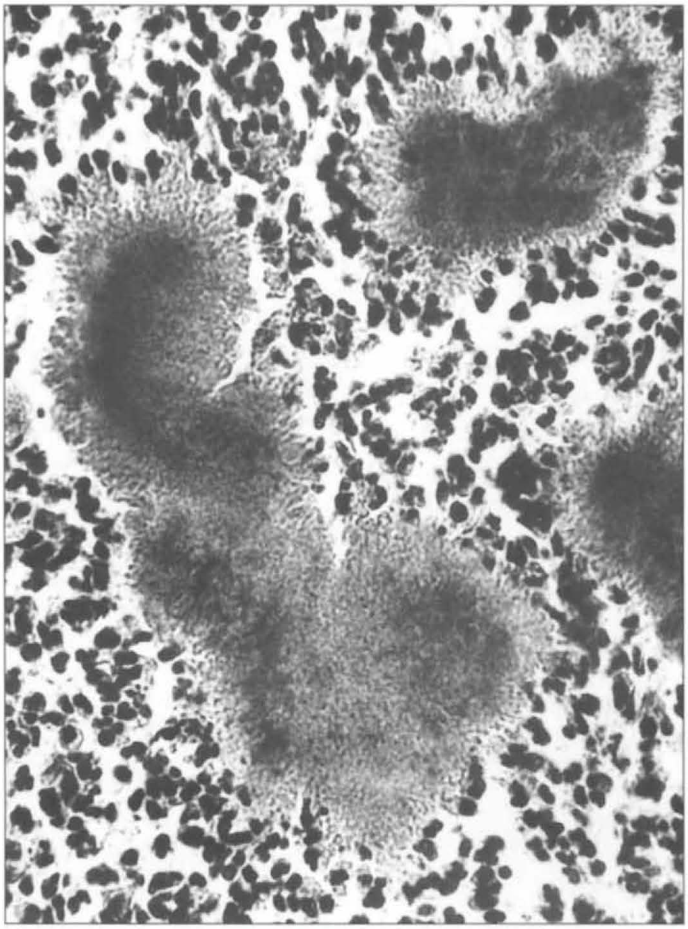

Figure 1.92 Colonies of *Actinomyces bovis* with characteristic club formation. The colonies are surrounded by neutrophils.

light yellow granules referred to as "sulfur granules." These consist of an internal mass of tangled, gram-positive filaments mixed with some bacillary and coccoid forms, and a periphery consisting of closely packed, club-shaped, gram-negative bodies (Fig. 1.92).

A similar tissue reaction, accompanied by club-colonies, occurs in association with some other bacteria, in particular *Actinobacillus lignieresi*, but the colonies in actinomycosis are much larger and the clubs are smaller and less discrete than in actinobacillosis. Furthermore, actinobacillosis is a disease of soft tissues rather than bone. *Fusobacterium necrophorum* and a variety of nonspecific bacteria may cause osteomyelitis by direct spread from periodontitis, but the lesions are usually more destructive and less proliferative than with *Actinomyces bovis*.

Mandibular osteomyelitis associated with loosening or loss of molar teeth (Fig. 1.93A) is sometimes detected in ill-thrifty **sheep** in the absence of other likely causes of weight loss, and may be a more important problem than is currently recognized in commercial sheep flocks. Grass awns or other plant matter may be wedged into pockets between teeth and the alveolar bone (Fig. 1.93B), providing a route of entry for opportunistic bacteria into the mandible.

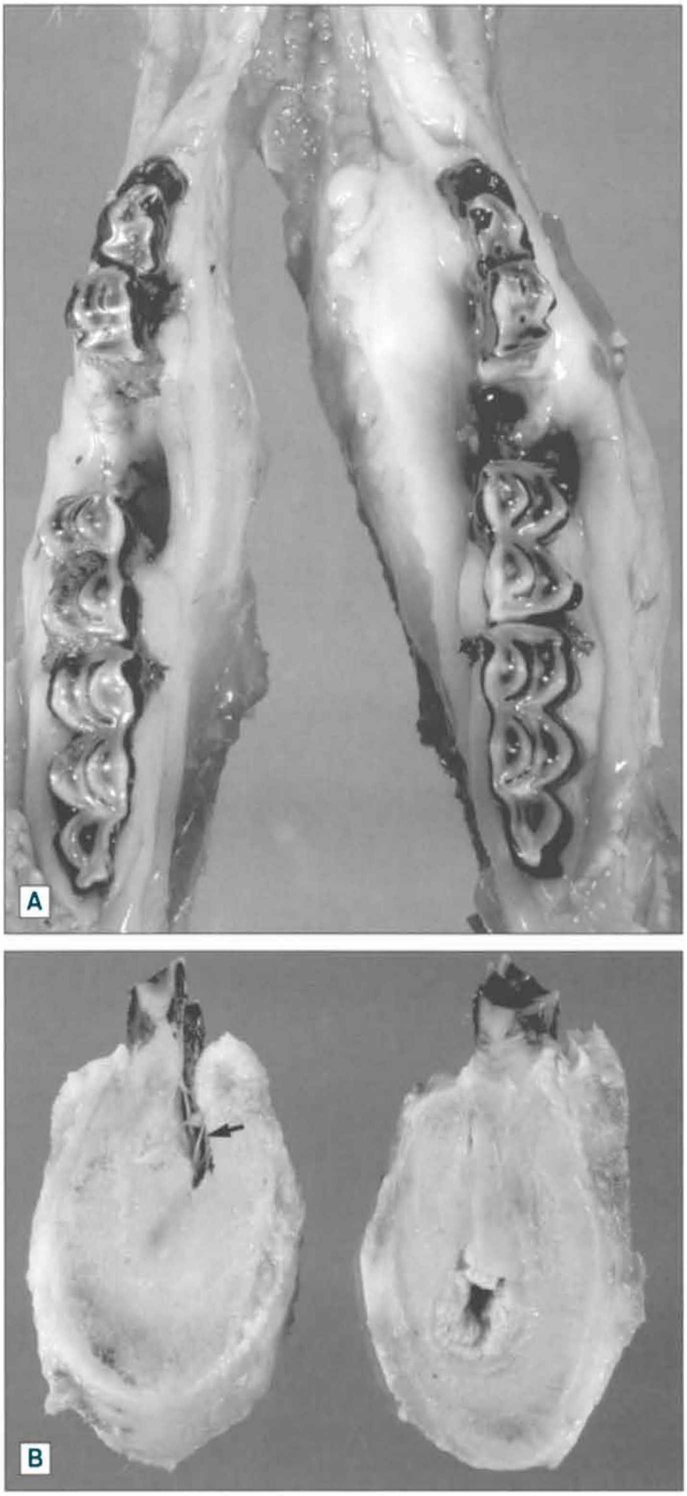

Figure 1.93 Mandibular osteomyelitis, sheep. **A.** Bilateral loss of individual molar teeth and swelling of the mandible on the right. **B.** Sections through swollen mandible shown in (**A**). Note the plant material (arrow) wedged between the tooth and adjacent bone in one section and the lytic focus filled with necrotic debris near the base of the tooth in the other.

Mycotic infections of bones

Mycotic infections of bone are less common than those caused by bacteria but certain pathogenic fungi, in particular the yeasts *Coccidioides immitis, Blastomyces dermatitidis, Cryptococcus neoformans*, and *Histoplasma capsulatum* may cause osteomyelitis following inhalation of spores and hematogenous dissemination. Multiple bones may be involved and the lesions may vary from lytic to highly proliferative, depending on the stage of the disease and the immune status of the host. Histologically, *the inflammatory response is pyogranulomatous*

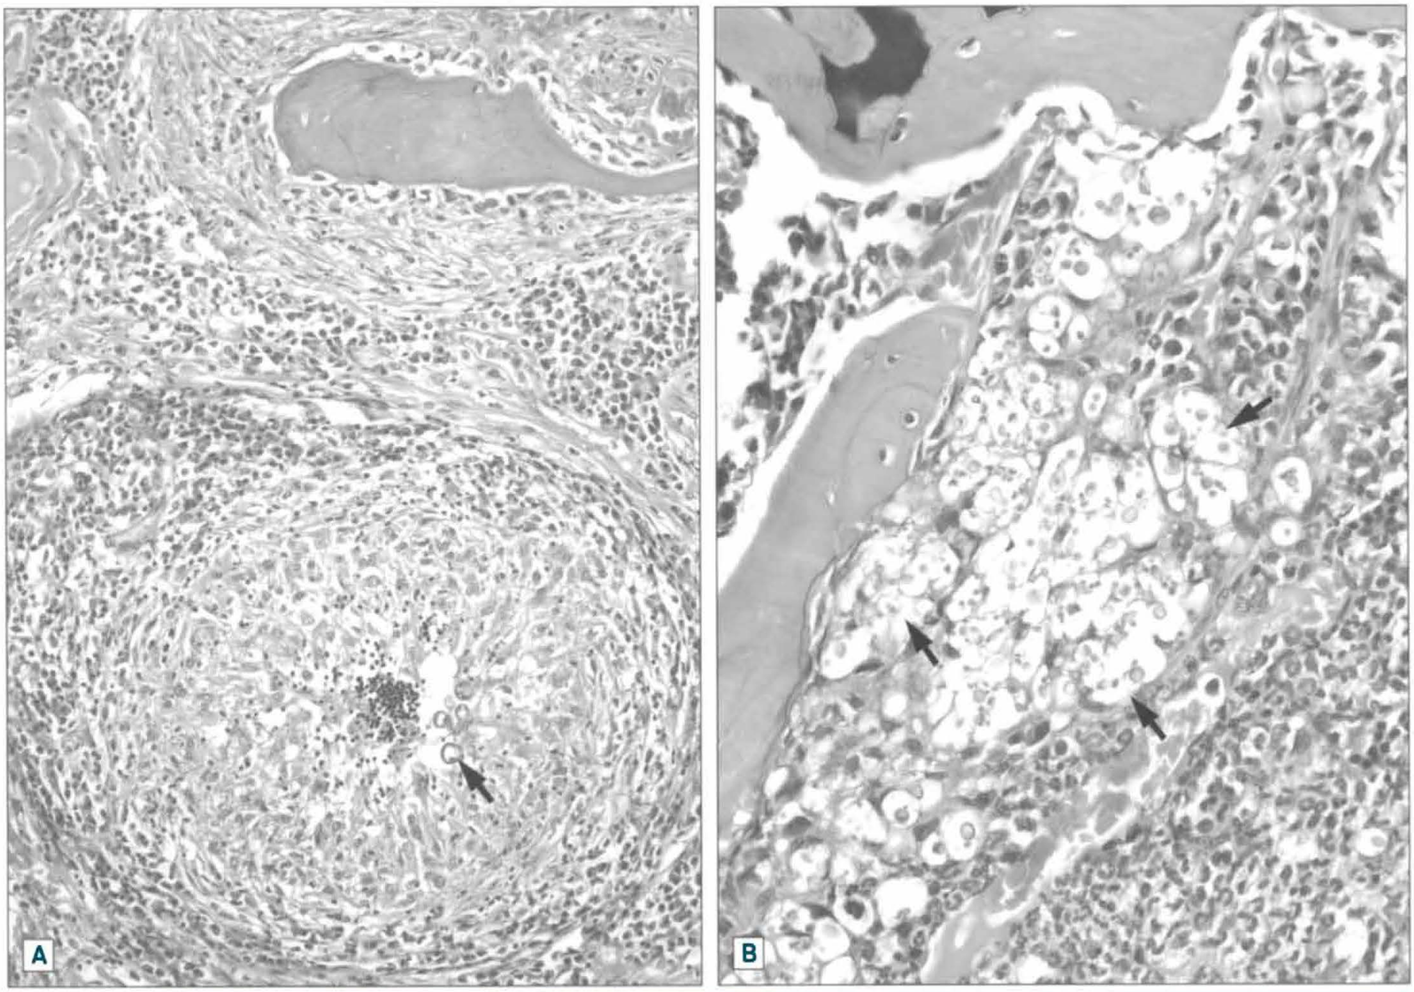

Figure 1.94 Mycotic osteomyelitis, dog. **A.** *Coccidioides immitis* infection. Focus of pyogranulomatous inflammation containing occasional organisms (arrow) and surrounded by a mantle of plasma cells. **B.** *Cryptococcus neoformans* infection. Numerous clusters of organisms with characteristic thick capsule (arrows) in marrow spaces of the rib.

(Fig. 1.94A) and is generally confined to the medullary cavity, at least in the early stages. The organisms can usually be detected readily, especially in cryptococcosis, where the host response may be minimal, perhaps reflecting impaired immunity (Fig. 1.94B). Lesions may also be present in a range of other tissues in animals with systemic mycoses and the presence of bone involvement may be overlooked.

Paecilomyces sp., a saprophyte in soil and decaying organic material, is generally considered nonpathogenic but is occasionally reported to cause osteomyelitis in dogs in association with systemic infection. The bone lesions may be multifocal and lytic, resembling plasma cell myeloma radiographically and grossly, especially when vertebral bodies are involved. Alternatively, they may be associated with extensive periosteal new bone formation leading to marked thickening of long bones (Fig. 1.95A, B). *Aspergillus* infections occasionally cause osteomyelitis in dogs, less so in other species. Other fungi, such as *Pithium insidiosum,* localize sporadically in bone and cause osteomyelitis.

Viral infections of bones

Several viruses are known to cause distinctive lesions in bones. Zones of metaphyseal sclerosis may be associated with ***Canine distemper virus*** infection and the **pestiviruses** of **bovine viral diarrhea** and ***Classical swine fever***, presumably due to destruction of osteoclasts or their precursors. This has been discussed in more detail earlier in this chapter.

***Canine adenovirus* type I** infection in pups may be accompanied by grossly visible metaphyseal hemorrhages at costochondral junctions due to virus-induced injury to endothelial cells, some of which contain characteristic intranuclear inclusion bodies. Necrosis of all cellular elements in the metaphysis also occurs, possibly due to ischemia, but there are no reports of residual lesions.

Feline herpesvirus causes necrosis in the turbinate bones of germ-free cats following intranasal inoculation, and produces necrosis in the metaphyses and periosteum of growing bones when administered intravenously. Sites of active osteogenesis are most susceptible. The virus infects osteoprogenitor cells, osteoblasts, osteoclasts, and endothelial cells, all of which may contain intranuclear inclusions.

Medullary sclerosis may occur in cats infected with ***Feline leukemia virus***, and is associated with nonregenerative anemia (see Vol. 3, Hematopoietic system). It is not clear whether the osteosclerosis is a direct result of the viral infection or is secondary to chronic anemia or hypoxia. Myelofibrosis may also be a feature of this infection.

Metaphyseal osteopathy

Although *the cause of canine metaphyseal osteopathy is unknown*, and a variety of noninfectious etiologies have been proposed, the disease

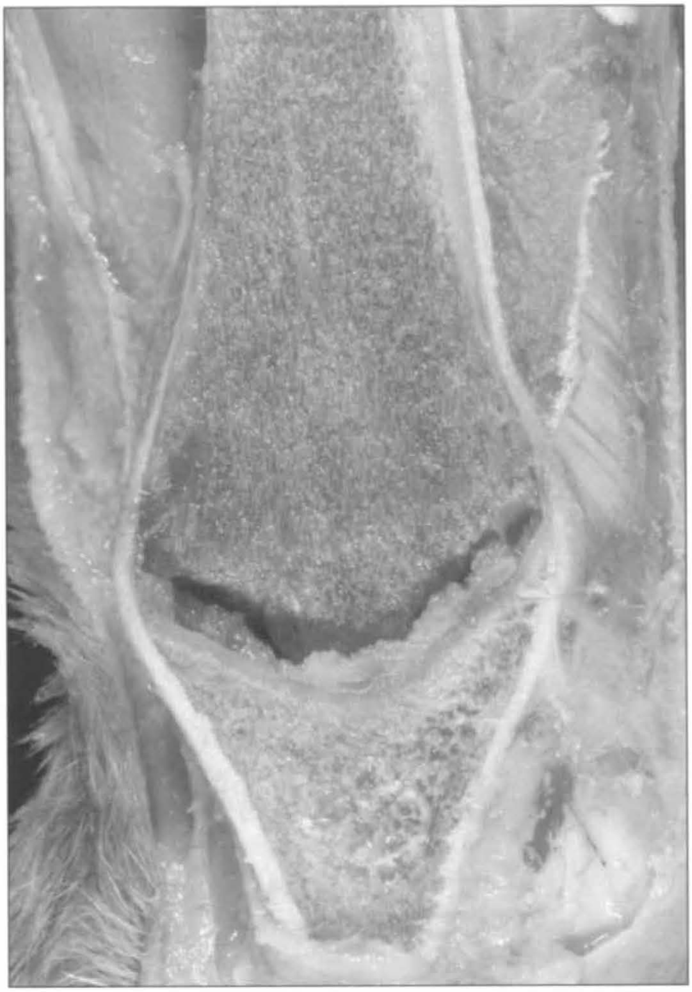

Figure 1.96 Metaphyseal osteopathy, dog. Acute lesion showing an infraction line through weakened trabeculae in the primary spongiosa of the distal ulna. (Courtesy of DJ Meuten.)

is included here amongst inflammatory diseases of bones because of the nature of the early lesions and increasing evidence that it is a manifestation of infectious osteomyelitis and periostitis. The disease is commonly referred to as "*hypertrophic osteodystrophy*" but *this term implies a metabolic rather than an inflammatory origin and should be discontinued*. Similarly, the term "skeletal scurvy" is purely historic and is inappropriate.

Metaphyseal osteopathy is a *disease of young growing dogs*, mainly those of large and giant breeds, although Weimaraners are over-represented in published reports. Affected dogs are usually 3–6 months of age at the time of initial presentation and typically show signs of fever, anorexia and severe lameness associated with swelling and pain of the metaphyseal regions of long bones. Some animals are reported to show diarrhea, or some other clinical abnormality, 7–10 days prior to the onset of fever. The *distal radius and ulna* are usually most severely affected but all fast-growing bones including ribs may be involved. Bones distal to the tarsus and carpus are usually spared. Radiographs taken early in the disease show alternating radiodense and radiolucent zones in the metaphysis parallel to the physis, and there is often lipping of the metaphyseal margins. Acute lesions are characterized grossly by a narrow band of pallor in the primary spongiosa adjacent to rapidly growing physes. Infractions (antemortem or postmortem) may be present through the primary spongiosa of some bones (Fig. 1.96) reflecting the fragility of the trabeculae in these areas of acute inflammation.

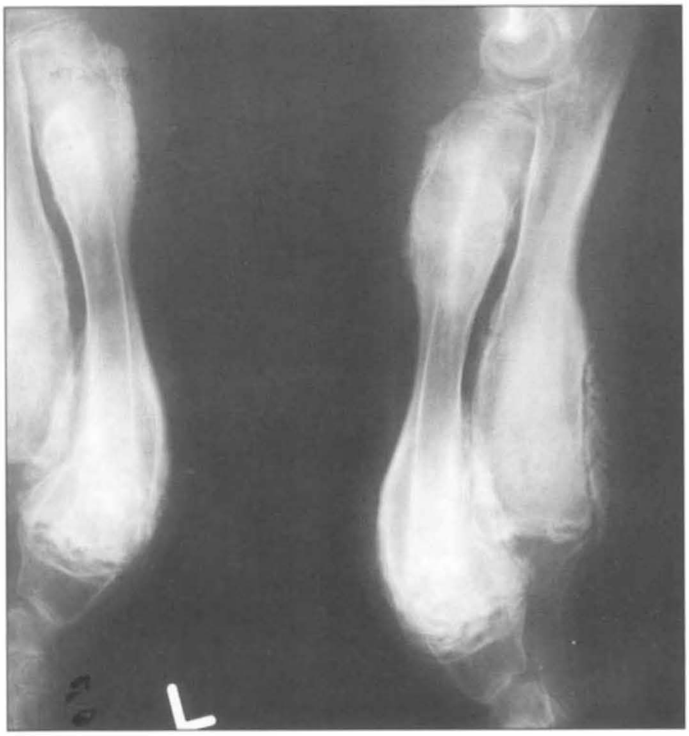

Figure 1.97 Metaphyseal osteopathy, dog. Radiograph of chronic lesion with extensive periosteal reaction involving the radius and ulna.

In most cases, the lesion does not progress but in others, periosteal and extraperiosteal ossification develops and the ends of the long bones become swollen and hard. Occasionally these swellings are extensive and involve almost two-thirds of the length of the bone, excluding only the mid-diaphysis and epiphyses (Fig. 1.97). The lesions are *usually bilaterally symmetrical*. Remissions and exacerbations may occur over a period of weeks to months and, rarely, a chronically affected dog dies or, more commonly, is killed for humane reasons. Most animals recover completely without, or in spite of, treatment and the excess metaphyseal bone is gradually removed.

The *histologic lesions* in acute cases are characteristic. The growth plates and primary spongiosa are structurally normal but there is *persistence of the calcified cartilage lattice of the primary spongiosa and intense intertrabecular, suppurative inflammation with necrosis and disappearance of osteoblasts* (Fig. 1.98A, B). Deposition of osteoid on the calcified cartilage spicules of the primary spongiosa is absent and the delicate trabeculae frequently fracture. Osteoclastic activity is prominent in some areas. The suppurative inflammation and necrosis of marrow contents may extend throughout much of the metaphysis and fibrin thrombi may be present in small blood vessels. Aggregates of segmented neutrophils are often present in the periosteum, associated with hemorrhages, as well as in cartilage canals of the epiphyses, and in bones such as vertebrae, mandibles, and turbinates. Enamel hypoplasia associated with inflammation of the dental crypt may also occur.

If the disease progresses, periosteal and extraperiosteal woven bone may develop in areas of previous hemorrhage and inflammation, eventually forming a collar of bone around metaphyses. At the same

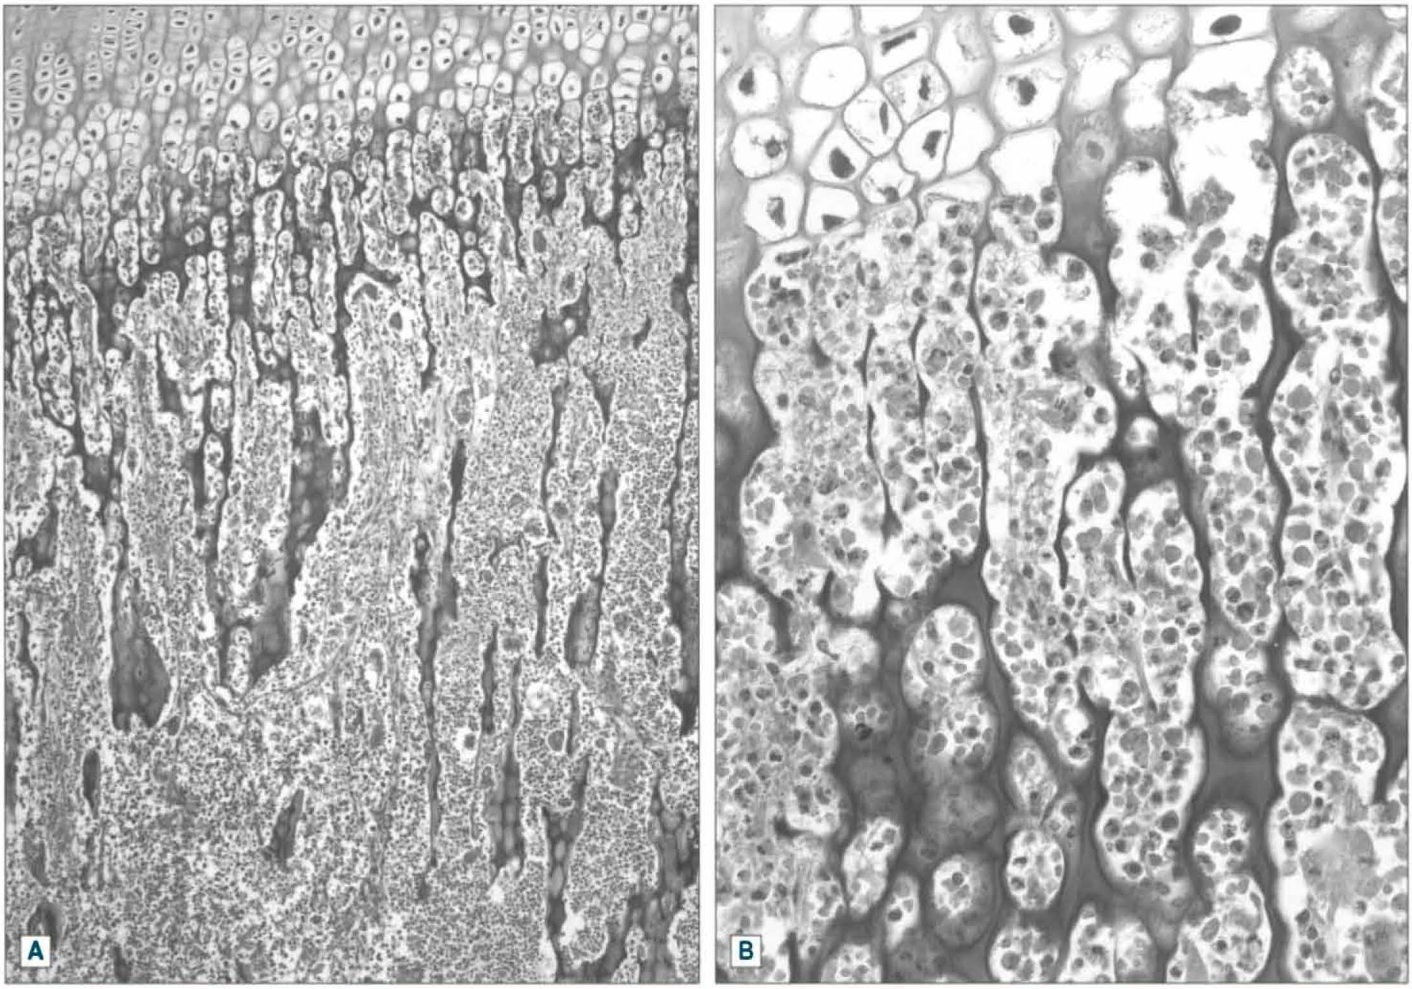

Figure 1.98 Metaphyseal osteopathy, dog. **A.** Acute disease showing normal physis and intense inflammatory reaction between trabeculae in the primary and secondary spongiosa. Trabeculae are delicate and consist largely of calcified cartilage with little, if any, osteoid. **B.** Higher-power view of primary spongiosa from the same animal. Calcified cartilage spicules devoid of an osteoid layer are separated by neutrophils and necrotic cellular debris. No osteoblasts are apparent.

time there is proliferation of mesenchymal tissue in the marrow spaces, replacing the suppurative exudate and providing precursor cells for the reconstruction of the damaged tissues. In those animals that have recurrences of the disease, acute inflammatory changes are superimposed on the osteogenic fibrous tissue in marrow spaces. Radiologically, the collar of periosteal bone may obscure metaphyseal lesions.

Although there have been numerous proposed causes for metaphyseal osteopathy, none has been proven. Initial reports suggested vitamin C deficiency as a likely cause because of the radiographic similarity between this disease and scurvy of children, but the histological changes are quite different and, in cases of metaphyseal osteopathy where liver levels of ascorbic acid were measured, they were normal. Hypervitaminosis D and "overnutrition" have also been incriminated, but neither of these, nor imbalances of other nutrients such as calcium, phosphorus, or vitamin A would be expected to produce the inflammatory lesions typical of metaphyseal osteopathy. Arguments in support of a nutritional cause are unconvincing. Based on clinical signs, the suppurative nature of the early lesions, and their predilection for osteochondral complexes of metaphyses and epiphyses, *an infectious etiology, probably bacterial, seems likely*. This possibility was suggested in an excellent description of metaphyseal osteopathy in a litter of Weimaraner pups, which also had suppurative lesions in soft tissues (see Woodard 1982). Although hematogenous osteomyelitis is considered uncommon in dogs, it is a consistent feature of Border Collie puppies with an inherited form of persistent neutropenia, and occurs in some puppies that survive canine parvovirus infection, probably following bacteremia established during a period of neutropenia. The lesions in affected animals are indistinguishable from those of metaphyseal osteopathy (Fig. 1.99). Further support for an infectious etiology in metaphyseal osteopathy is provided by the demonstration of *E. coli* bacteremia in a dog with characteristic radiographic lesions.

A possible link has been suggested between metaphyseal osteopathy and canine distemper vaccination, at least in Weimaraner puppies, but radiographic evidence has not been supported by histopathology. Canine distemper virus mRNA has been detected in osteoblasts and osteoclasts from metaphyseal bone of dogs with metaphyseal osteopathy, but viral mRNA can also be detected in the metaphysis of distemper-infected dogs without metaphyseal osteopathy. Canine distemper virus is known to induce metaphyseal sclerosis secondary to its action on osteoclasts (see above), but this change does not resemble the suppurative, inflammatory lesion of metaphyseal osteopathy.

Based on the clinical and histological evidence available, the concept of an infectious, probably bacterial, etiology for metaphyseal osteopathy is the most appealing. This does not however imply the involvement of a specific agent. Several bacteria are known to cause hematogenous osteomyelitis in other species, and a similar range of organisms may be involved in dogs. Proof of bacterial infection in metaphyseal osteopathy is difficult as most affected animals survive, and those that are subjected to postmortem examination are usually either at an advanced stage of the disease or have been treated with antibiotics prior to death or euthanasia. In reality, many cases of metaphyseal osteopathy caused by bone infection in dogs could remain undetected, especially in dogs that are able to re-establish an effective immune response and eliminate the infection. Perhaps clinical disease is confined to animals with defective immunity or those that receive an overwhelming infection during a period when their defense mechanisms are reduced by an immunosuppressive viral infection.

Canine panosteitis

Canine panosteitis (panostosis, juvenile osteomyelitis, enostosis, eosinophilic panosteitis) is a disease of unknown cause that, like metaphyseal osteopathy, usually affects dogs of the large and giant breeds between 5–12 months of age. Occasionally, small dogs such as Miniature Schnauzer and Scottish Terrier are affected and the age range extends from 2 months

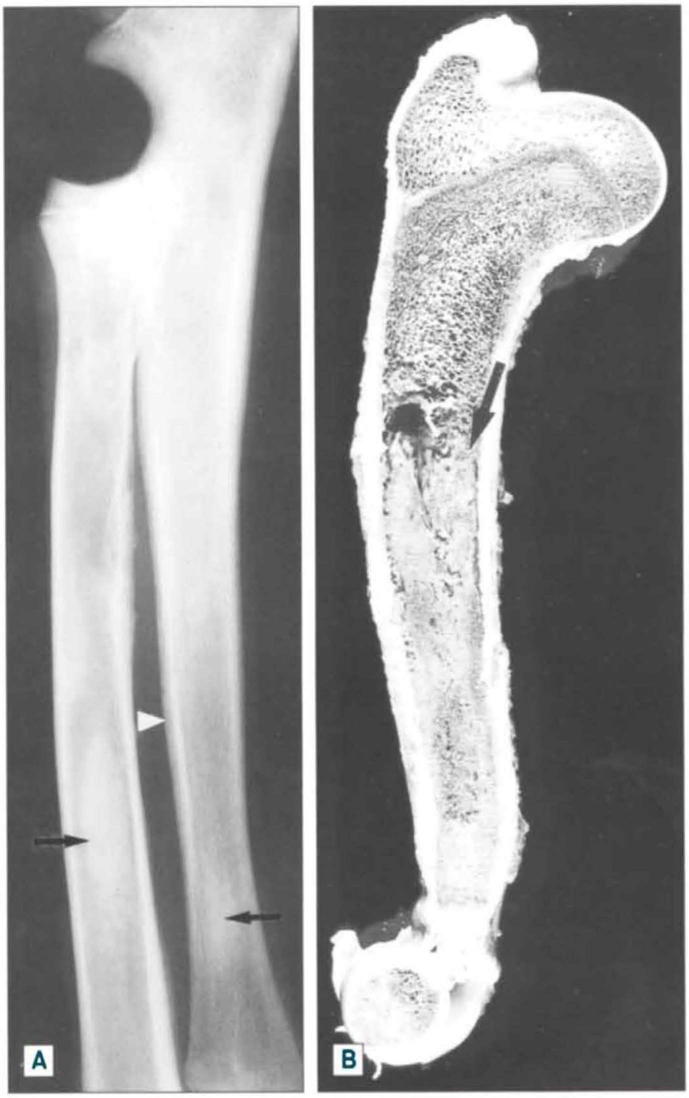

Figure 1.100 Panosteitis, dog. **A.** Radius and ulna showing focal and diffuse medullary densities (arrows) and periosteal reaction (arrowhead). (Courtesy of DC Van Sickle.) **B.** Humeral marrow distal to arrow is filled with woven bone.

to 5 years. The disease was first described as eosinophilic panosteitis of German Shepherds and 75% of reported cases involve this breed. More than two-thirds of affected dogs are males. Although an inflammatory origin for panosteitis is not convincing, the disease is included here for convenience.

Clinical signs vary from *mild to severe lameness*, which may shift from one bone to another. The disease is prone to remission and exacerbation, and is *usually self-limiting* after one to several months. The lameness is associated with abnormalities in the diaphysis of a long bone, usually in the foreleg. Multiple bone involvement occurs in about 50% of cases and rarely, other bones such as ilium and metatarsals are affected.

Because the disease is self-limiting and is well recognized by radiologists, pathologic studies are few and the lesions are defined in terms of their radiographic appearance. At the time when clinical signs begin, no lesions may be visible. About 10 days later, initial involvement of the long bone is seen as an increased density or densities of the medulla in the region of the nutrient foramen. The density may increase in size, sometimes filling the entire medullary cavity, or may remain localized (Fig. 1.100A, B). If the reaction extends to the cortex, marked cortical thickening may result due to periosteal proliferation. When the animal recovers, the increased density disappears over a period of weeks to months.

The initial increased radiodensity is due to expanding areas of fibrovascular tissue in the bone marrow, which are rapidly replaced by woven bone (Fig. 1.101A). This bone is subject to consecutive episodes of formation and resorption, thus reversal and resting lines are often present in the same trabeculae, and osteoclasts and osteoblasts are active in the same microscopic field. Cartilage is sometimes formed in the fibrovascular tissue. Periosteal woven bone formation may be stimulated and this, like the medullary bone, is replaced by lamellar bone before being replaced over the ensuing months (Fig. 1.101B). The older, more mature bone in the center of the medullary lesions is removed first.

In most dogs, there is no evidence of inflammatory infiltrates in the lesions, but sometimes plasma cells and histiocytes are present. Eosinophilia is an inconstant feature of the hemogram and serum chemistry is unremarkable. Abnormalities in clotting times are inconstant findings.

The cause of canine panosteitis is not known. Genetic and allergic factors, hyperestrogenism, filterable agents, and various bacteria have been proposed, but the evidence is inconclusive. A viral etiology, particularly *Canine distemper virus*, has also been suggested because of the pyrexia, tonsillitis, and leukocytosis that occur in some cases. In females, the onset of signs is sometimes associated with estrus and it is thought that other physiological stress may precipitate the disease. The occurrence of panosteitis in dogs with hemophilia A suggests that sometimes the disease might be a sequel to intraosseous hemorrhage.

HYPEROSTOTIC DISEASES

Excessive bone formation or hyperostosis occurs as a nonspecific response to various forms of bone injury, including trauma, infection, metabolic disturbances, mineral and vitamin imbalances, subperiosteal hemorrhage, and neoplasia. Many of these have been discussed already in this chapter. The periarticular exostoses or osteophytes that develop in association with degenerative joint disease further illustrate this predictable response of bone to injury or inflammation in adjacent tissues. This section includes a group of poorly understood diseases of humans and animals, characterized by marked hyperostosis in the absence of any apparent cause.

Craniomandibular osteopathy

Craniomandibular osteopathy, also known as *"lion jaw", is a proliferative disorder usually confined to the bones of the skull, in particular the mandibles, occipital, and temporal bones.* The tympanic bullae are often severely affected. Lesions are bilateral but irregular and may also involve the parietal, frontal, and maxillary bones. Occasionally, there is subperiosteal and extraperiosteal proliferation of new bone associated with long bones. The disease is most common in West Highland White Terriers, but is also described in several other breeds, including Scottish Terriers, Labrador Retrievers, Great Danes, Doberman Pinschers, Cairn Terriers, German Wirehaired Pointers, Pyrenean Mountain Dogs, and in a Boxer, a Boston Terrier and an English Bulldog.

The disease is usually recognized at approximately 4–7 months of age because of either discomfort while chewing or inability to open the mouth to eat. Proliferative changes may be palpable or grossly visible, and pain is elicited when attempting to open the mouth. Radiographic findings are characterized by more or less symmetrical enlargement of the mandibles and tympanic bullae, although the lesions may occur independently. Ossification of soft tissues, especially near the angular processes of the mandibles, may result in fusion of the processes to the bullae and ankylosis. The disease has an intermittent, progressive course lasting several weeks to a few months. It is often self-limiting and nonfatal, although some dogs are killed because they cannot eat. During clinical exacerbations, which tend to recur every 2–3 weeks, fever is present but laboratory data are normal.

At the height of the disease, atrophy of the muscles of mastication and increased fibrous and osseous tissue of the head are obvious. The full extent of the bone changes is best demonstrated in radiographs and macerated specimens (Fig. 1.102). In the mandible, new bone deposition is usually most prominent in the region of the angle, involving medial, ventral, and lateral aspects but tending to avoid the alveolar bone. The tympanic bullae are often enlarged two to three times and filled with new bone.

Histologic changes in the mandible involve the endosteum, periosteum, and trabecular bone and present a complex pattern of intermittent and concurrent formation and resorption. The mosaic of reversal and resting lines resulting from this cellular activity (Fig. 1.103) bears some resemblance to the changes seen in Paget's disease of man, but further comparison is unjustified. The significance of this mosaic pattern is easily overemphasized since the mandible of growing dogs is a site of intense bone modeling as teeth mature, erupt, and drift during normal development. Bone resorption in craniomandibular osteopathy appears to be random and disoriented, involving both pre-existing lamellar trabeculae and newly formed woven bone. Similarly, bone formation occurs simultaneously in many areas, evolving from fibrous tissue, which frequently fills the marrow

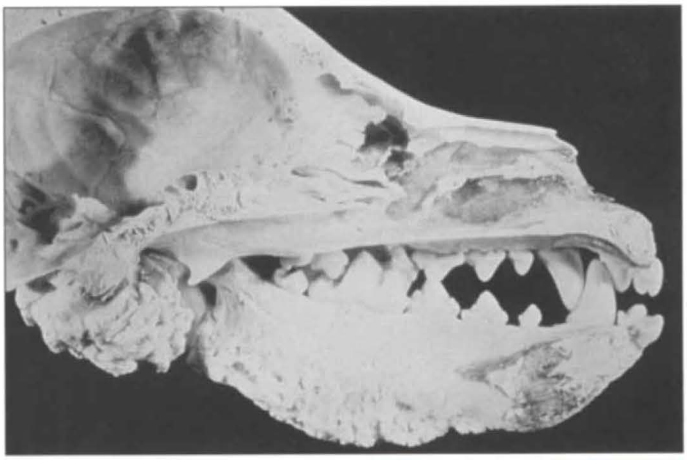

Figure 1.102 Craniomandibular osteopathy, dog. Macerated specimen showing extensive new bone formation along the mandible and around the tympanic bulla.

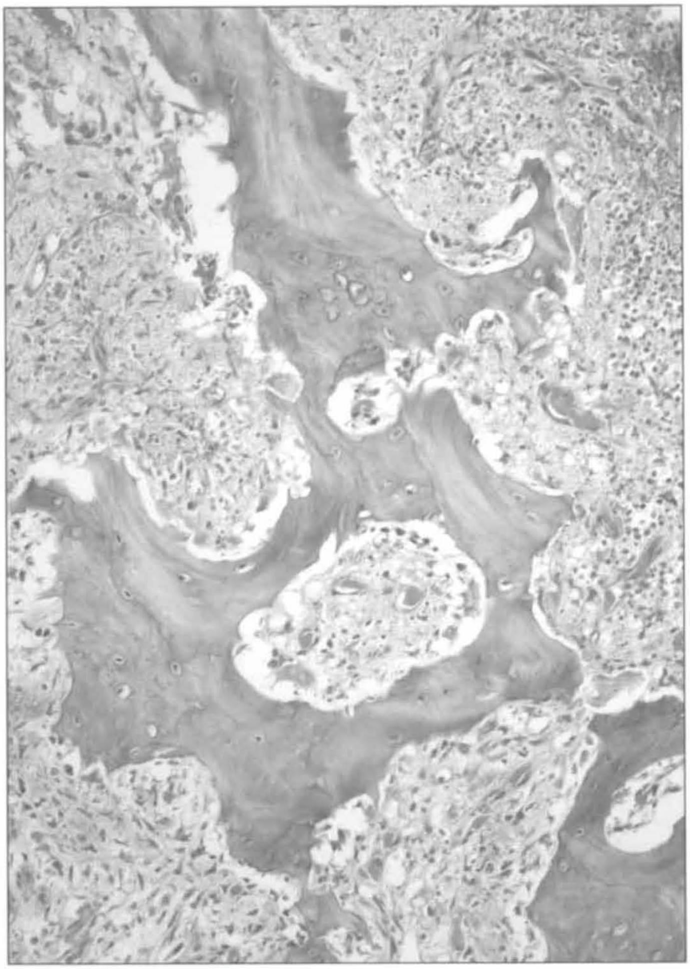

Figure 1.103 Craniomandibular osteopathy, dog. Ragged bone trabeculae with scalloped margin indicating active osteoclastic resorption. The trabeculae contain a mosaic of woven and mature lamellar bone demarcated by cementing lines.

spaces and thickens the periosteum. Lymphocytes, plasma cells, and neutrophils are sometimes present in areas of active osteogenesis.

As the disease subsides, formation of woven bone may be superseded by lamellar bone production, and existing woven trabeculae are replaced by lamellar bone, which is then gradually resorbed. In some cases, especially where fusion of mandibles to tympanic bullae is present, resorption is insufficient to allow restitution of normal function.

The cause of craniomandibular osteopathy is not known. The presence of inflammatory infiltrates raises the possibility of an infectious agent, but none has been demonstrated. In West Highland White and Scottish Terriers, there is evidence of a genetic etiology with autosomal recessive inheritance. However, the occurrence of the syndrome in diverse breeds suggests that there may be more than one cause of the condition. Alternatively, there may be an inherited predisposition in several breeds but the presence of an additional factor, perhaps an infectious agent, is required for the disease to be expressed. The etiology and pathogenesis of a similar condition in children, infantile cortical hyperostosis, are also unknown.

Hypertrophic osteopathy

This syndrome, which is also known as "Marie's disease" or hypertrophic pulmonary osteopathy, is characterized by diffuse, periosteal new bone formation along the diaphyses and metaphyses of certain limb bones in association with a chronic inflammatory or neoplastic lesion, usually in the thoracic cavity. It occurs in humans, and is reported in several domestic animal species, most often dogs. Occasionally, hypertrophic osteopathy occurs in association with nonthoracic lesions, such as botryoid rhabdomyosarcoma of the urinary bladder in dogs and ovarian tumors in horses. Rarely, the disease occurs in animals with no detectable visceral lesions.

The thoracic lesions associated with hypertrophic osteopathy are diverse. In dogs, it occurs most often with primary or secondary pulmonary neoplasms, but also with granulomatous pleuritis, granulomatous lymphadenitis of bronchial or mediastinal nodes, chronic bronchitis, *Dirofilaria immitis* infection, esophageal granulomas, and tumors provoked by *Spirocerca sanguinolenta,* and with neoplastic disease of the thoracic wall. In horses, it is more often associated with granulomatous inflammatory diseases involving the thoracic cavity. Hypertrophic osteopathy is present only in a minority of animals with thoracic lesions, but the incidence is much higher in some types than in others. For example, dogs with pulmonary metastases from osteosarcoma are much more likely to develop the syndrome than are dogs with metastatic carcinoma. It is also possible that many mild cases of hypertrophic osteopathy are missed both clinically and through incomplete examination of the limb bones at necropsy.

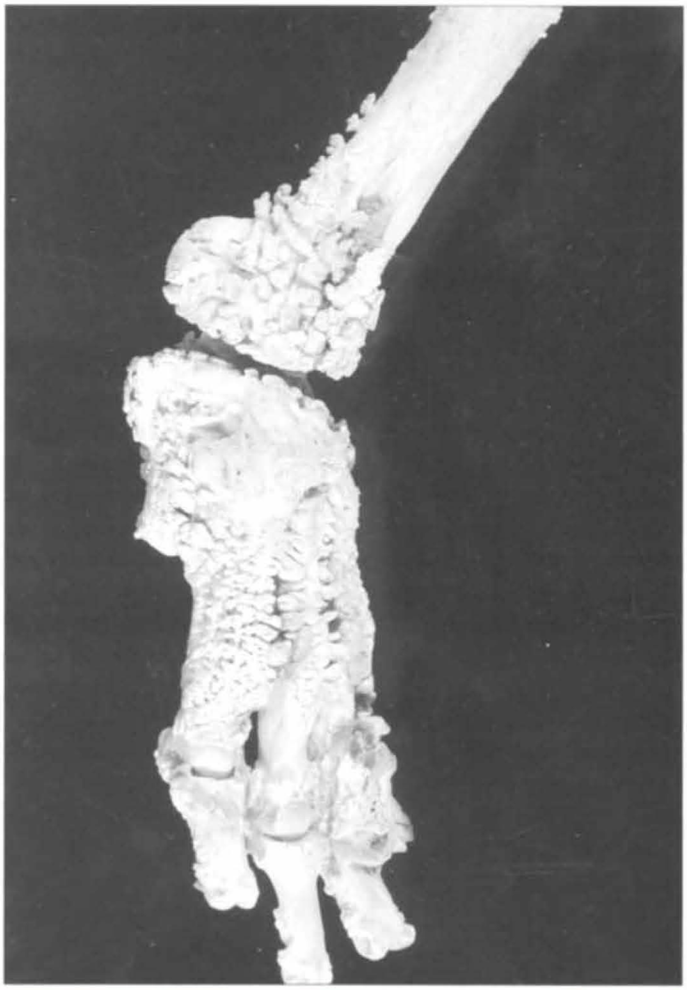

Figure 1.104 Hypertrophic osteopathy, dog. Periosteal new bone involving the metacarpals and radius-ulna, but with relative sparing of the phalanges.

The *periosteal new bone formation in hypertrophic osteopathy is usually confined to the limbs*, and in the dog, involves particularly the radius, ulna, tibia, metacarpals, and metatarsals, with relative sparing of the bones of the upper limbs and phalanges (Fig. 1.104). The more distal limb bones are generally affected first, the lesions then extending proximally. The extent of the osteophytes is best demonstrated in radiographs and macerated specimens where, in florid cases, they appear as wart or cauliflower-like accretions extending along the whole length of the bone (Fig. 1.105). Cross-sections of bone demonstrate the asymmetric development of these accretions, which tend to occur initially and most severely where the periosteum is free of tendinous insertions or adjacent bones. Occasionally, osteophytes occur on the vertebrae and skull, and minor endosteal lesions occur infrequently. *Articular surfaces are not involved in animals but are often affected in human cases*, hence the frequent use of the term hypertrophic osteoarthropathy for the human disease. Although the lesions of hypertrophic osteopathy are progressive, they regress if the primary thoracic lesion is removed.

Histologically, the earliest changes are hyperemia and edema, with proliferation of highly vascular connective tissue in the periosteum, in some cases leading to extensive hemorrhage. These changes are associated with a rapid increase in peripheral blood flow in the distal half of the limbs and may be accompanied by a light infiltrate of lymphocytes and plasma cells. Shortly thereafter, osteoblasts deposit osteoid on the existing cortical bone and then, if the disturbance is severe, begin to lay down new trabeculae perpendicular to the original cortex. The new bone may be deposited with extraordinary rapidity, and the width of the cortex may be doubled in a few weeks. In the early and active stages of the disease, the new bone is clearly distinguishable from the original cortex because the former is trabecular and the latter compact. Later, the distinction may be less distinct because the original cortex is converted to spongy bone by resorption from within the vascular canals and the endosteal surface.

The *pathogenesis of hypertrophic osteopathy is obscure* but increased blood flow to the limbs is a consistent early change. Several hypotheses have been proposed, including hypoxia, arteriovenous shunting, neurogenic and humoral mechanisms, but none consistently fits the clinical and experimental observations. According to the *neurogenic theory*, impulses originating in the thoracic lesion travel via the vagus nerve to the brainstem and initiate reflex vasodilation in the limbs, either by humoral or neural means. Limited support for this theory is provided by the regression of bone lesions in some, but not all, human and canine cases treated by vagotomy. The *humoral hypothesis* proposes either that the primary lesion produces a hormone or hormone-like substance or that arteriovenous anastomoses in the primary lesion prevent catabolism of such a substance in the lung. The hormone then produces the secondary skeletal lesions. Support for this hypothesis is derived from the production of typical skeletal lesions following experimental venoarterial shunts in dogs, but there is no evidence of such shunts in most spontaneous cases. In a very limited number of cases, Marie's disease has been restricted to one limb, and vascular abnormalities are generally found in those cases. It has also been suggested that reduced oxygenation of peripheral blood, resulting from congenital or acquired arteriovenous shunts, stimulates periosteal osteophyte production. More recently, it has been proposed that the primary lesion in hypertrophic osteopathy might cause inappropriate stimulation of an extra-renal volume receptor system controlled by innervation of blood vessels by branches of the vagus and glossopharyngeal nerves. It is suggested that stimulation of this system as a result of blood flow in anomalous vascular channels associated with the primary thoracic lesion, may activate the cerebral salt center leading to retention of extracellular sodium, fluid retention, and increased blood supply to the limbs. This does not however explain the occurrence of hypertrophic osteopathy in animals in association with tumors of the urinary bladder or ovary.

Canine diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis is a hyperostotic disorder of man that appears to have a counterpart in dogs, particularly large and giant breeds such as Labrador Retrievers and Great Danes. *The disease in dogs is characterized by progressive new bone formation along vertebral bodies, sometimes leading to fusion; progressive osseous fusion of the ilium, pubis, femur, and ischium; and development of para-articular bony lesions around certain joints of the appendicular skeleton.*

The vertebral exostoses tend to occur at ligamentous insertions (enthesiophytes) and appear to vary in their distribution between different regions of the spine. The lesions are more extensive than those of ankylosing spondylosis, involving the ventral and lateral aspects of three or more contiguous vertebral bodies, and are not accompanied by evidence of disk degeneration. Furthermore, the new bone formation also occurs on vertebral arches, dorsal spinous processes, and articular processes, where it is very unlikely to be associated with degenerative disk disease. The initial para-articular lesions in the appendicular skeleton are fibrocartilaginous, but undergo endochondral ossification to produce bony lesions, which may progress to result in joint fusion. Intra-articular structures are not affected.

There are several other hyperostotic diseases in dogs that must be differentiated from diffuse idiopathic skeletal hyperostosis. These include ankylosing spondylosis, spondylosis deformans, spinal osteoarthrosis, vitamin A toxicity, and hepatozoonosis, all of which are discussed elsewhere in this chapter. *Radiographic criteria* that might suggest a diagnosis of diffuse idiopathic skeletal hyperostosis in dogs include the following:

- flowing calcification and ossification along ventral and lateral aspects of three contiguous vertebral bodies leading to bony ankylosis;
- preservation of normal disk width in affected areas and absence of significant degenerative disk disease, such as end-plate sclerosis, nuclear calcification and localized spondylosis deformans;
- osteophytes around vertebral articular facets;

- formation of pseudoarthroses between the bases of spinous processes;
- periarticular osteophytes in addition to calcification and ossification of soft-tissue attachments (enthesiophytes) in the axial and appendicular skeleton;
- periarticular osteophytes, sclerosis and ankylosis of sacroiliac joints; and
- bony ankylosis of the symphysis pubis.

The presence of any four of the first five criteria is considered sufficient to support the diagnosis.

The *etiology of diffuse idiopathic skeletal hyperostosis is unknown*, but it appears to represent an exaggerated response to stimuli that would normally induce little, if any new bone formation. For this reason, *the disease has been referred to as an ossifying diathesis*. In human patients with diffuse idiopathic skeletal hyperostosis, excessive heterotopic ossification occurs after hip surgery, and in dogs, the formation of periarticular osteophytes is out of proportion to any degenerative changes in the associated joint. No predisposing cause can be found for most of the skeletal lesions in this syndrome but their close association with joints, and insertion sites for ligaments, tendons, and muscles cannot be ignored. Perhaps minor traumatic episodes at these sites result in excessive local production of specific growth factors, (e.g., TGF-β, FGFs, and BMPs) in susceptible individuals.

Canine hepatozoonosis

Periosteal new bone formation, similar to that occurring in hypertrophic osteopathy, is a feature of canine hepatozoonosis caused by *Hepatozoon americanum* infection of dogs in the southern USA. The osseous lesions also consistently develop in experimentally infected dogs and coyotes. *The periosteal reaction occurs primarily on the diaphyseal regions of the more proximal limb bones* (Fig. 1.106A), but also may involve bones of the axial skeleton, including the ilium (Fig. 1.106B) and vertebrae, the lesions differing in distribution to those of hypertrophic osteopathy. In early reports of canine hepatozoonosis, it was suggested that the periosteal new bone formation was secondary to local irritation caused by the presence of *Hepatozoon americanum* cysts in adjacent muscle fibers. The absence of microscopic evidence to support this hypothesis, and the widespread, often symmetrical, distribution of lesions *suggests that humoral rather than local factors are involved in the pathogenesis of the bony lesions.*

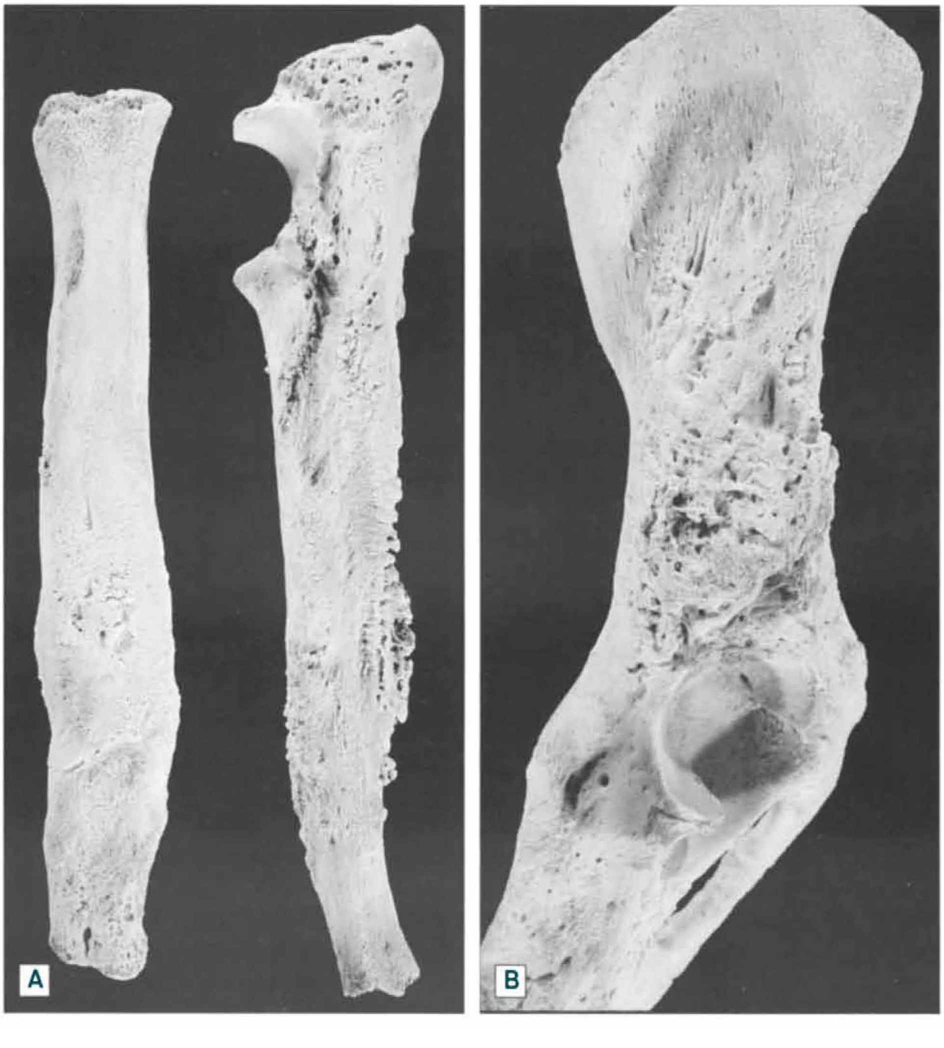

Figure 1.106 Canine hepatozoonosis. A. Periosteal reaction along the diaphyses of the radius and ulna of a 1-year-old dog that had been infected with *Hepatozoon americanum* for approximately 9 months. **B.** Ilium from the same dog, showing prominent periosteal reaction.

Clinical signs of canine hepatozoonosis include pyrexia, depression, weakness, muscle atrophy, and gait abnormalities ranging from stiffness to recumbency. Leukocytosis due to mature neutrophilia, and sometimes a left shift, is a consistent laboratory finding. The disease leads to *chronic debilitation and eventual death*. Different stages of this protozoon agent may be found in skeletal muscles throughout the body, often inducing a pyogranulomatous inflammatory response. The parasite is not present in bone, but may be detected in muscle fibers close to the periosteal surface. Except for a single report from Japan, periosteal new bone formation has not been described in association with *Hepatozoon canis* infection, which occurs in the Old World. The agent of canine hepatozoonosis in North America was initially considered a more virulent strain of *Hepatozoon canis*, but differences in the nature and distribution of lesions, in addition to morphologic differences in gamonts, led to its classification as a separate species.

TUMORS AND TUMOR-LIKE LESIONS OF BONES

Primary tumors of bones are common in dogs and to a lesser extent in cats, but occur infrequently or rarely in other domestic animals. They may arise from any of the mesenchymal tissues present in bones, including precursors of bone, cartilage, fibrous tissue, adipose tissue, and vascular tissue, but *tumors of bone and cartilage-forming cell lines are the most common*. In humans, most primary tumors of bones are benign but this does not apply to all animal species. In dogs, most tumors of bones are malignant. Benign and malignant tumors of bones occur with approximately equal frequency in cats, but in horses, cattle, and other domestic animals, benign tumors of bones are much more common than malignant ones. Secondary tumors of bones, in particular metastatic carcinomas, are very common in humans but are seldom diagnosed in animals. The prevalence of secondary bone tumors in animals is no doubt underestimated as the skeleton is seldom examined in detail either radiographically or at necropsy, but it is almost certainly much lower than in humans. Several comprehensive surveys and reviews of bone tumors have been published and are included in the bibliography at the end of this section.

The classification of primary tumors and tumor-like lesions of bones in domestic animals is generally similar to that developed for humans, but there are too many differences in morphology and prognosis to allow direct extrapolation. The system used in this chapter is based on that proposed in the most recent World Health Organization fascicle on *Histological Classification of Bone and Joint Tumors of Domestic Animals* (Table 1.3). Rather than discuss benign and malignant tumors separately, as in the WHO system, the most important of these tumors will be grouped according to the nature of the predominant matrix that they produce. This reflects the manner in which a pathologist is likely to approach the diagnosis of a bone tumor.

Table 1.3 Histological classification of tumors and tumor-like lesions of bones*

Benign tumors
- Chondroma
- Feline osteochondromatosis
- Hemangioma
- Myxoma of the jaw
- Ossifying fibroma
- Osteoma
- Osteochondroma

Malignant tumors
- Central
    1. Chondrosarcoma
    2. Fibrosarcoma
    3. Giant cell tumor of bone
    4. Hemangiosarcoma
    5. Liposarcoma
    6. Multilobular tumor of bone
    7. Osteosarcoma
        a. poorly differentiated
        b. osteoblastic
            — nonproductive
            — productive
        c. chondroblastic
        d. fibroblastic
        e. telangiectatic
        f. giant cell type
- Peripheral
    1. Maxillary fibrosarcoma (dogs)
    2. Parosteal osteosarcoma
    3. Periosteal chondrosarcoma
    4. Periosteal fibrosarcoma
    5. Periosteal osteosarcoma
- Tumors of bone marrow
    1. Malignant lymphoma
    2. Plasma cell myeloma

Tumor-like lesions
- Aneurysmal bone cyst
- Epidermoid cyst of the phalanx
- Exuberant fracture callus
- Fibrous dysplasia
- Solitary (unicameral) bone cyst
- Subchondral (juxtacortical) bone cyst

**Based on World Health Organization International Histological Classification of Tumors of Domestic Animals.*

It is often difficult to classify a bone tumor into one category or another with confidence, as the predominant matrix may vary throughout the tumor and poorly differentiated sarcomas may reveal little evidence of their lineage. Since the prognosis of different bone tumors varies markedly, accurate classification by the pathologist will greatly assist the clinician or surgeon and should be attempted, but only in cases where sufficient tissue and information is provided. The pathologist must not feel pressured into making a definitive diagnosis in cases where either the specimen or the history is inadequate. There are many benign lesions of bones that may resemble malignant bone tumors and the consequences of an incorrect diagnosis can be substantial.

The clinical history and radiographic appearance are often crucial to an accurate diagnosis of a bone lesion and the pathologist should not rely on microscopic features alone. In addition to knowledge of the species, breed, and age of the animal, it is important to be aware of the location of the lesion and its duration. Certain bone tumors in man and animals occur with increased frequency at specific sites, hence the value of knowing the exact location of the lesion. It is also important to know if there has been a previous fracture or infection at the site, or whether the animal has recently suffered from a systemic disease or soft tissue tumor, which may have spread to the bone. Radiographs provide valuable additional information on the extent, nature, and behavior of a bone tumor. They can also be of considerable value to the surgeon or pathologist in establishing a list of likely differential diagnoses, and selecting sites for histological or cytological examination. Radiographs of a bone lesion at necropsy will often provide more information of diagnostic relevance than gross examination of the affected bone, but the radiographic appearance can seldom allow reliable differentiation of primary tumors, secondary tumors, and inflammatory lesions of bones.

Proliferation of new, woven bone is a common response to various forms of bone injury and should not be misinterpreted as osteosarcoma. This reactive bone may be deposited beneath an elevated periosteum and form the so-called *Codman's triangle* (see Fig. 1.16), which often occurs in osteosarcoma but also in other lesions where the periosteum is separated from the underlying bone. When the periosteum is breached, the radiating spicules of reactive bone expanding out from the original lesion may create a "sunburst" effect in radiographs. Reactive bone is not confined to the periosteal surface. Many primary and secondary tumors growing within the bone marrow stimulate endosteal new bone formation, as do many inflammatory lesions. In the early stages of formation, reactive bone consists of rapidly proliferating, immature mesenchymal cells producing spicules of unmineralized osteoid. These spicules usually merge with broader trabeculae of woven bone lined by a single layer of plump osteoblasts (Fig. 1.107), unlike osteosarcoma, where the spaces between spicules or islands of tumor bone are generally filled with malignant osteoblasts (see Fig. 1.109B). However, in small biopsy samples, differentiation of early reactive bone from osteosarcoma may be extremely difficult, if not impossible.

In addition to new bone formation, *osteolysis is also a feature of many bone tumors* and osteoclasts can often be seen resorbing mature bone as the advancing tumor permeates the marrow cavity or invades the cortex. The gross and radiographic appearance of a bone tumor reflects the balance between bone resorption and new bone formation. *Biopsy samples, or samples collected for histology or cytology from a suspected bone tumor during necropsy, should always include areas of lysis, as these areas are most likely to contain cells of diagnostic significance.* Too often, samples submitted to the pathologist for examination consist entirely of reactive bone and no diagnosis is possible. In such cases, it is important that the pathologist does not exclude the possibility of an underlying tumor and if the history and radiographic appearance suggest neoplasia, examination of further biopsies, including areas of lysis, is recommended.

Bone-forming tumors

Osteoma, ossifying fibroma, and fibrous dysplasia

These benign tumors are uncommon in domestic animals and there is considerable confusion over their classification and diagnosis. All three arise primarily from the bones of the skull, particularly those bones that develop by intramembranous ossification. Fibrous dysplasia is not a true neoplasm of bones but is included in this group because of the need to differentiate it from osteoma and ossifying fibroma. Furthermore, some authors have suggested that osteomas are hamartomas rather than true tumors, while others claim that they represent the sclerotic end stage of fibrous dysplasia.

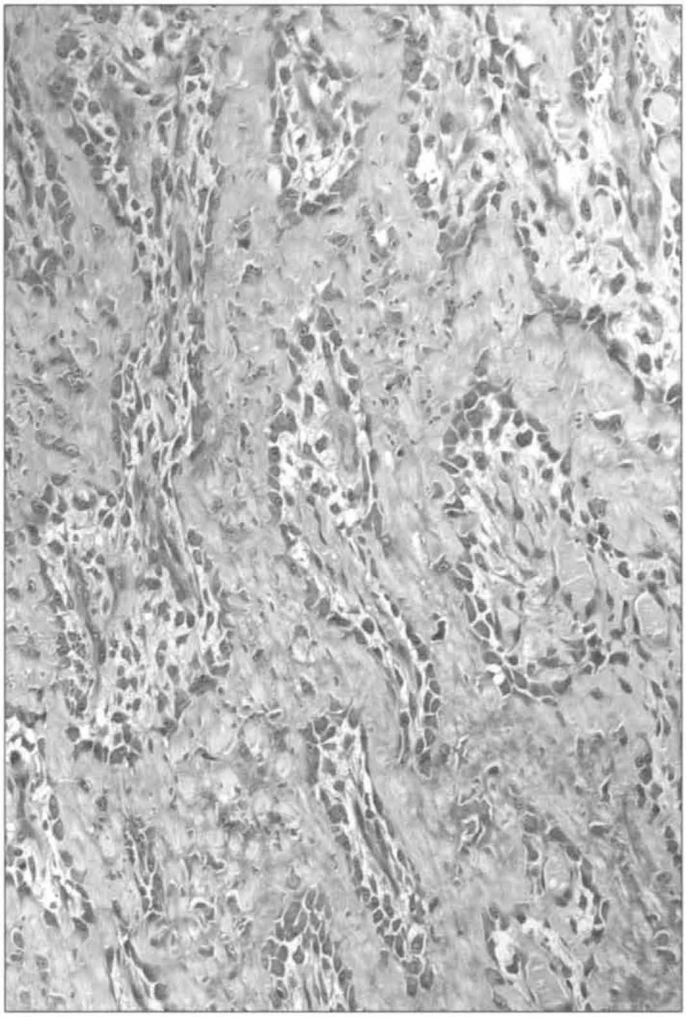

Figure 1.107 Trabeculae of **reactive, woven bone** lined by a single layer of plump osteoblasts.

An **osteoma** is a *dense, smoothly contoured, protruding mass of well-differentiated bone* originating from a periosteal surface and merging with the underlying bone. Exostoses induced by localized periosteal damage may closely resemble osteomas, but osteomas generally show *slow, progressive enlargement* and sometimes achieve a very large size. They are found most often in the mandible, maxilla, nasal sinuses, and bones of the face and cranium in horses and cattle, but also occur in other species. Osteomas occasionally arise from bones of the pelvis, or tubular bones of the limbs, and *must be differentiated from osteochondromas.* In osteochondroma, the bone forms by endochondral ossification beneath a cap of hyaline cartilage and there is continuity between the intertrabecular spaces of the tumor and the marrow cavity of the bone.

Osteomas are often extremely hard, especially if they have been growing for some time, and must be cut with a saw. Clinical signs, other than disfigurement, may be nonexistent or may relate to compression of adjacent structures.

Histologically, osteomas consist of trabecular bone formed by osteoblasts, remodeled by osteoclasts and ultimately converted almost entirely to *lamellar bone*. The trabeculae are gradually thickened by appositional growth so that ultimately the spaces between them are relatively inconspicuous, and the density of the tumor mass approaches that of mature cortex. Such tumors are virtually indistinguishable from exostoses; location and clinical history should be considered in differentiating the two. Actively expanding osteomas have a border of connective tissue resembling periosteum and the slender trabeculae forming beneath this layer are arranged approximately perpendicular to the surface. The superficial trabeculae of an osteoma may consist of woven bone while those in deeper regions are broader and consist largely or completely of lamellar bone.

Osteoid osteoma, a distinct form of osteoma in humans, has also been reported in a cat. This tumor is characterized by a discrete, intra-osseous nidus of active bone formation in which disorganized trabeculae are surrounded by a rim of sclerotic bone. The trabeculae of immature bone are lined by plump osteoblasts but show no evidence of malignancy.

Ossifying fibroma is a rare fibro-osseous tumor of the head, occurring most frequently in young horses less than a year of age, and primarily involving the rostral mandible. There are occasional reports of the tumor in cats, dogs, and sheep. Typically, ossifying fibroma is a sharply demarcated, expansile mass, which distorts the normal contours of the affected bone. The tumor *consists of spindle-shaped fibroblasts, which appear to transform into osteoblasts and form irregular spicules of woven bone*, which are lined by plump osteoblasts. Lamellar bone is extremely rare in ossifying fibroma, but may be formed where woven bone trabeculae are resorbed and replaced.

There are several lesions from which ossifying fibroma must be distinguished, including osteoma, fibrous dysplasia, osteosarcoma, and perhaps even fibrous osteodystrophy, especially in horses. In osteomas, the spaces between trabeculae may contain marrow rather than fibrous connective tissue, and the trabeculae are larger and denser with a much greater proportion of lamellar bone. The bone spicules of fibrous dysplasia are usually more uniform and are not rimmed by osteoblasts. The connective tissue cells of ossifying fibroma lack the pleomorphism and high mitotic index of osteosarcoma and the bone is formed in a more regular and uniform manner. Confusion with fibrous osteodystrophy is unlikely as long as an adequate history accompanies a small bone biopsy. The lesions of fibrous osteodystrophy are bilaterally symmetrical and large osteoclasts are often present amongst the loose connective tissue surrounding trabeculae of woven bone.

The biologic behavior of ossifying fibroma is obscure but *malignant transformation is not known to occur*. Bone is not an inert tissue and it seems reasonable that remodeling of woven trabeculae and replacement by lamellar bone within the tumor could occur. If so, then a maturing ossifying fibroma might eventually resemble an osteoma with hematopoietic cells colonizing spaces between trabeculae of lamellar bone.

Fibrous dysplasia is a rare, fibro-osseous lesion of bone that is thought to be a *developmental abnormality of bone-forming mesenchyme rather than a neoplasm*. It is characterized by smoothly contoured, expanding fibro-osseous lesions involving one or several bones. Although well documented in humans, there are few reliable reports of fibrous dysplasia in animals, but there seems little doubt that the condition does occur in several animal species, including horses, dogs, and domestic cats. As in humans, young animals are most commonly affected.

Some published reports of fibrous dysplasia in animals are questionable, the lesions in some cases appearing more consistent with ossifying fibroma. Furthermore, a description of familial canine polyostotic fibrous dysplasia in three Doberman Pinscher pups most likely represents a polyostotic form of unicameral bone cysts. It is also possible that some cases of fibrous dysplasia have been misdiagnosed as various tumors of bones.

Osteosarcoma

This malignant tumor is the most common primary neoplasm of the appendicular skeleton in dogs and cats. In general, it is a rapidly progressive tumor with early metastasis to the lungs leading to early mortality. Most osteosarcomas arise from within bones, particularly in the metaphyseal regions of long bones, and are referred to as **central osteosarcomas**. Less commonly, osteosarcomas arise in the periosteum or even in extraskeletal tissues. Two types of **peripheral osteosarcoma** may arise in the periosteum. One is referred to as **periosteal osteosarcoma** and may show similar biologic behavior to central osteosarcoma; the other is **parosteal (juxtacortical) osteosarcoma**, which shows greater differentiation, slower growth, and a much better prognosis than central osteosarcoma.

Osteosarcoma accounts for approximately 80% of primary bone tumors in dogs and 70% in cats. In **dogs**, the mean age of occurrence is around 7.5–8 years, but the range is broad and animals less than 2 years of age are sometimes affected. The tumor occurs predominantly in large and medium-sized breeds and has a strong site preference. The appendicular skeleton is affected three to four times as often as the axial skeleton and the forelimbs 1.6–1.8 times as often as the hindlimbs. Most osteosarcomas in the forelimbs involve the *metaphyses of either the distal radius or proximal humerus* (Fig. 1.108A). The *distal femur and proximal tibia* (Fig. 1.108B) are favored sites in the hindlimb. Approximately 50% of osteosarcomas of the axial skeleton occur in bones of the head and 50% in the ribs, vertebrae, and pelvis. Osteosarcomas of the appendicular skeleton occur more often in male dogs than in females, but this sex difference does not appear to apply to tumors of the axial skeleton. In addition to the sites mentioned above, osteosarcomas occasionally occur at sites of chronic irritation and repair, such as those associated with osteomyelitis, bone infarcts, or the presence of an internal fixation device. In such cases, the tumor may originate from the diaphyseal region of long bones, or other locations not normally considered predilection sites for osteosarcoma.

The mean age of osteosarcoma in **cats** is 10.5 years (range 3–18 years) and there is no apparent breed predisposition. Most studies of osteosarcoma in cats involve fewer cases than in dogs and information on predilection sites is less precise. Although the appendicular skeleton appears to be involved more frequently than the axial skeleton, the ratio is less than in dogs and there is no apparent predilection for the forelimbs. Unlike dogs, most osteosarcomas in cats arise in the diaphyses of long bones, rather than the metaphyses.

Osteosarcomas are rare in domestic animals other than dogs and cats, but are reported occasionally in horses, cattle and sheep. In these species, the tumor generally involves bones of the head, particularly the mandible.

The *gross and radiographic appearance of central osteosarcoma varies markedly*, depending on the behavior of the tumor cells and the matrix they produce. Some subtypes are predominantly lytic, some

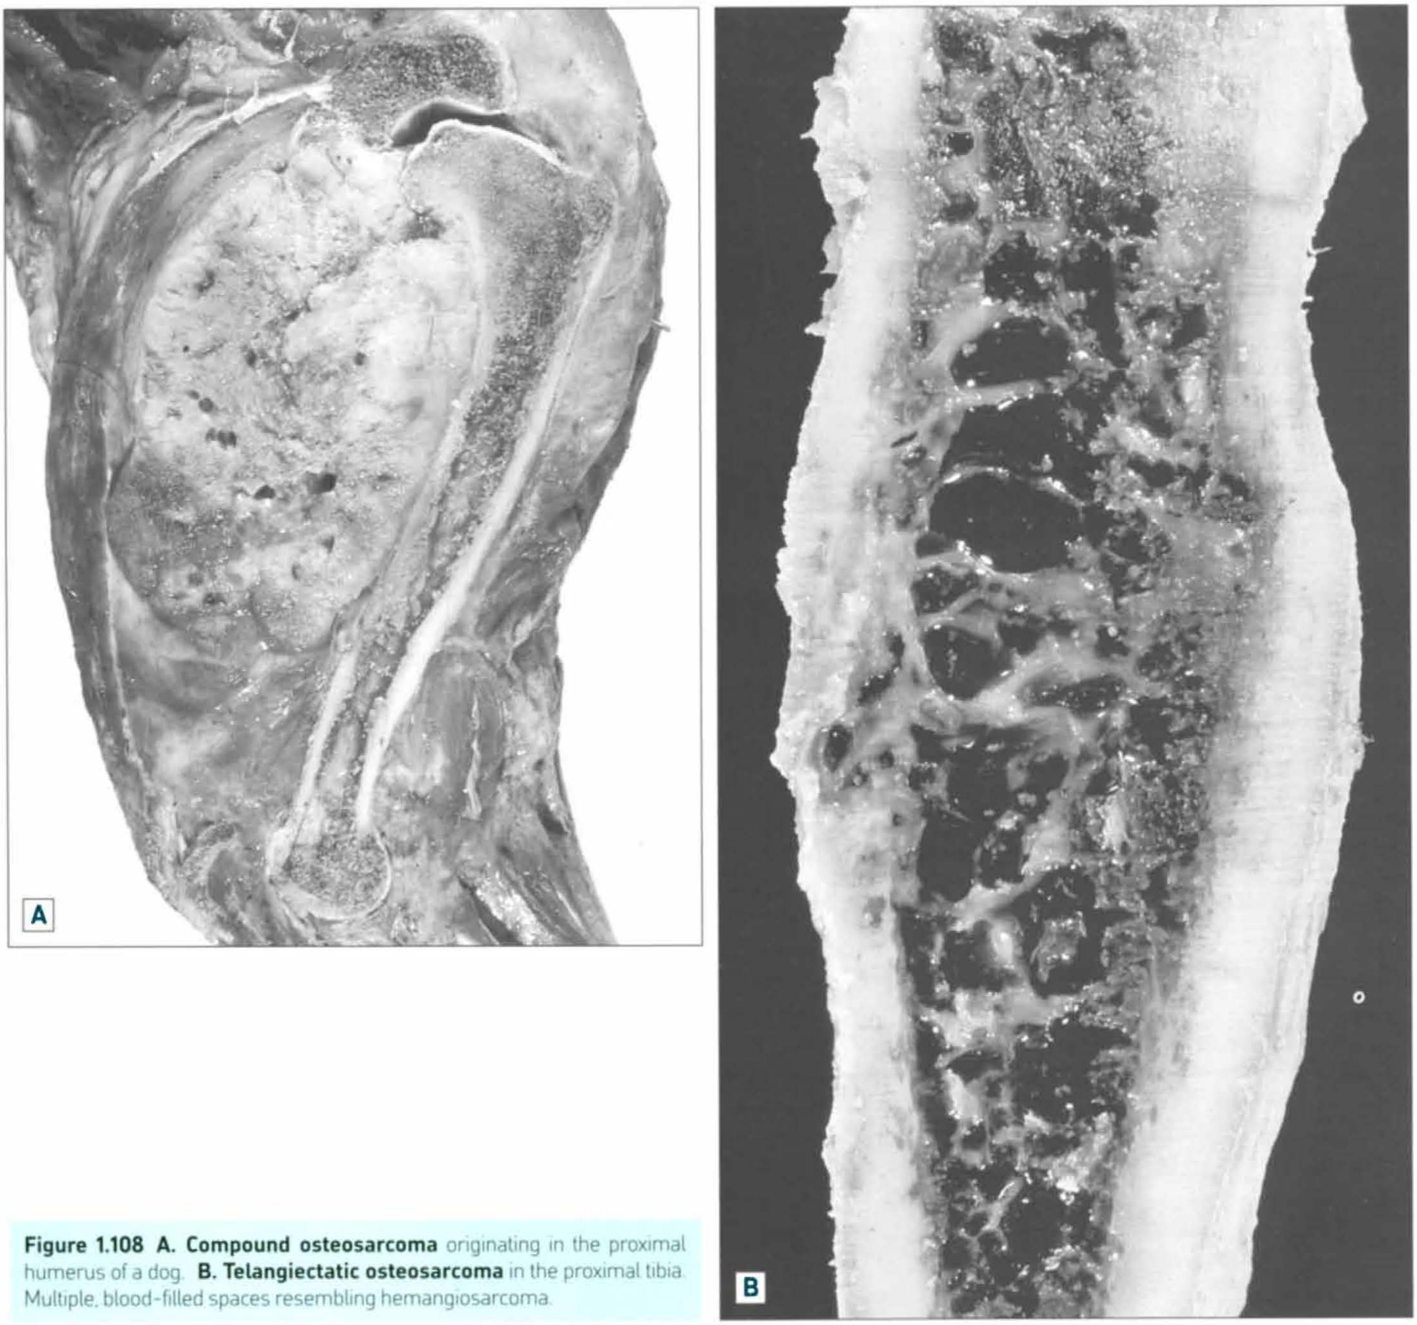

Figure 1.108 A. Compound osteosarcoma originating in the proximal humerus of a dog. **B. Telangiectatic osteosarcoma** in the proximal tibia. Multiple, blood-filled spaces resembling hemangiosarcoma.

are productive, while others comprise a mixture of both destructive and proliferative elements. Assessment of the gross features is greatly enhanced by radiographs of dissected and bisected specimens. Radiolucent or osteolytic tumors are usually hemorrhagic and soft, and often contain light yellow areas of necrosis. Pathological fractures may accompany erosion of cortical bone and osteolytic tumors tend to invade the adjacent soft tissues early in their course. Radiodense tumors are various shades of gray on gross examination and areas of tumor bone and tumor cartilage give a stippled appearance to radiographs and a gritty texture when cut. In compound osteosarcomas, tumor cartilage is sometimes recognizable by its texture and color, and tends to be located at the periphery of the neoplasm. Productive tumors frequently provoke a more marked periosteal reaction than the osteolytic tumors. Osteosarcomas of long bones commonly, perhaps invariably, erode cortical bone but although they tend to invade the epiphysis rather than the diaphysis, they rarely penetrate the adjacent articular cartilage. Telangiectatic osteosarcomas are soft and dark red, and closely resemble hemangiosarcomas grossly.

The *histologic appearance of osteosarcomas varies markedly,* but the production of osteoid and/or tumor bone by malignant osteoblasts is a common factor. The tumor matrix may also contain variable quantities of cartilage and collagen, but *if tumor osteoid is present then the tumor is classified as osteosarcoma.* This reflects the greater malignant potential of malignant osteoblasts than either chondroblasts or fibroblasts. Bone formation also occurs in some chondrosarcomas, but indirectly through endochondral ossification of tumor cartilage, and should not be misinterpreted as tumor bone. Similarly, osseous metaplasia of multipotential mesenchymal cells in tumors of nonosseous origin, such as mammary carcinomas, may create confusion.

Malignant osteoblasts may be spindle-shaped cells resembling fibroblasts or plump, oval or rounded cells with basophilic cytoplasm and eccentric, hyperchromatic nuclei, more closely resembling non-neoplastic osteoblasts. Mitotic figures are often very common. The nature and amount of osteoid is highly variable. In some cases, it consists of hyaline, eosinophilic material arranged in thin strands or narrow ribbons amongst the malignant cells, producing a lace-like pattern (Fig. 1.109A). In others, the osteoid is present as irregular islands or spicules separated by malignant osteoblasts (Fig. 1.109B). Thin strands of osteoid may closely resemble collagenous fibrous tissue and distinguishing the two forms of matrix may be impossible. Both are birefringent, reflecting their collagen content, and reliable differentiation is not possible using histochemical stains. Fibrin in areas of hemorrhage may also be mistaken for osteoid, but is not birefringent. In general, osteoid is less fibrillar than collagen, more amorphous, and often partly or completely surrounds the tumor cells, entrapping them in lacunar spaces.

Formation of endosteal and periosteal new bone is a feature of a variety of inflammatory and neoplastic bone lesions, not just osteosarcoma, and must be differentiated from tumor bone. This may be difficult in small biopsy samples. Distinguishing between osteosarcoma and an early fracture callus presents an even greater challenge. Rapidly proliferating, plump mesenchymal cells surrounding themselves with osteoid are a feature of fracture repair (see Fig. 1.19), especially during the first few days, and may easily be confused with osteosarcoma. Evidence of maturation within the callus is a useful differentiating feature, and the cell population would be expected to show less atypia than most osteosarcomas. Not surprisingly, the histologic appearance may be extremely difficult to interpret in cases where pathological fracture has occurred in association with an osteosarcoma. *Knowledge of the clinical history and radiographic findings are particularly important adjuncts to histology in such cases.*

Multinucleate giant cells with features of osteoclasts are often scattered throughout osteosarcomas, sometimes in sufficient numbers to suggest a diagnosis of giant cell tumor, but demonstration of osteoid production by the tumor cells allows exclusion of the latter option. In rapidly growing osteosarcomas, large areas of coagulation necrosis and hemorrhage are often present, probably due to localized ischemia.

As shown in Table 1.3, osteosarcomas may be subclassified according to the predominant histologic pattern. This scheme is an adaptation of a system developed for use in human medicine and is now well accepted by veterinary pathologists. *Subclassification of osteosarcomas can be justified in that it may lead to the identification of correlations of osteosarcoma subtype with prognosis, and susceptibility to therapy.* For example, fibroblastic osteosarcomas in dogs and human patients have been shown to possess a relatively favorable prognosis, while the prognosis for the telangiectatic form is very poor. However, the exercise is not always straightforward because of the inherent variability present within many osteosarcomas, and the fact that a subdominant pattern may appear to be the most malignant. *Classification into one of the six categories is determined by the predominant pattern in representative sections from the tumor*, but if no single pattern is dominant, the tumor is best categorized as a *combined type osteosarcoma*. In cases where only small fragments of tissue are received for examination, the main aim should be to determine whether the tumor is an osteosarcoma, rather than what subtype it belongs to.

- In **poorly differentiated osteosarcoma**, the tumor cells vary from small cells resembling those of bone marrow stroma, to large, pleomorphic cells of an undifferentiated sarcoma. The only clue that the tumor is an osteosarcoma is the presence of small quantities of *unequivocal tumor osteoid*. These tumors are generally highly aggressive, forming lytic bone lesions, and often are associated with pathological fractures.
- **Osteoblastic osteosarcomas** are recognizable by the presence *of cells with features of anaplastic osteoblasts* throughout much of the tumor (Fig. 1.109C). The tumor cells have hyperchromatic, often eccentric nuclei and variable quantities of basophilic cytoplasm. The cell borders are often angular and there may be a pale Golgi zone adjacent to the nucleus. Osteoblastic osteosarcomas may be *further subclassified into nonproductive and productive osteosarcomas* depending on the quantity of tumor bone produced. Moderately productive osteoblastic osteosarcoma (Fig. 1.109A, B) is the most common subtype of osteosarcoma in dogs. Radiographically, there is a mixed pattern of destruction and production. In some cases with abundant tumor bone formation, differentiation of tumor bone from reactive bone may be difficult or impossible.
- In **chondroblastic osteosarcomas**, *the malignant mesenchymal cells directly produce both osteoid and chondroid matrices.* Although the two components are usually intermixed, they remain separate in some tumors and small biopsy specimens may lead to an incorrect diagnosis of chondrosarcoma.
- **Fibroblastic osteosarcomas** consist of a population of *spindle cells* similar to those of fibrosarcoma, within which there is evidence of *osteoid or bone formation by tumor cells.* The spicules of bone may be sparse, especially in early lesions, and it is not uncommon for such tumors to initially be diagnosed as fibrosarcomas then later reclassified as osteosarcoma following examination of further biopsies. In one study, the prognosis for dogs with fibroblastic osteosarcoma was more favorable than for other subtypes.
- **Telangiectatic osteosarcoma** is an *aggressive, osteolytic tumor* consisting of a mixture of solid areas and blood-filled spaces, grossly and radiographically resembling hemangiosarcoma (Fig. 1.108B). Histologically, telangiectatic osteosarcoma can be *differentiated from hemangiosarcoma by the presence of occasional spicules of osteoid among pleomorphic, malignant mesenchymal cells* (Fig. 1.110), although a careful search is often required in order to detect osteoid. Furthermore, the blood-filled spaces present throughout the tumor are lined by tumor cells, not endothelium. Metastases of telangiectatic osteosarcomas generally resemble the primary tumor, containing many cystic spaces filled with blood. In human patients and dogs, *this subtype is associated with a less favorable prognosis than all other forms of osteosarcoma.*
- **Giant cell osteosarcomas** resemble nonproductive osteoblastic osteosarcoma histologically, but possess areas in which tumor giant cells predominate and must be differentiated from malignant giant cell tumors of bone.

Although cytology is usually less reliable than histology in the diagnosis of mesenchymal tumors, central osteosarcomas can often be diagnosed with confidence on examination of *fine-needle aspiration biopsies or imprints* prepared from tissue biopsy samples. Cytological preparations from osteosarcomas are usually more cellular than aspirates or imprints from soft tissue sarcomas, and the cells may have characteristic features of malignant osteoblasts. In many cases,

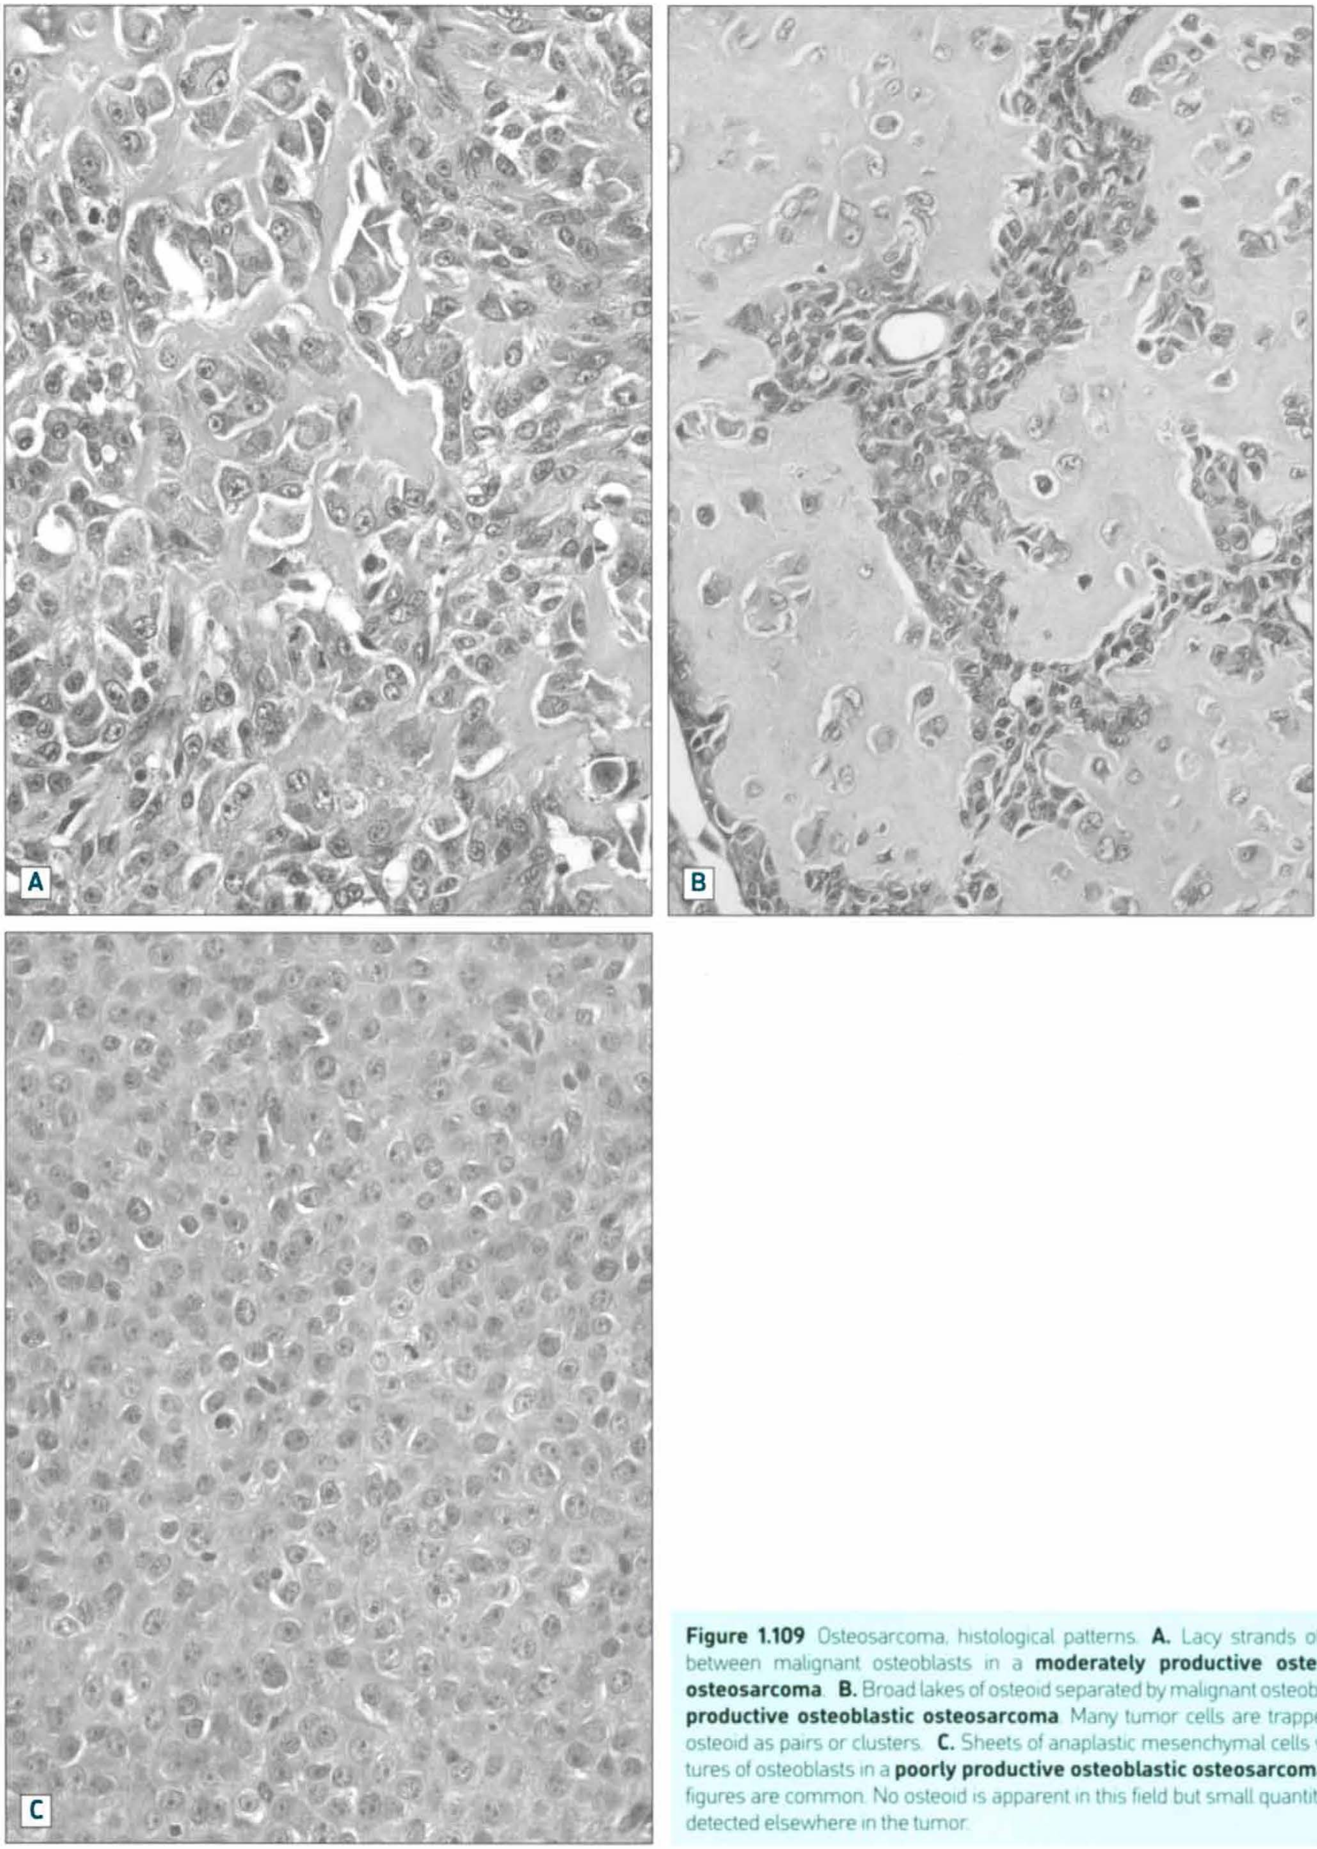

Figure 1.109 Osteosarcoma, histological patterns. **A.** Lacy strands of osteoid between malignant osteoblasts in a **moderately productive osteoblastic osteosarcoma**. **B.** Broad lakes of osteoid separated by malignant osteoblasts in a **productive osteoblastic osteosarcoma**. Many tumor cells are trapped in the osteoid as pairs or clusters. **C.** Sheets of anaplastic mesenchymal cells with features of osteoblasts in a **poorly productive osteoblastic osteosarcoma**. Mitotic figures are common. No osteoid is apparent in this field but small quantities were detected elsewhere in the tumor.

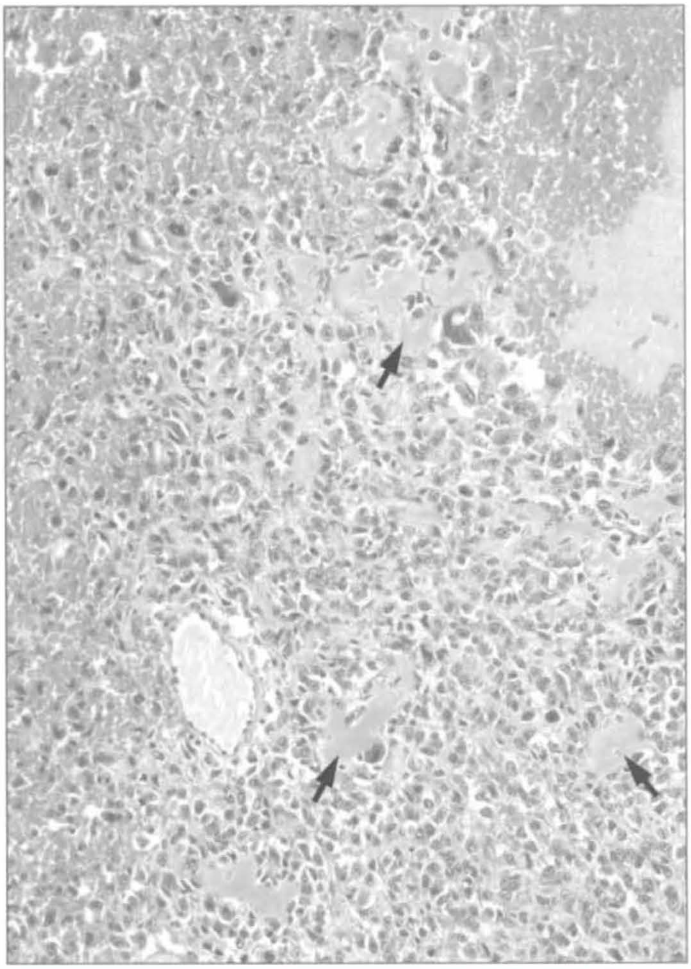

Figure 1.110 Telangiectatic osteosarcoma, dog. Malignant mesenchymal cells forming spicules of matrix resembling osteoid (arrows) and closely associated with large, blood-filled spaces.

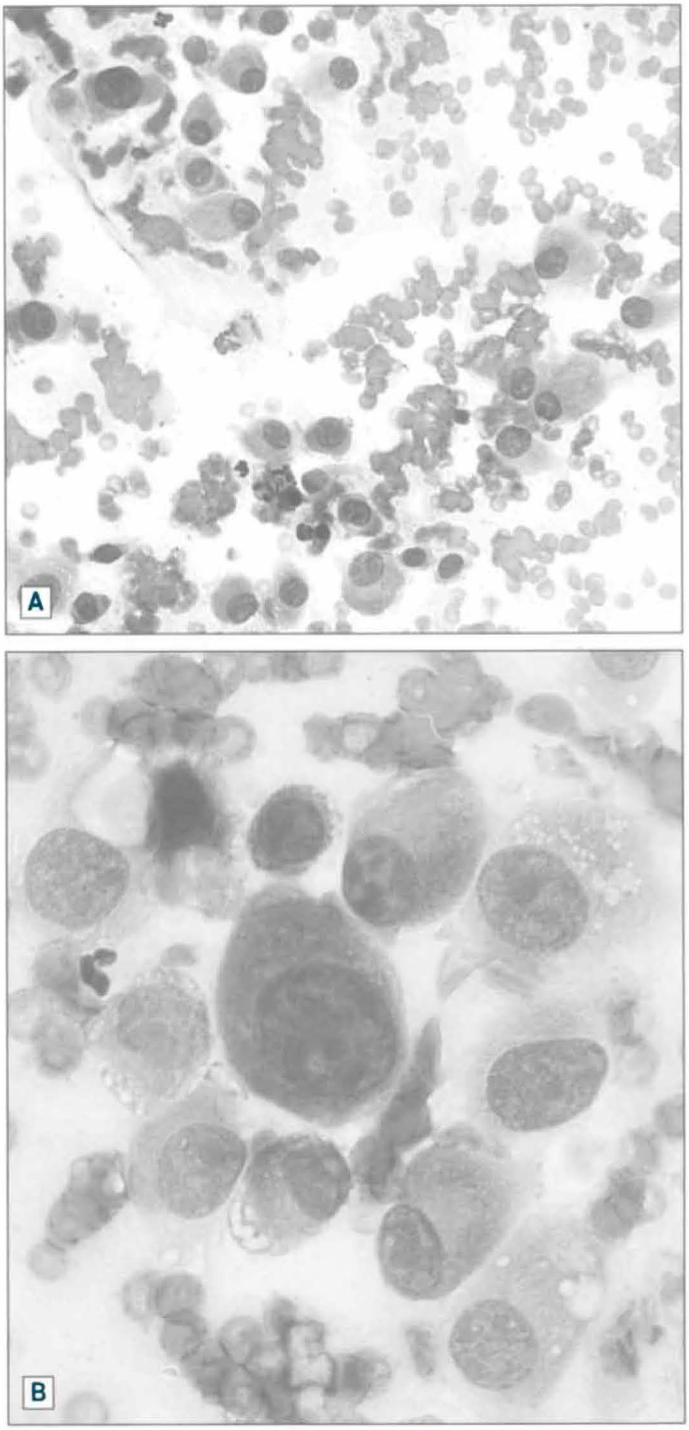

Figure 1.111 Cytological appearance of **osteosarcoma**. **A.** Moderate numbers of oval to pyriform-shaped cells with eccentric nuclei, basophilic cytoplasm and pale Golgi zone adjacent to the nucleus of some cells. There is moderate variation in nuclear size and N:C ratio. **B.** Higher-power view of malignant osteoblasts including one cell with a very large, hyperchromatic nucleus and deeply basophilic cytoplasm.

the cytological characteristics, together with clinical history and radiography, will be sufficient to allow a definitive diagnosis of osteosarcoma, but malignancy cannot be excluded on the basis of cytology as the sample may not be sufficiently representative of the lesion. Since most osteosarcomas originate from within the medullary cavity, shallow aspirates may be largely acellular or, at best, just contain a small number of reactive osteoblasts (see Fig. 1.2). Furthermore, some productive subtypes of osteosarcoma with extensive tumor bone formation may not yield significant numbers of tumor cells to cytological preparations and aspirates from telangiectatic osteosarcomas may be too heavily contaminated with blood to be of value. Even in cases where a cytological diagnosis of osteosarcoma can be made, classification of the tumor into one of the subtypes listed above is not possible.

Malignant osteoblasts may be present individually or in clusters in cytological preparations and are sometimes closely associated with brightly eosinophilic strands or islands of *osteoid*. They vary from round or oval to plump, fusiform cells, often with an eccentric nucleus and deeply basophilic cytoplasm (Fig. 1.111A, B). The cytoplasm may have a pale Golgi zone adjacent to the nucleus and, in some cases, there are variable numbers of *small, clear, intracytoplasmic vacuoles and/or fine pink granules*. Similar pink granules may also be present in tumor cells from chondrosarcomas or occasionally fibrosarcomas. In anaplastic osteosarcomas, there may be marked anisokaryosis, multiple large, irregular-shaped nucleoli and variable nuclear to cytoplasmic ratio. Mitotic figures are common and may be abnormal. In contrast, well-differentiated osteosarcomas may consist largely of relatively uniform-sized cells with many features of reactive

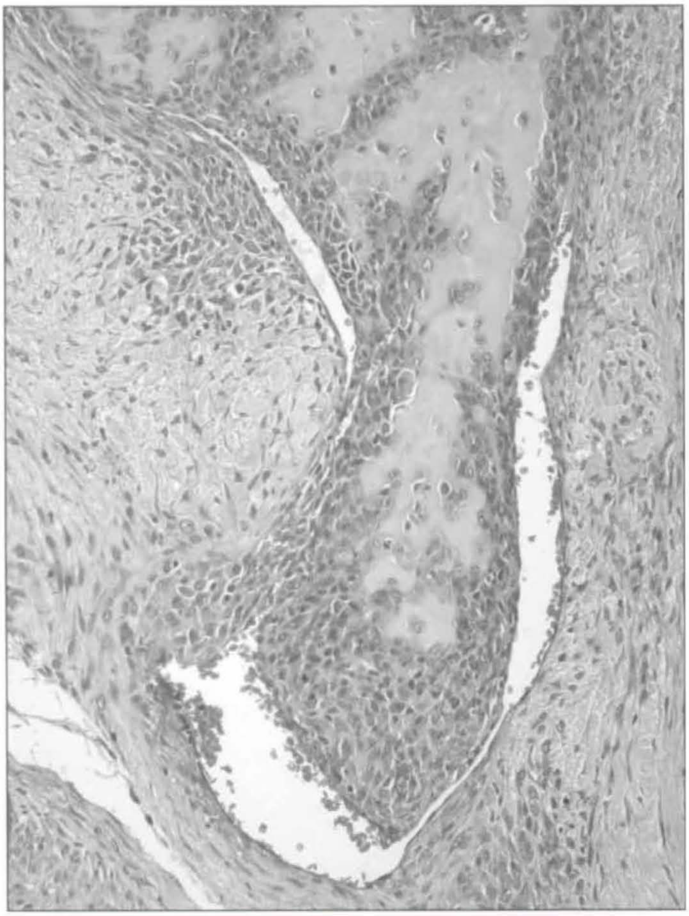

Figure 1.112 Tumor tissue containing osteoid invading a large vein at the margin of an **osteosarcoma**.

osteoblasts. A similar population of reactive osteoblasts associated with strands of osteoid may be harvested from an early fracture callus, highlighting the importance of clinical history and knowledge of the radiographic appearance of the lesion. *Unless the characteristics of malignancy are unequivocal, histological examination is recommended.*

Central osteosarcoma is perhaps the most malignant group of tumors of animals, at least in dogs. *The prognosis for all subtypes is very poor.* Hematogenous metastasis to the lungs commonly occurs early in the disease. Vascular invasion can sometimes be detected at the tumor margins (Fig. 1.112). Pulmonary metastases are detected radiographically in approximately 10% of canine appendicular and axial osteosarcomas at the time of initial diagnosis and it is likely that most dogs with osteosarcoma will eventually develop metastases if their lives are prolonged by surgery or other forms of treatment. In one study, dogs with telangiectatic osteosarcoma had a 100% metastatic rate. Hematogenous metastasis to other organs, including the skeleton, also occurs but osteosarcomas seldom spread to regional lymph nodes. The median survival time for dogs with appendicular skeletal osteosarcomas is only 14–19 weeks. Survival time is only marginally better (22 weeks) in dogs with osteosarcomas of the axial skeleton, although osteosarcomas of the mandible, and those with osteoblastic tumors of paranasal sinuses and calvaria generally have a better prognosis.

The incidence of *metastasis in cats* with central osteosarcoma is considerably less than in dogs and the prognosis is therefore more favorable. A median survival time of 49.2 months has been observed in cats with appendicular osteosarcoma following treatment by amputation, but the number of animals in most studies of feline osteosarcoma has been small.

Periosteal and parosteal (juxtacortical) osteosarcoma are referred to as **peripheral osteosarcomas** because of their origin on or near the surface of bones. Two types of **periosteal osteosarcoma** have been recognized in dogs. One is a highly aggressive tumor with similar histologic features and biologic behavior as central osteosarcoma, the other being more differentiated and with a more favorable prognosis. Too few cases of periosteal osteosarcomas have been reported in dogs and other domestic animals to provide reliable data on the age, sex, and site incidence. It is possible that the more aggressive forms of periosteal osteosarcoma in dogs are actually central osteosarcomas arising from the outer metaphyseal regions of a long bone and adopting an eccentric growth pattern.

Parosteal osteosarcomas also arise in the periosteal connective tissue but have a characteristic clinical behavior and histologic pattern. These tumors are reported in dogs, cats, and a horse and follow a longer clinical course than central osteosarcomas. Most cases are presented as a firm, slowly enlarging mass on the surface of a bone. Radiographically, the tumor has an evenly contoured margin and the underlying cortex is generally intact. This is in contrast to osteochondroma, where the marrow cavity of the tumor is continuous with that of the adjacent bone. In histological sections, parosteal osteosarcoma consists of *broad trabeculae of well-differentiated bone separated by moderately cellular fibrous connective tissue showing some pleomorphism, but no convincing evidence of malignancy* (Fig. 1.113). Differentiation from reactive bone may present a significant challenge. Metastasis of parosteal osteosarcoma to the lungs occurs late, if at all.

Osteosarcomas occasionally arise in soft tissues of dogs and cats, in the absence of a primary bone lesion. These **extraskeletal osteosarcomas** occur most often in the *mammary gland*, but may also arise in the gastrointestinal tract, subcutaneous tissues, spleen, urinary tract, liver, skin, muscle, eye, and thyroid gland. They also arise in the esophagus in association with *Spirocerca lupi* infestation. In general, extraskeletal osteosarcomas occur in older dogs than skeletal osteosarcomas (mean age 10.6–11.5 years) and show no apparent predilection for large breeds. Although distant metastases are common, the lungs are involved less often than in skeletal osteosarcomas, and death is usually due to either local recurrence or euthanasia at the time of diagnosis. The mean survival time is reported to be lower than for skeletal osteosarcomas, in part due to the later detection of intra-abdominal tumors and limited surgical options for tumors at some sites. Osteosarcoma of the mammary gland of bitches should not be confused with the *more common, nonneoplastic, osseous metaplasia* that occurs in association with mammary carcinomas.

Extraskeletal osteosarcoma appears to be less common in cats than in dogs, but has been reported in the eye following ocular trauma, and in the mammary area of a 12-year-old cat. In the latter case, the tumor recurred following surgical removal and widespread lung metastases were detected at necropsy.

Cartilage-forming tumors

Tumors consisting entirely or predominantly of cartilage are *uncommon* in the skeleton of domestic animals. They are diagnosed most frequently in dogs, where approximately 10% of skeletal tumors are cartilaginous, and in sheep, where chondromas comprise a relatively high proportion of skeletal tumors. Cartilaginous tumors often contain areas of bone formed by endochondral ossification of tumor cartilage. This should not be mistaken for the tumor bone formed directly from neoplastic mesenchymal cells in osteosarcoma. Repairing fractures also contain cartilage and bone in various proportions at different stages of maturity and could be confused with cartilage- or bone-forming tumors.

Extra-skeletal tumors containing cartilage also occur, particularly those arising as a component of lipomatous soft tissue masses (chondrolipomas). Cartilaginous tissue is also present and may become dominant in mixed tumors of mammary and salivary gland origin.

Chondroma

A chondroma is a benign neoplasm of cartilage but, in veterinary medicine, the term has often been used loosely to include benign proliferations of cartilage in several extraskeletal tissues. Primary chondromas of bone are separable into *enchondromas*, which originate within the medullary cavity of a bone and *ecchondromas*, which arise from cartilage elsewhere in the skeleton. Both forms are rare in animals. Enchondromas are sometimes polyostotic, in which case the syndrome is referred to as *enchondromatosis*. It is likely that many tumors diagnosed as chondromas in animals are in fact osteochondromas or low-grade chondrosarcomas, especially in cases where the pathologist is not provided with an adequate history or access to radiographs of the lesion.

Chondromas occur rarely in dogs, cats, and cattle, and although considered to be more common than other skeletal tumors in sheep, they are infrequently diagnosed in this species. The tumors are typically firm to hard, smooth or nodular, roughly spherical masses with a relatively thin fibrous capsule. They involve flat bones and ribs more commonly than long bones. On cut surface, a lobular pattern may be evident due to dissection of the blue-white cartilage by fibrous septa. Areas of mineralization or ossification appear as chalk-white stippling. Myxomatous tissue, which occurs in some chondromas, has a gelatinous texture grossly and seems prone to hemorrhage and necrosis.

Histologically these benign tumors consist of irregular lobules of hyaline cartilage with cells that are, by definition, quite regular in size and appearance and typically chondrocytic. This is especially true of enchondromas. The matrix is usually more fibrous than that of normal hyaline cartilage. Foci of endochondral ossification and mineralization may be present, and lobules of myxomatous tissue sometimes develop. Differentiation between chondroma and low-grade chondrosarcoma is difficult on the basis of histopathology and may require the assessment of biological behavior in sequential radiographs.

Chondromas expand slowly, and a rapid change in size may indicate malignant transformation. Expanding tumors within the medullary cavity cause bone deformation and may predispose to fracture.

Osteochondroma

An osteochondroma is a benign, cartilage-capped tumor-like exostosis arising from the surface of an endochondral bone adjacent to a physis or subarticular growth cartilage. The tumor may be monostotic or polyostotic, in which case the terms **multiple cartilaginous exostosis** or **osteochondromatosis** are often used. In **humans, dogs**, and **horses**, the disease is inherited as an autosomal dominant trait and would be more appropriately classified as a *skeletal dysplasia* than a neoplasm, but is included here for convenience.

In dogs, the lesions usually are not present at birth but arise in young animals and continue to enlarge until the skeleton matures. In affected horses, the lesions are often present at birth and tend to be bilaterally symmetrical. During the phase of expansion, the outgrowths consist of a thin outer cap of hyaline cartilage resembling poorly organized growth plate, adjacent to the epiphyseal plate, which undergoes endochondral ossification from its deep surface (Fig. 1.114A). *Trabecular bone and bone marrow within the mass are continuous with the marrow cavity of the parent bone. This is a useful diagnostic feature in the differentiation of osteochondromas from some other hyperplastic or neoplastic bony masses.* Once bone growth ceases, the cartilage cap is replaced by bone. The trabecular bone in osteochondromas is not remodeled and the mineralized cartilage cores persist. *The nature of the genetic defect in osteochondroma is not known but is suspected to involve the perichondrial ring.* Peripheral nodules of physeal cartilage are pinched off and grow laterally, the lesions eventually finishing up in the metaphyseal region some distance from the original growth plate.

The lesions of osteochondroma are variable in their location but common sites in dogs and horses are the metaphyses of long bones, the pelvis, ribs, scapula, and vertebrae. Although many cases are merely of esthetic rather than clinical significance, lesions in some locations interfere with the action of ligaments or tendons and exostoses derived from vertebrae sometimes protrude into the spinal canal, resulting in spinal cord compression (Fig. 1.114B). Furthermore, *they may undergo malignant transformation into chondrosarcoma or osteosarcoma.* From 5 to 25% of human patients with the syndrome eventually develop chondrosarcoma, and similar cases have occurred in dogs and horses. In one series of eight cases of multiple cartilaginous exostoses in dogs, three developed chondrosarcoma, suggesting that the risk of malignant transformation in affected dogs is relatively high.

Osteochondromatosis in **cats** occurs in mature animals and tends to involve flat bones, including bones derived from intramembranous ossification. Long bones are seldom affected. The lesions in cats appear to arise as *multifocal areas of osteocartilaginous hyperplasia in the periosteum and undergo progressive enlargement.* Their behavior is therefore more consistent with that of a true tumor, unlike that of osteochondromas in dogs and horses. Furthermore, the lesions in cats are usually not continuous with the marrow cavity of the adjacent bone. It seems likely that this syndrome in cats is not analogous to that in the other species and a link with *Feline leukemia virus* has been made, and virus particles identified within lesions. Malignant transformation of feline osteochondroma is also reported.

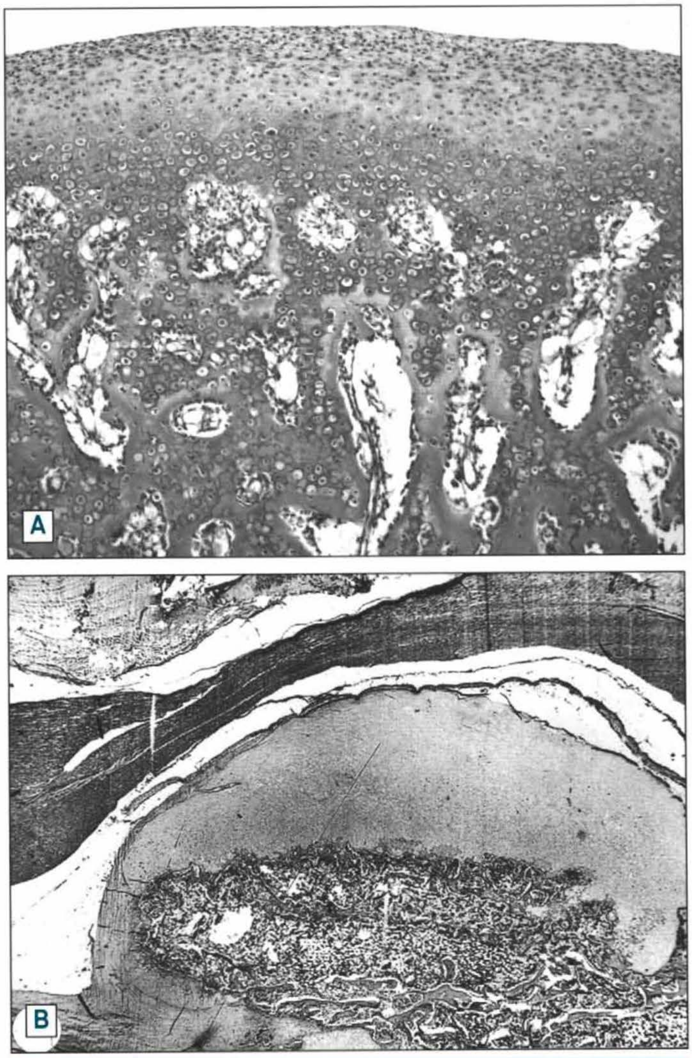

Figure 1.114 Osteochondroma, dog. **A.** Outer layer of proliferating chondrocytes differentiating into disorganized hyaline cartilage with randomly distributed hypertrophic chondrocytes. Endochondral ossification is occurring at the deep surface of the cartilage cap. **B.** Compression of spinal cord by osteochondroma originating from vertebra.

Multilobular tumor of bone

Multilobular tumor of bone is a slow-growing but locally aggressive and potentially malignant tumor, occurring most often in the skull of dogs, but occasionally in the cat and horse. Many alternative terms have been proposed for the tumor, including chondroma rodens, cartilage analogue of fibromatosis, calcifying aponeurotic fibroma, multilobular chondroma or osteoma, and multilobular osteochondrosarcoma. In dogs, it is primarily a disease of middle-aged to older animals, occurring most often in medium or large breeds, but rarely in giant breeds. In one study of 39 cases, the median age was 8 years (range 4–17 years) and the median weight was 29 kg, although four dogs weighed less than 25 kg. Three cases have been recorded in cats, varying in age from 9 months to 8 years, and there is one report in a 12-year-old Thoroughbred mare.

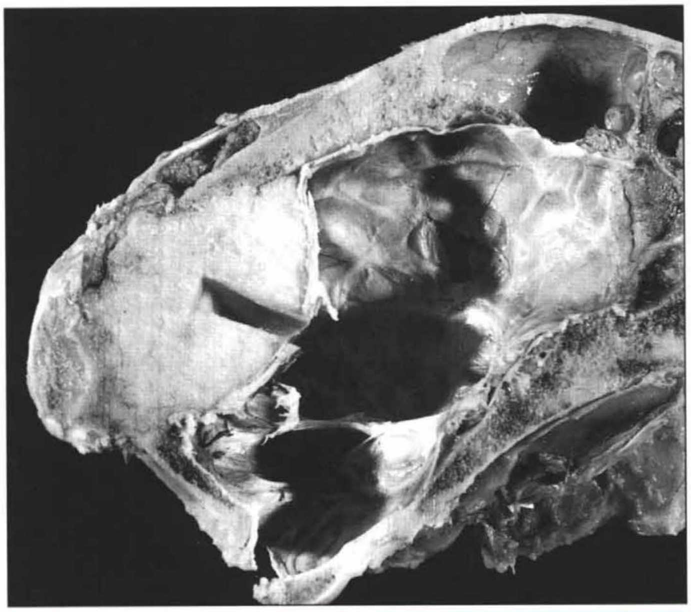

Figure 1.115 Multilobular tumor of bone impinging on the brain of a dog.

The tumor is usually present as a *firm, immovable mass on the surface of skull bones* and clinical signs relate to the compression and disturbance of function in adjacent structures. The swelling apparent from the skull surface may provide little indication of the degree to which the tumor impinges on adjacent organs, such as the brain (Fig. 1.115). Multiple small gritty foci are usually evident grossly on cut surface and a stippled appearance may be observed in radiographs of the tumor.

Histologically, the multilobular tumor of bone has a characteristic pattern consisting of multiple circular, oval or irregular-shaped nodules of cartilaginous, osseous, or osteocartilaginous tissue separated by narrow fibrovascular septa (Fig. 1.116A, B). In certain areas of some tumors, broad, ill-defined zones of mesenchymal tissue merge with the nodules. The cartilaginous nodules usually are surrounded by spindle-shaped septal cells, contiguous with the plump oval nuclei of the neoplastic chondrocytes in the center of each lobule. The tumor cells produce a pale, eosinophilic or faintly basophilic matrix, which mineralizes at the center of the lobule. Resorption of mineralized cartilage and endochondral bone formation sometimes occurs and occasionally, osteoclastic remodeling of bone develops. In these nodules, the matrix-producing cells are unequivocally chondrocytic in appearance. In bony nodules, the mesenchymal cells produce a matrix that

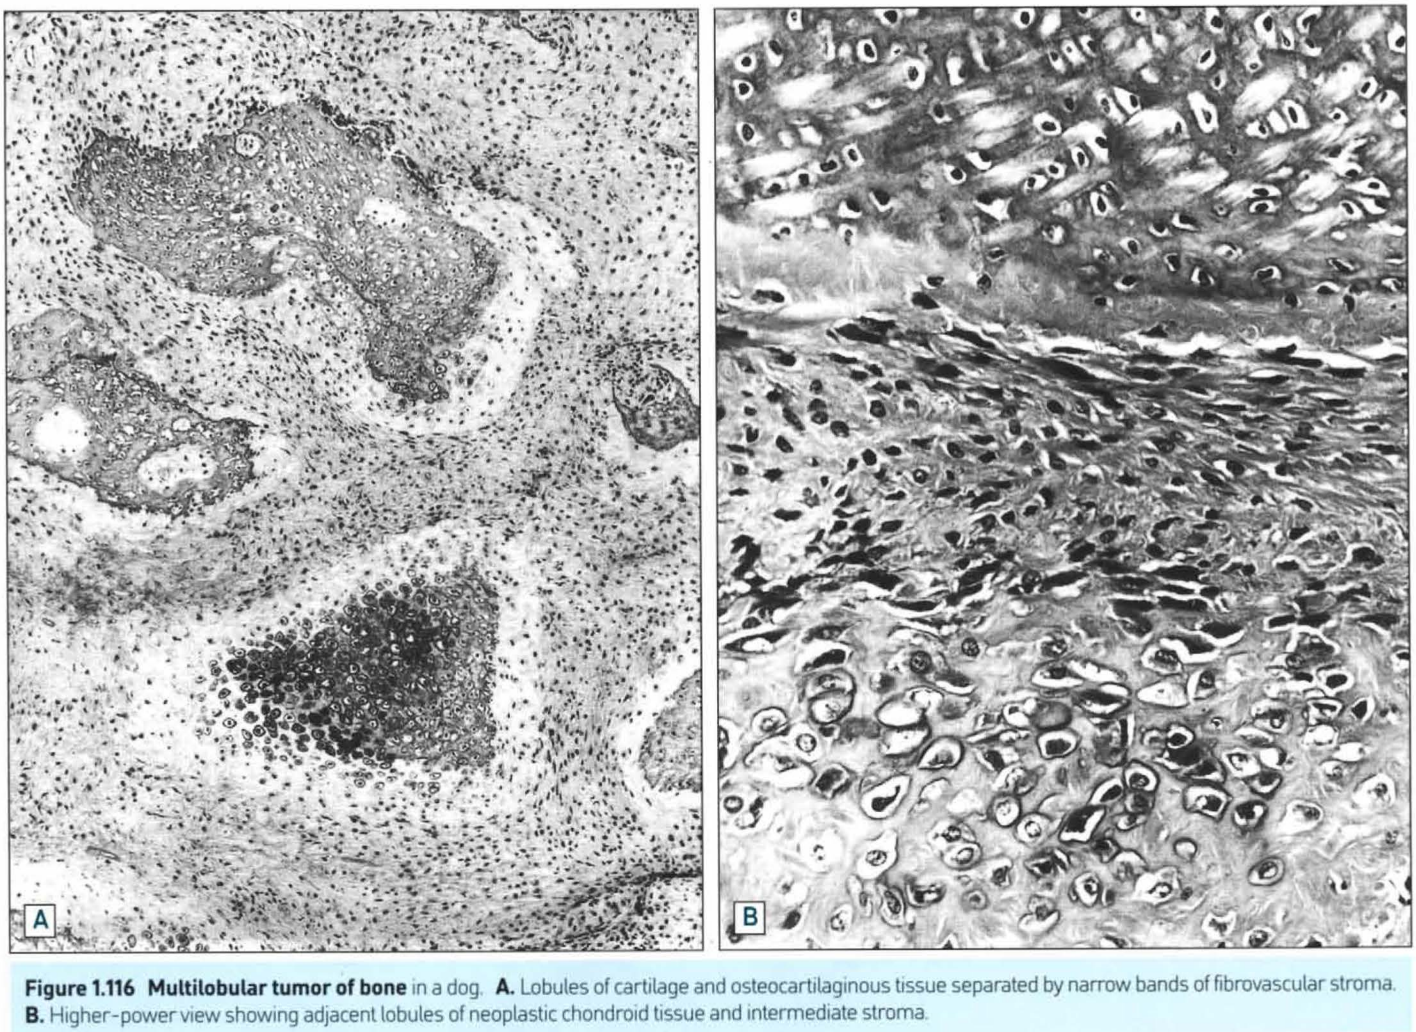

Figure 1.116 Multilobular tumor of bone in a dog. **A.** Lobules of cartilage and osteocartilaginous tissue separated by narrow bands of fibrovascular stroma. **B.** Higher-power view showing adjacent lobules of neoplastic chondroid tissue and intermediate stroma.

ossifies rather than mineralizes. In some tumors, the bone is produced by angular osteoblasts with abundant basophilic cytoplasm but in others, oval cells of indeterminate type produce a tissue reminiscent of chondroid bone. The mineralization process tends to progress centrifugally to involve the entire nodule, and the septal tissue then consists of dense collagen. In these areas, the tumor is extremely hard. Osseous and cartilaginous tissue may be present in the same nodule and some tumors contain both osseous and cartilaginous nodules. Although the nodular pattern predominates, resorption of the hard tissues does occur and nodules may be replaced by dense connective tissue containing areas of cartilaginous metaplasia.

Surgical removal is often difficult because of the location of these tumors and local recurrence occurs in about 50% of cases. Malignant transformation often occurs in tumors that are long-standing or recurrent. Indicators of malignancy include mitotic activity, loss of the orderly lobular architecture, necrosis, hemorrhage, and overgrowth of one of the mesenchymal elements. The characteristic appearance of multilobular tumors is retained in metastases.

Chondrosarcoma

Chondrosarcomas are malignant mesenchymal tumors in which the neoplastic cells produce variable quantities of cartilaginous or fibrillar matrix, but not osteoid. Although bone may be present in chondrosarcomas, it forms by endochondral ossification of tumor cartilage, rather than being produced directly by malignant mesenchymal cells.

Primary chondrosarcomas are those that arise from either within a bone (central or medullary chondrosarcoma) or from the periosteal surface (peripheral chondrosarcoma), the former being the most common in animals. The term *secondary chondrosarcoma* refers to those that develop by malignant transformation of cartilage in an osteochondroma.

Chondrosarcoma is *reported most frequently in the dog,* where it accounts for approximately 10% of primary tumors of bones and is second only to osteosarcoma in incidence. In most other domestic species, chondrosarcoma is a relatively rare tumor and too few cases are reported to provide reliable information on its clinicopathological features. In sheep, chondrosarcoma is considered to occur more frequently than osteosarcoma, but it remains a rare tumor in this species.

In dogs, chondrosarcoma occurs most often in medium to large breeds, particularly Boxers, German Shepherds, Golden Retrievers and various mixed breeds, but is rare in small and giant breeds. Although a broad age range is reported, the tumor is *most common in middle-aged to older dogs,* the mean age of affected animals varying from 5.9 to 8.7 years. No sex predilection is recognized. There are fewer data on the age incidence of chondrosarcoma in cats, but in one review, a mean age of 8.8 years was reported.

In all species, chondrosarcomas *involve flat bones more often than long bones.* The ribs, turbinates, and pelvis are common sites in dogs, although nasal chondrosarcomas are rare in Boxers. Chondrosarcomas may also occur in the appendicular skeleton of dogs, including, but not restricted to, sites of predilection for osteosarcomas. In cats, chondrosarcomas are reported in both flat bones (especially the scapula) and long bones, but in this species, the published data are inadequate to draw reliable conclusions regarding site predilection. In sheep, the cartilages of the sternocostal complex were the most common site for chondrosarcoma in one survey, followed by the scapula and tuber coxae. In cattle and horses, chondrosarcomas are found most often on flat bones, but long bones are occasionally affected.

Grossly, central chondrosarcomas are firm or hard and may consist of either several large lobules resembling hyaline cartilage or multiple small, contiguous nodules of translucent, blue-white or pink tissue. In some tumors, especially those in the nasal cavity, there are soft, mucoid areas, and in others, there are chalky white foci of mineralization or ossification. Chondrosarcomas *tend to grow expansively* and have a smooth surface and a capsule that merges with surrounding fibrous tissue. The more highly malignant tumors may contain areas of necrosis and hemorrhage. Nasal chondrosarcomas tend to destroy turbinates, fill the nasal cavity (Fig. 1.117A, B) and may either spread into adjacent sinuses or penetrate overlying bone and infiltrate adjacent soft tissues. When in long bones, chondrosarcomas may produce lytic lesions similar to osteosarcomas. Periosteal chondrosarcomas are less common in animals than central chondrosarcomas and usually occur as slow-growing, nodular masses on the surface of flat bones in older dogs and cats.

Histologically, well-differentiated chondrosarcomas show few indications of malignancy and closely resemble benign tumors of cartilage (Fig. 1.118A). Endochondral ossification of tumor cartilage may be present and should not be mistaken for the formation of tumor bone. *Knowledge of the clinical and radiographic features is often essential to accurate classification of cartilaginous tumors.* Fortunately for the veterinary pathologist, most chondrosarcomas in animals are well advanced before the owner seeks veterinary advice and biopsy samples are collected. In fact, the challenge may be to decide whether a malignant mesenchymal tumor involving bone is a chondrosarcoma, osteosarcoma, or some other sarcoma of bone. Such a decision is important, bearing in mind the differences in prognosis. In some chondrosarcomas, the matrix becomes fibrillar and hyalinized, resembling osteoid, and differentiation from osteosarcoma may be very difficult, especially in small biopsy samples. Chondrosarcomas in the sinonasal region of dogs are often characterized by nodules of variously differentiated chondroid tissue forming within poorly differentiated mesenchymal elements (Fig. 1.117C, D).

Microscopic features of malignancy in central chondrosarcomas include the presence of many tumor cells with plump nuclei and prominent nucleoli, binucleate tumor cells, and large chondrocytes with single or multiple nuclei (Fig. 1.118A, B). Mitotic figures are seldom present in well-differentiated chondrosarcomas and even a single mitotic figure strongly supports a diagnosis of malignancy in this tumor. In poorly differentiated, more malignant chondrosarcomas, mitotic figures may be relatively common (Fig. 1.119).

Fine-needle aspiration biopsies from chondrosarcomas usually contain fewer cells than osteosarcomas but, on low-power examination, *lakes of bright pink chondroid matrix* may be evident (Fig. 1.120). The tumor cells are similar to those from osteosarcomas, varying from round to fusiform, possessing large, hyperchromatic nuclei and basophilic cytoplasm, which sometimes contains fine pink granules. Anisokaryosis is generally a prominent feature and there may be multinucleate tumor cells. Although a presumptive diagnosis of chondrosarcoma may be possible in cytologic specimens, *confirmation requires histopathology.* Malignant chondroblasts and osteoblasts have too many features in common to allow reliable differentiation cytologically, and some osteosarcomas have extensive chondroid matrix.

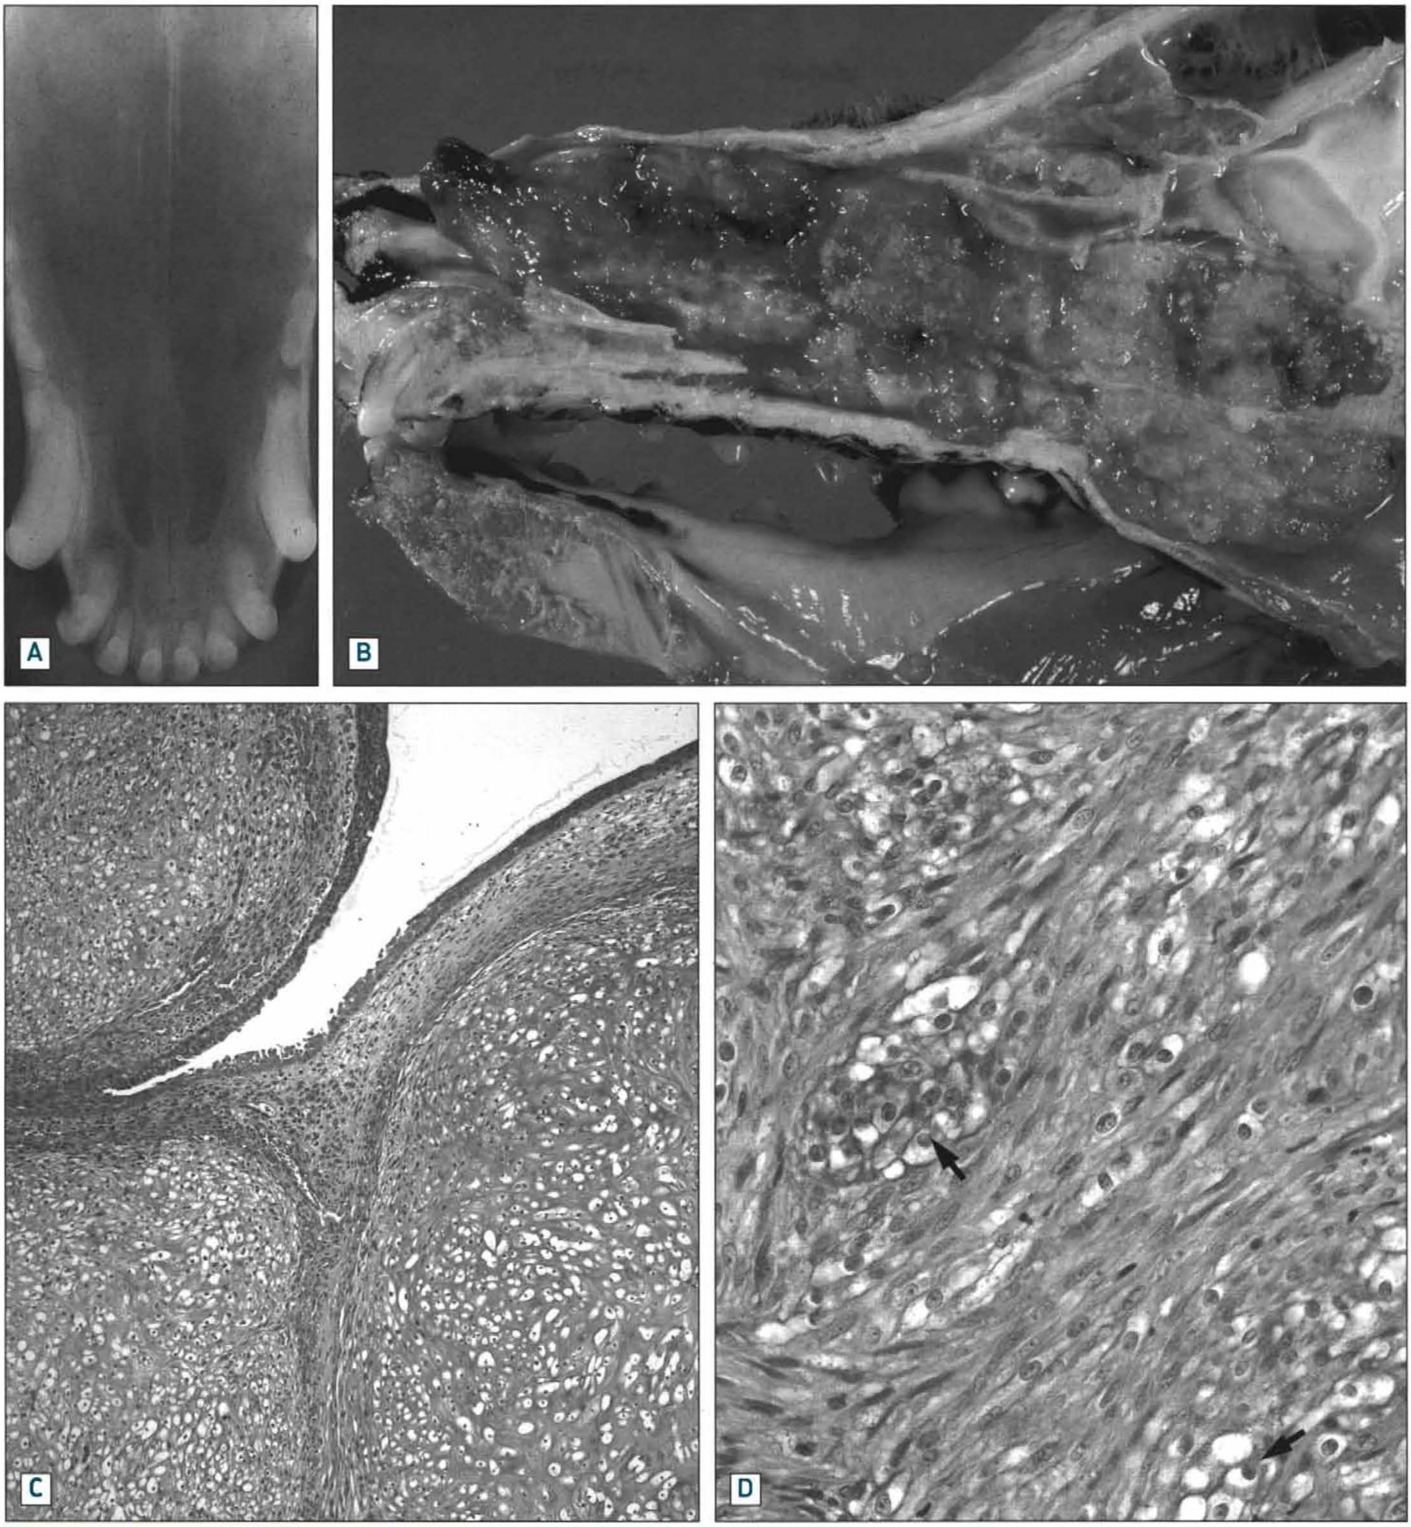

Figure 1.117 Nasal chondrosarcoma, dog. **A.** Radiograph showing loss of trabeculae and replacement by tumor tissue with radiodensity similar to soft tissue. **B.** Sagittal section through the skull of the same dog. Nodules of tumor tissue resembling hyaline cartilage fill the nasal cavity and extend into the nasopharynx. The tumor is eroding into the presphenoid bone, cribriform plate, and hard palate. **C.** Nodules of relatively well-differentiated hyaline cartilage beneath the nasal mucosa bulge into the attenuated lumen of the nasal cavity. **D.** Higher-power view of the same tumor, showing areas of chondroid differentiation (arrows) closely associated with poorly differentiated mesenchymal elements.

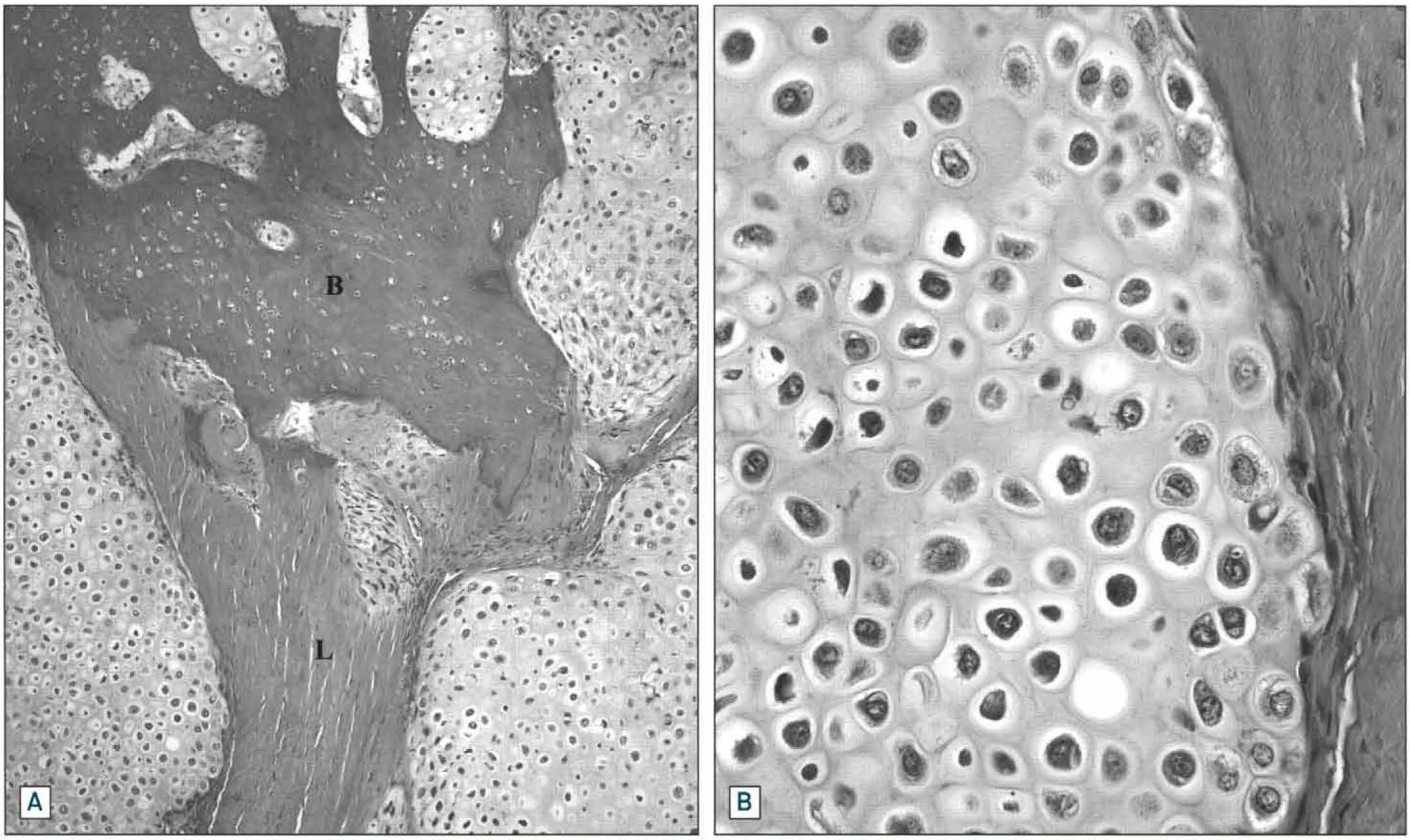

Figure 1.118 Chondrosarcoma, dog. Distal radius. **A.** Nodules of well-differentiated hyaline cartilage surrounding a ligament (L) at its insertion site and invading the adjacent bone (B). **B.** Higher-power view showing the plump, neoplastic chondrocytes compressing the ligament. Most of the tumor cells have large, variably sized nuclei and prominent nucleoli. Some lacunae contain more than one cell.

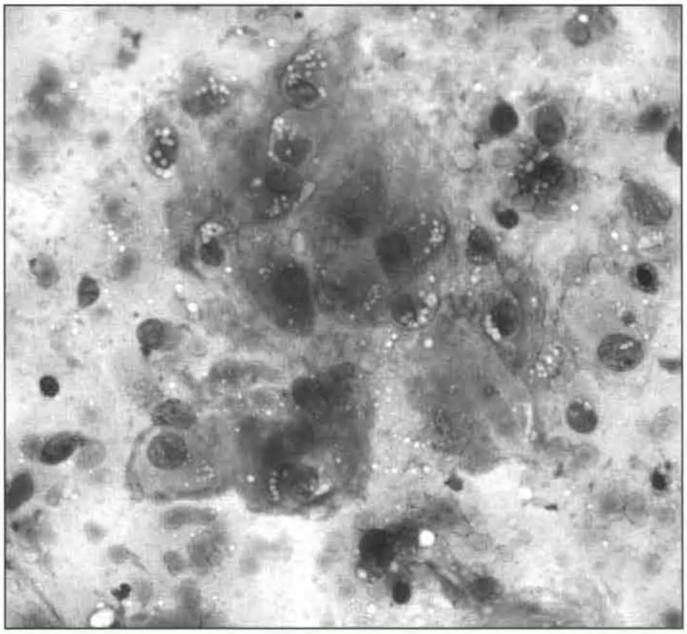

Figure 1.120 Cytological preparation from a **chondrosarcoma** in a dog. Several oval to fusiform cells, often with eccentric nuclei, prominent nucleoli, and basophilic cytoplasm, are closely associated with a background of brightly eosinophilic matrix.

Chondrosarcomas tend to grow more slowly and metastasize later than osteosarcomas, and typically follow a longer clinical course. Local invasion is common, as is recurrence following surgical removal, but the chance of successful removal from accessible sites is much greater than for osteosarcoma. Metastasis is usually to the lungs, but other visceral organs such as the kidney, liver, heart, and skeleton are sometimes involved.

Fibrous tumors of bones

Fibrous tumors of bones are less common in domestic animals than tumors forming bone or cartilage. Ossifying fibroma and fibrous dysplasia are discussed above with osteoma, because of the similarities between these three benign tumors. Skeletal **fibromas** are extremely rare in animals, unlike humans where nonossifying fibromas are relatively common.

Skeletal **fibrosarcomas** arise from connective tissue stroma in either the medullary cavity or periosteum. Their histologic and gross appearances are essentially the same as that of fibrosarcomas elsewhere, although their innocuous microscopic appearance often belies their invasive tendencies. Central (medullary) fibrosarcomas are less common than those originating from the periosteum. They probably comprise about *5% of primary skeletal tumors in dogs* and occur predominantly in mature male dogs of large and medium breeds, but are rarely reported in other species.

In dogs, **central fibrosarcomas** arise most often in *metaphyses of long bones* and cause lytic lesions that must be differentiated from fibroblastic osteosarcomas. They are also reported in the mandible and vertebral column of dogs. It is likely however, that the prevalence of skeletal fibrosarcoma is overestimated. In one study, six of 11 tumors originally diagnosed as skeletal fibrosarcoma were reclassified as osteosarcoma following re-examination and identification of areas of osteoid production by tumor cells. Because of the poorer prognosis of osteosarcoma, an accurate diagnosis carries considerable clinical relevance. The pathologist should not be tempted to diagnose skeletal fibrosarcoma if the quantity of tissue available for examination is inadequate. Sequential radiographs of the lesion may be of diagnostic value because *fibrosarcomas of bone, although they are primarily destructive, usually progress more slowly than osteosarcomas or other highly malignant bone tumors.*

Periosteal fibrosarcomas occur in most species and *tend to involve flat bones* especially those of the head, but also occur on the scapula and occasionally on long bones. They enlarge slowly, causing disfigurement of the involved bone and are intimately attached to the bone surface. Erosion of the adjacent bone cortex may eventually predispose to pathological fracture.

Maxillary fibrosarcoma of the dog is technically a periosteal fibrosarcoma but it is classified separately from other tumors of this type because of its more frequent occurrence, and evidence that *it responds to combined radiation–hyperthermia therapy*. Maxillary fibrosarcomas occur primarily in middle-aged dogs, usually around 7 years of age, and appear to be most common in the Golden Retriever, Doberman Pinscher and German Shepherd breeds. In one large survey of canine bone tumors, ten of 31 fibrosarcomas involved the maxilla. Typically, the mass is broadly adherent to the periosteal surface of the maxilla (Fig. 1.121A, B).

Classification of periosteal fibrosarcomas as low-grade fibrosarcomas is based more on their invasive behavior than their histological appearance, which is often deceptively benign. They are less cellular than fibrosarcomas in other sites, lack the characteristic pattern of interwoven bundles and often contain a highly collagenous stroma with minimal pleomorphism of tumor cells (Fig. 1.121C). Biopsy samples from such tumors will often be misinterpreted as fibroma or fibrous repair tissue, especially if the pathologist is unaware of the clinical history or radiographic findings.

Although periosteal fibrosarcomas can often be dissected free from the underlying bone, *they often recur*. Metastasis to the lungs rarely occurs.

Vascular tumors of bones

Although tumors of vascular tissue are described with the circulatory system, *they can occur as primary bone tumors* and will therefore be mentioned briefly here. Intraosseous **hemangioma** is extremely rare in domestic animals. **Hemangiosarcoma** occurs occasionally as a primary bone tumor, especially in dogs, and is considered slightly less common than primary fibrosarcoma of bone. In one survey of 152 primary bone sarcomas in dogs, four were hemangiosarcomas. The tumor is found mainly in large and medium-sized breeds, with Boxers, German Shepherds and Great Danes overrepresented. The *proximal and distal ends of long bones are most often affected* but tumors are also reported in the pelvic bones, sternum, ribs, maxilla, and vertebrae.

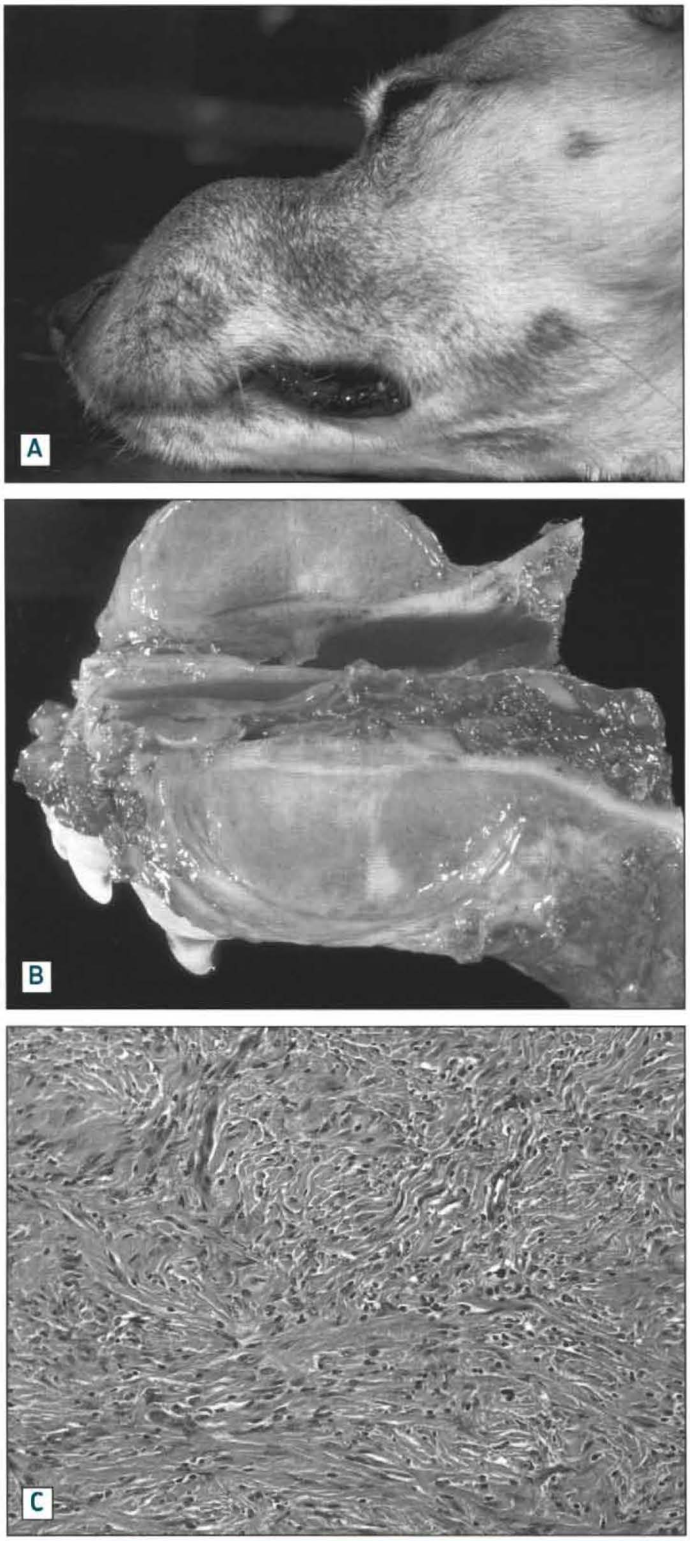

Figure 1.121 Maxillary fibrosarcoma, dog. **A.** Firm swelling over the rostral maxilla. **B.** Sagittal section through the nasal cavity of the same dog. The mass is firmly adherent to the outer surface of the maxillary bone and partly surrounding it. **C.** Interwoven bundles of well-differentiated fibrous tissue showing little microscopic evidence of malignancy.

Skeletal hemangiosarcoma is an aggressive tumor causing bone destruction and often predisposing to pathological fracture. The tumor tends to remain within the medullary cavity rather than invade adjacent soft tissues, but erodes and weakens the cortex. *Grossly*, the tumor resembles hemangiosarcomas of other organs, consisting of spongy, dark red tissue, and *cannot be reliably differentiated from telangiectatic osteosarcoma and aneurysmal bone cysts. Diagnosis is based on the demonstration in microscopic sections of malignant endothelial cells forming vascular channels*, at least in some areas of the tumor. The supporting stroma may become impregnated with plasma proteins, forming a hyaline material resembling osteoid and leading to an incorrect diagnosis of telangiectatic osteosarcoma. *In telangiectatic osteosarcoma, malignant osteoblasts rather than endothelial cells line the blood-filled spaces*, but the distinction is often difficult, especially in small biopsy samples or at sites of pathological fracture. Hemangiosarcomas occasionally metastasize to bones from other tissues and thorough postmortem examination of an affected animal is required before the tumor can be considered to be of bone origin.

Other primary tumors of bones

Giant cell tumor of bone is a recognized entity in humans but is rare in domestic animals with only isolated reports in **dogs** and **cats**. Some reported cases in animals are not convincing and may represent other tumors in which osteoclasts are prominent. Giant cell tumors of humans and animals *typically cause expansile osteolytic masses in the ends of long bones*, often involving much of the subchondral epiphyseal bone. Involvement of metacarpal bones and of the axial skeleton is also recorded in dogs and cats. As the mass expands, it destroys cortex but tends to remain at least partly circumscribed by a thin shell of bone. The osteolytic nature of the tumor combined with its bony shell creates a characteristic "soap-bubble" appearance in clinical radiographs.

The tumor is characterized *histologically* by the presence of *large numbers of multinucleated giant cells closely associated with neoplastic mononuclear cells*. The giant cells, which resemble osteoclasts, are often very large and are scattered uniformly throughout the tumor (Fig. 1.122). Their nuclei resemble those of the mononuclear cells. In some tumors there may be areas of collagen and/or osteoid formation, but this is not a prominent feature and the matrix may be produced by reactive fibroblasts and/or osteoblasts respectively, rather than by the tumor cells. The tumor is highly vascular and may contain cavernous spaces and areas of hemorrhage, leading to possible confusion with aneurysmal bone cyst, which also contains variable numbers of multinucleated giant cells. Osteosarcomas may also contain many osteoclasts in some areas and be mistakenly diagnosed as giant cell tumors.

In cytological preparations, the presence of a large percentage of multinucleated giant cells among many plump, spindle-shaped, or ovoid mesenchymal cells, suggests the possibility of giant cell tumor. Giant cells may also be present in aspirates from other bone lesions, particularly osteosarcoma, but the percentage in giant cell tumors is likely to be much higher. In one report of this tumor in a dog, 25% of all cells obtained by fine-needle aspiration biopsy were multinucleated giant cells. However, definitive diagnosis still requires histological examination of sections from representative areas of the mass. The histogenesis of giant cell tumor is uncertain, but immunochemical staining suggests that the mononuclear tumor cells are of histiocytic origin and that the giant cells arise from their fusion. C-type viral particles were found to be budding from tumor cells in one feline giant cell tumor but their significance is unknown.

Because there are so few documented cases of giant cell tumor in animals, there is inadequate information to provide an indication of their biological behavior. Benign and malignant forms are also reported in animals, the former being most common. In humans, most giant cell tumors are benign, but they commonly recur following surgery and approximately 5–10% are malignant, metastasizing predominantly to the lungs.

Because of the marked differences in prognosis between giant cell tumor and osteosarcoma, both of which may contain many multinucleated giant cells, *a diagnosis of giant cell tumor should never be made from small biopsy samples that are not representative of the lesion.*

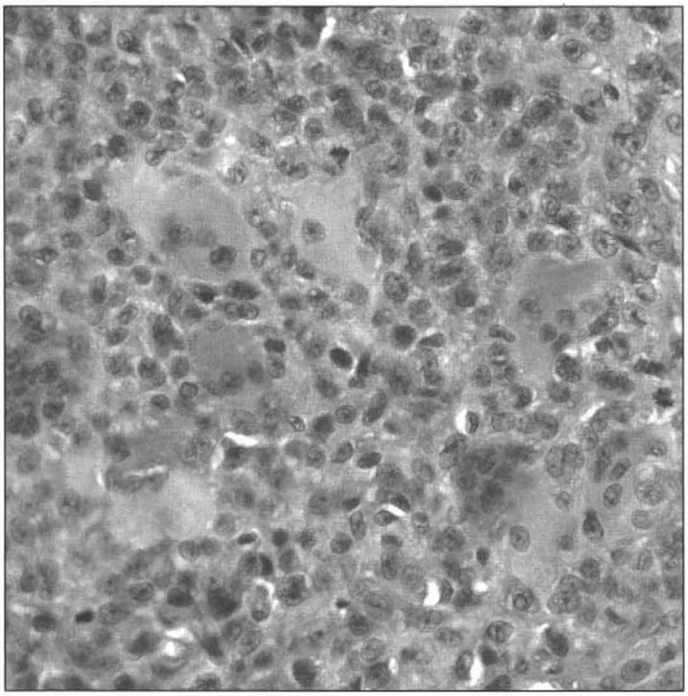

Figure 1.122 Giant cell tumor of bone, cat. Several large, sometimes abnormally shaped, multinucleated giant cells resembling osteoclasts scattered amongst a population of mononuclear cells.

Liposarcoma is a rare primary bone tumor in animals, resembling its soft-tissue counterpart but forming osteolytic bone lesions. The tumor cells typically contain variable numbers of intracytoplasmic vesicles, often with an eccentrically positioned nucleus but, in some areas, may consist of less well-differentiated spindle cells. **Osteoliposarcoma**, a form of **malignant mesenchymoma**, is a malignant neoplasm containing liposarcomatous and osteosarcomatous tissue and is recorded in the dog.

Plasma cell myeloma, a malignant tumor of plasma cells within the bone marrow, typically produces discrete, multicentric, lytic lesions in bones, especially those involved in active hematopoiesis. The disease occurs most often in **dogs** but is also reported occasionally in **cats** and **horses**. The mean age of affected dogs is approximately 9.5 years (range 2.5 to 16 years) and males are affected more frequently than females. In cats, like dogs, there is a higher incidence in males but no sex predilection is recognized in the small number of cases reported in horses.

A feature of plasma cell myeloma in all species is the *production of a homogeneous immunoglobulin or immunoglobulin fragment (paraprotein or M-component),* which appears as a monoclonal spike on serum protein electrophoresis. The disease may also be accompanied by Bence–Jones proteinuria, hyperviscosity syndrome, and hypercalcemia. Involvement of vertebral bodies may result in paraplegia due to protrusion of tumor masses into the spinal canal, or secondary to pathological fractures of vertebral bodies. Discrete, "punched-out" foci of osteolysis (Fig. 1.123A), of various sizes, and often involving multiple bones, are present in approximately two-thirds of dogs with plasma cell myeloma, but appear to be less common in affected horses. In dogs, the principal sites of bone involvement are vertebrae, especially in the thoraco-lumbar region, femur, pelvis, humerus, and ribs. Bones of the distal limb are seldom involved in dogs, unlike cats where they appear to be involved as often as proximal bones of the limb.

Grossly, the lytic foci consist of soft, fleshy or gelatinous, dark red nodules, replacing trabecular bone. The lesions are often multiple and may be associated with a pathological fracture. Histological or cytological examination reveals a relatively pure, dense population

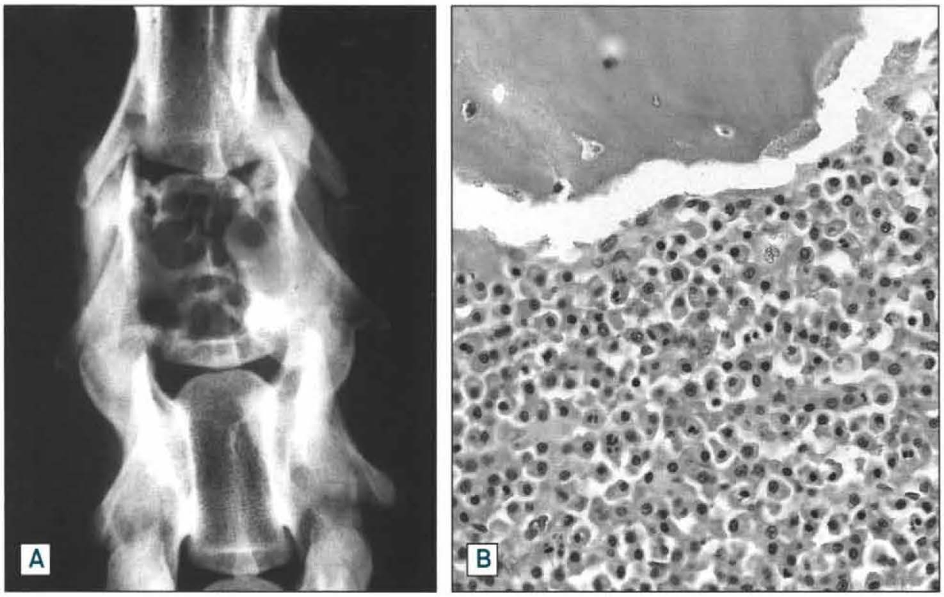

Figure 1.123 Plasma cell myeloma, dog. **A.** Discrete, "punched out" osteolytic foci in a cervical vertebra. **B.** Monomorphic population of plasma cells replacing normal marrow architecture.

of plasma cells (Fig. 1.123B), which may be either well-differentiated or large, anaplastic round cells with a high mitotic index.

Malignant lymphoma may also occur as a primary tumor of bone in humans and animals but, more frequently, bone involvement occurs in association with multicentric lymphoma. There are few reported cases of primary skeletal lymphoma in **dogs**, but most have occurred in animals less than 1 year of age. The lesions in dogs are typically lytic and multiple, and cannot be distinguished radiographically or grossly from plasma cell myeloma. Pathological fractures and hypercalcemia are reported, but hypercalcemia is not a consistent feature of the disease, even when the bone lesions are extensive. Microscopically, sheets of monomorphic lymphocytes replace bone trabeculae and the contents of the marrow cavity in areas of lysis.

Infiltration of bone marrow, together with *multifocal to locally extensive bone infarction*, is reported in **calves** with the juvenile, sporadic form of malignant lymphoma. Affected calves also have generalized lymph node enlargement and variable involvement of other organs, including liver, kidney, and spleen. The bone infarcts are readily visible grossly as discrete, pale areas (Fig. 1.124A), but are not detected unless the bones are sectioned during postmortem examination. The mechanism of the tumor-associated bone marrow necrosis is not clear, but ischemia secondary to infiltration of the marrow with malignant cells is the most likely explanation. Histologically, the infarcted areas may include either neoplastic or nonneoplastic tissue and are often bordered by a zone of edematous connective tissue (Fig. 1.124B).

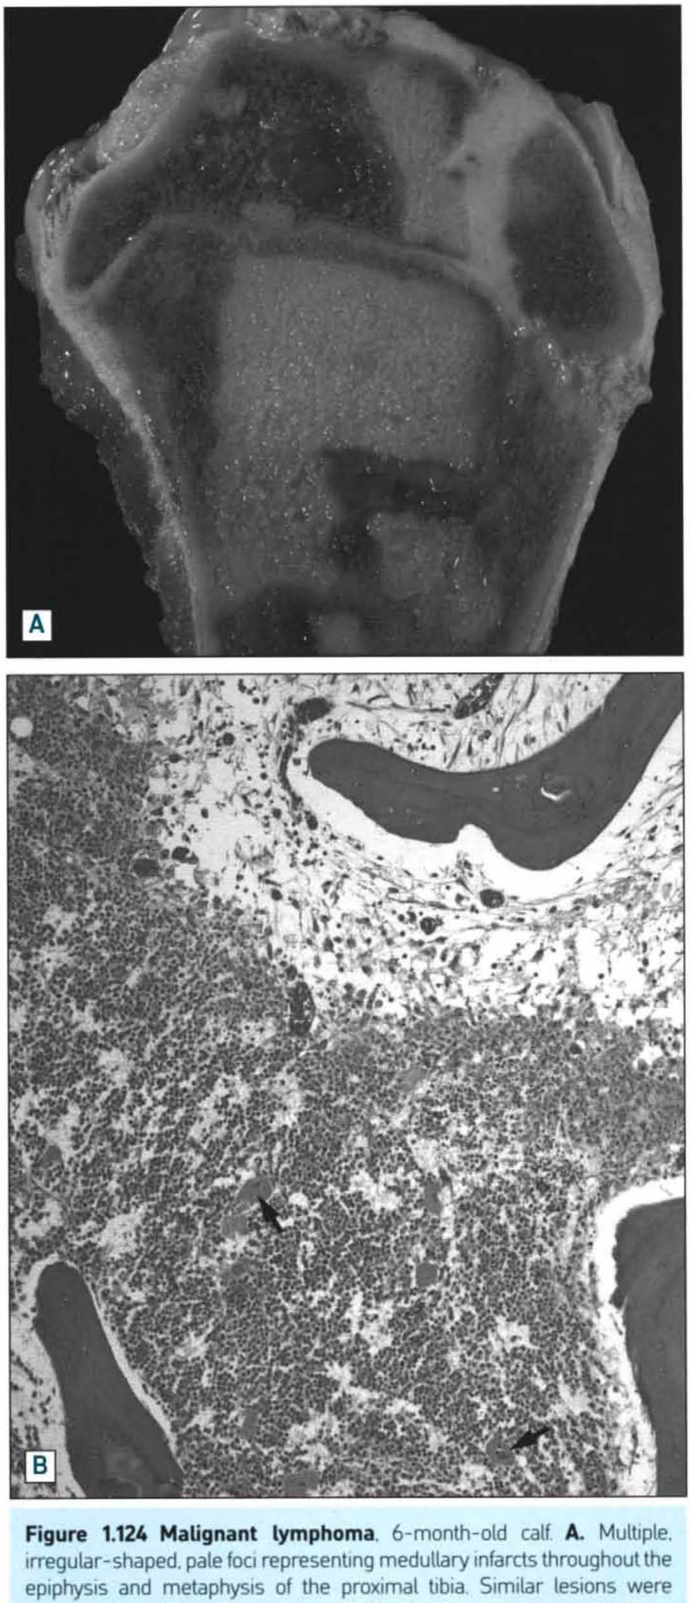

Figure 1.124 Malignant lymphoma. 6-month-old calf. **A.** Multiple, irregular-shaped, pale foci representing medullary infarcts throughout the epiphysis and metaphysis of the proximal tibia. Similar lesions were detected in most other long bones. **B.** Sheets of necrotic tumor cells in an infarcted area, bordered by a zone of edematous connective tissue. Several necrotic megakaryocytes (arrows) are scattered amongst the tumor cells.

Secondary tumors of bones

Malignant neoplasms originating in soft tissues or in the skeleton may involve bone secondarily either by hematogenous metastasis or direct

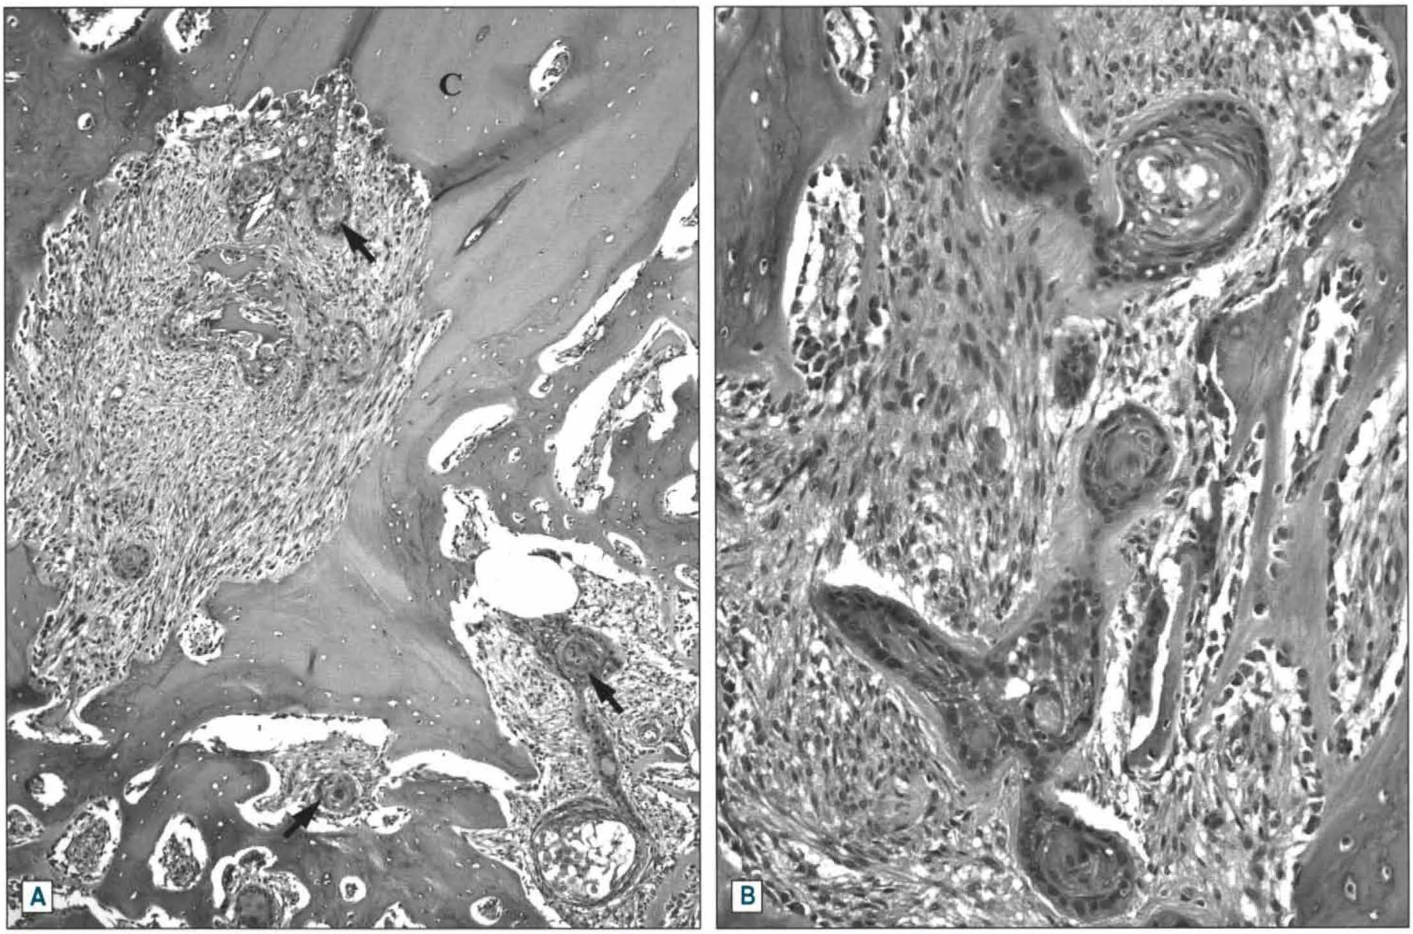

Figure 1.125 Squamous cell carcinoma, cat. Mandible. **A.** Cords of epithelial cells (arrows) surrounded by a marked fibroblastic response invading the dense cortical bone (C) and adjacent reactive bone. **B.** Closer view of tumor cells showing evidence of squamous differentiation.

extension. **Metastatic bone disease** is very common in humans but is *generally considered rare in domestic animals*. Several explanations for this discrepancy have been proposed. The life span of most farm animals is abbreviated by slaughter, and that of many pets by euthanasia, thus limiting the time for tumors to develop, metastasize and, perhaps most importantly, produce signs of metastatic disease.

While there appears to be a genuine difference between the frequency of skeletal metastases in humans and domestic animals, *metastatic bone disease in animals is likely to be much more common than is realized*. The skeleton of animals with malignancies at other sites is seldom examined in detail, either radiographically or during necropsy, and skeletal metastases could easily be missed. In one survey, skeletal metastases were identified in 5.8% of dogs with metastatic carcinoma, but since fewer than 20% of the dogs underwent bone scan, skeletal radiography, or necropsy, the true prevalence was probably much greater. In another study, 98 dogs with a variety of carcinomas were subjected to thorough examination of the skeleton at necropsy. The spine, pelvis, and long bones were sectioned longitudinally and the ribs inspected visually. Macroscopic metastases were detected in 21 (21.4%) of the 98 dogs. The prevalence of metastases would almost certainly have been even higher had the bones been scanned or radiographed, or if the skeleton had been subjected to detailed microscopic examination.

Carcinomas metastasize to the skeleton of dogs much more commonly than sarcomas and the most common tissues of origin are the mammary gland, thyroid, prostate, ovary, and lung. The ribs, vertebrae, and proximal long bones are the favored locations for skeletal metastases in dogs.

Information on the prevalence of skeletal metastases in cats is scarce, but there are occasional reports of pulmonary and mammary carcinomas metastasizing to the bones in this species. Interestingly, metastatic carcinomas in the skeleton of cats more frequently involve bones of the distal limb (acrometastases), unlike humans and dogs where skeletal metastases are uncommon in bones distal to the elbow or stifle.

Secondary bone tumors generally produce osteolytic lesions that are difficult, if not impossible, to distinguish radiographically from primary bone tumors. This may contribute to the underdiagnosis of secondary bone tumors in cases where the radiographic diagnosis is not confirmed by histological or cytological examination of biopsy specimens. For example, in a report of 20 metastatic bone tumors in dogs, the radiographic diagnosis was primary bone tumor in all but one case.

In general, dogs with skeletal metastases are older than dogs with primary tumors of bones (median age 8.5–10 years), and there is no obvious breed or size predilection. Unlike primary bone sarcomas, metastatic skeletal carcinomas are found most commonly in dogs weighing less than 25 kg and approximately 30% of such tumors are found in small dogs weighing less than 15 kg.

A definitive diagnosis of metastatic bone tumor is based on either cytological or histological examination of fine-needle aspirates or tissue biopsies respectively but, in most cases, the tumor cells provide few indications as to the tissue of origin. Even after thorough postmortem examination, the primary site of a metastatic skeletal carcinoma may not be apparent, although malignant epithelial cells within a skeletal lesion can only be derived from an extraskeletal carcinoma. Osteosarcomas sometimes metastasize from the bone of origin to other skeletal sites, in which case the secondary lesions may be in atypical locations and may appear to have been present for different lengths of time. For some sarcomas, such as hemangiosarcoma, which may originate in bone or other tissues, it may be impossible to determine whether skeletal involvement is primary or secondary but if the tumor is present in several skeletal sites then metastasis is more likely.

Malignant tumors in soft tissues adjacent to a bone may penetrate the bone by direct extension and can be referred to as **invasive tumors of bones**. *This is a feature of some types of tumor, in particular squamous cell carcinoma of the digits and oral cavity in dogs and cats.* These aggressive tumors frequently invade the periosteum of the underlying bone, erode the cortex, and penetrate the medullary cavity. In dogs, bone invasion is reported to occur in 77% of oral squamous cell carcinomas. Microscopically, cords of anaplastic epithelial cells, showing evidence of squamous differentiation, permeate the osseous and extra-osseous tissues, and are accompanied either by an osteoblastic reaction or a prominent fibroblastic response with osteoclastic resorption of adjacent bone (Fig. 1.125A, B). Squamous cell carcinomas of the canine digit not only invade bone but also metastasize to local lymph nodes, and eventually to the lungs.

Other tumors that appear to have an affinity for bone invasion are *malignant melanomas of the oral cavity in dogs* and *fibrosarcomas of the canine skull and long bones*. Tumors of dental origin, including acanthomatous epulis, ameloblastoma, and fibroameloblastoma, may also extend into the maxilla or mandible of dogs and cats.

Tumor-like lesions of bones

Several nonneoplastic lesions of bones occur in humans and domestic animals and must be differentiated from primary and secondary bone tumors. Included amongst these are various forms of **bone cysts**, some of which are not true cysts as defined by pathologists but appear "cystic" radiographically.

Solitary or **unicameral bone cysts** are reported in the *metaphyses of long bones in children and young dogs*, a breed predisposition having been suggested in Doberman Pinschers. The lesions may be monostotic or polyostotic and are generally lytic and expansile, with erosion of the cortex and little or no periosteal new bone formation. In radiographs, shelves of bone often project from the cyst wall, but in most cases, these are incomplete and the cysts are unicameral. Pathological fracture may occur due to the localized bone destruction. *The cyst cavity is filled with clear or sanguineous fluid and lined by a connective tissue membrane of variable thickness, with scattered multinucleate giant cells and hemosiderin-containing macrophages.* The pathogenesis of unicameral bone cysts is uncertain but they may be the result of impaired venous drainage from sites of active endochondral ossification. Recurrence following surgical drainage and curettage is uncommon.

Aneurysmal bone cysts have been reported rarely in dogs, cats, horses, and cattle. Radiographically, they appear as *expansile, osteolytic lesions* (Fig. 1.126A) *contained by a thin, "ballooned" periosteum and with an internal "soap-bubble" appearance* and must be differentiated from osteosarcoma, hemangiosarcoma, fibrosarcoma, and plasma cell myeloma. Too few cases are reported in animals to establish age or site prevalence, although lesions are described in bones of both the axial and appendicular skeleton. The gross appearance of aneurysmal bone cysts closely resembles telangiectatic osteosarcoma and hemangiosarcoma, typically exuding blood from the cut surface, and may contain solid areas in addition to multiple blood-filled cysts. Pathological fracture may be present.

Fine-needle aspiration biopsies are unlikely to be useful in the diagnosis of either aneurysmal or unicameral bone cysts as the preparations are likely to be heavily contaminated with blood. Confirmation of the diagnosis requires histopathological examination of biopsy specimens. *The lesion consists of cavernous blood-filled spaces* (Fig. 1.126B) *separated by septa of loosely arranged spindle cells with scattered multinucleate giant cells and hemosiderin-containing macrophages*, similar to the lining of unicameral bone cysts. Osteoid or spicules of reactive bone may be present in the surrounding connective tissue (Fig. 1.126C) and should not be mistaken for tumor bone. The pathogenesis of these lesions is not known, but altered blood flow, perhaps secondary to trauma or some other bone disease, such as malignancy, is believed to play a role.

Subchondral (juxtacortical) bone cysts occur in young horses, pigs, and occasionally in other species, as a manifestation of osteochondrosis. The lesions are typically 5–10 mm in diameter and may be multilocular. In horses, subchondral cysts are found most frequently beneath the articular surfaces of phalanges, but also occur in femoral condyles and a range of other bones. *The cysts may develop either from residual nodules of epiphyseal cartilage or within foci of subarticular hemorrhage.* Histologically, the lesions are not always cystic, instead consisting of fibrous tissue with extensive myxoid matrix or, in some cases, degenerate cartilage. Cystic spaces lined by fibrous tissue and containing fluid, possibly of synovial origin, are present within some lesions. In humans, subchondral cysts occur in association with degenerative joint disease and are thought to be secondary to either synovial fluid intrusion or bony contusion.

Intraosseous epidermoid cysts *are reported rarely in dogs as a cause of lytic lesions in the distal phalanx.* At this site, they must be differentiated from nail-bed carcinomas, malignant melanomas, and osteomyelitis. One reported case involved the tenth thoracic vertebral body of a dog. Similar lesions occur in the distal phalanx and skull of humans. Radiographically, there may be a sclerotic reaction around one or more lytic foci and extensive periosteal new bone formation. Grossly, the lesion consists of multilocular cysts containing pale cream, crumbly material. Microscopically, *the cysts are lined by well-differentiated, stratified squamous, keratinizing epithelium and filled with layers of keratinized squames.* The squamous epithelium may show marked pseudoepitheliomatous hyperplasia and could be mistaken

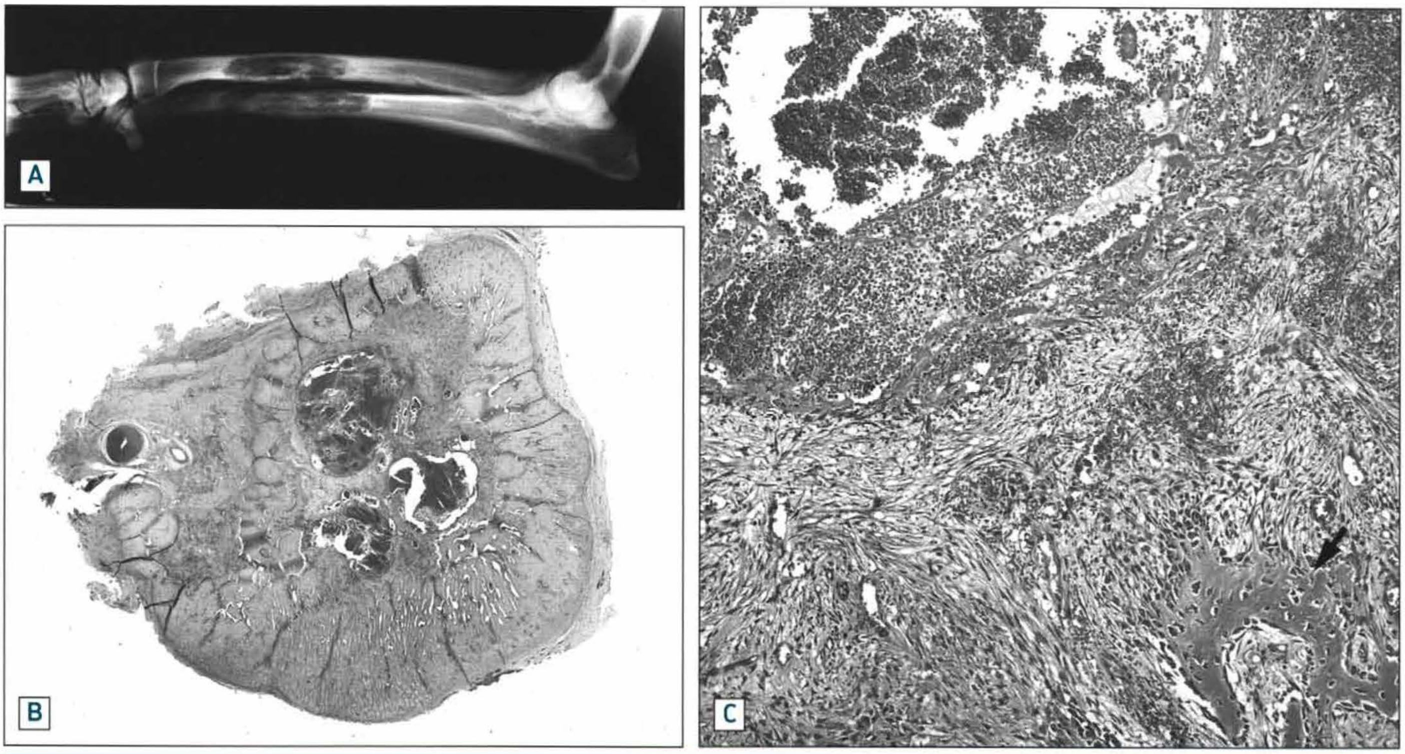

Figure 1.126 Aneurysmal bone cyst. 1-year-old dog. Radius and ulna. **A.** Radiograph showing expansile, osteolytic lesions in the distal diaphyseal regions of the radius and ulna. **B.** Subgross, transverse section of ulna showing cavernous, blood-filled spaces surrounded by loose connective tissue, reactive bone, and remnants of cortical bone. **C.** Reactive bone (arrow) forming in the connective tissue near a blood-filled space.

for squamous cell carcinoma, especially if a biopsy sample is inadequate. The cysts are generally supported by a dense fibrous stroma and surrounded by thickened bone trabeculae. The pathogenesis of intra-osseous epidermoid cysts is uncertain, but the digital lesions are believed to be *secondary to a penetrating wound*, with traumatic implantation of epidermal fragments into the underlying bone. Cysts involving the skull of humans, and vertebral body of a dog, may represent *rests of heterotopic ectoderm* that have become sequestered along lines of closure during embryonic development.

An **exuberant fracture callus** containing extensive areas of disorganized and primitive bone, cartilage, and fibrous tissue *may also resemble a primary bone tumor.* Even in cytological and histological preparations, differentiation of an early callus from osteosarcoma and chondrosarcoma can present a significant challenge, especially in cases where the clinical and radiographic history is inadequate.

Diseases of joints

GENERAL CONSIDERATIONS

Three main types of joints or articulations unite adjacent bones and/or cartilaginous structures throughout the skeleton. These are classified on the basis of their morphology and tissue composition as *fibrous, cartilaginous, or synovial joints.* This method of classification has limitations as some joints contain a mixture of the different tissue types, while others change their composition during maturation. Furthermore, even within each category, there is considerable variation in the amount of movement between adjacent skeletal structures.

In spite of these limitations, the system is widely accepted in the medical and veterinary literature and is used throughout this chapter.

Fibrous joints

In these joints the *bones are united by fibrous tissue*, which allows little movement between them. Fibrous joints are *subdivided into sutures, syndesmoses, and gomphoses.*

Sutures are limited to the *skull*, where they allow continued growth of cranial bones by intramembranous ossification as the brain matures. Osteogenic cells form a cambial layer adjacent to the bone-forming surfaces and are separated by intervening layers of fibrous tissue, which vary in thickness depending on their location. Broader sheets of fibrous tissue often occur at the junctions of three adjacent skull bones and are referred to as **fontanelles**. A bony union or **synostosis** replaces the fibrous tissue of many sutures once growth ceases.

A **syndesmosis** is a fibrous joint in which *adjacent bones are united by an interosseous ligament or membrane*, such as occurs in some species between the shafts of the tibia and fibula and between the radius and ulna. Syndesmoses contain fibrous and elastic connective tissue in variable proportions. Consequently, minor movement may occur between the bones due to stretching of the ligament or membrane.

Gomphoses are specialized fibrous *joints between the teeth and either the mandible or maxilla.* The membrane between tooth and bone is termed the **periodontal ligament**, and although it contains no elastic fibers, it allows slight movement of the tooth.

Cartilaginous joints

These are joints in which the *union consists of either hyaline or fibrocartilage*, or a combination of the two. There are two types of cartilaginous joints, *synchondroses and symphyses.*

Synchondroses are *temporary joints* that exist only while the skeleton is growing and are replaced by bone once the skeleton matures. *Physeal growth plates*, which unite the separate centers of ossification in long bones, are synchondroses consisting of well-organized hyaline cartilage. Synchondroses also exist between bones forming by endochondral ossification in the basicranium.

Symphyses are located in the *mid-sagittal plane of the body and are permanent joints*, unlike synchondroses. The adjacent bones are capped by a thin layer of hyaline cartilage, which blends with fibrocartilage, forming a joint with great strength while still allowing a limited amount of movement. Examples are the *pubic symphysis and intervertebral disks.* Intervertebral disks unite each pair of vertebrae in the vertebral column, with the exception of the atlas and axis.

Diseases of **intervertebral disks** are very common in humans and certain domestic animals. For this reason, a brief discussion of the unique structure and function of these joints is appropriate. Each disk contains *a central core, the* **nucleus pulposus**, which is a remnant of the notochord. In young animals, the nucleus pulposus is gelatinous and translucent (Fig. 1.127). The matrix consists of glycosaminoglycans, particularly chondroitin-6-sulfate, keratan sulfate, and hyaluronan (hyaluronic acid), collagen (mainly type II) and a large amount of water. The cellular concentration is relatively sparse and consists predominantly of *chondrocytes*, which are often arranged in small clusters, and fibrocytes. The nucleus pulposus of immature animals may also contain clusters of notochordal or physaliferous cells, which have abundant finely vacuolated cytoplasm filled with glycogen. With aging, the glycosaminoglycan and water concentration of intervertebral disks declines and the number of fibrocytes increases. *The nucleus pulposus is surrounded by the* **annulus fibrosus**, which is broader ventrally than dorsally and consists of concentric layers of fibrocartilage. The direction of the collagen fibers alternates between each layer. The matrix of the annulus fibrosus consists predominantly of type I collagen, with lesser quantities of glycosaminoglycans. *Fibrocytes* are the predominant cell type. Fine nerve endings are present in the outer third of the annulus fibrosus. *The cranial and caudal boundaries of intervertebral disks are occupied by* **cartilaginous end plates**, which consist of hyaline cartilage and are in direct apposition to the vertebral bodies on either side of the joint. Collagen fibers from the annulus fibrosus merge with those of the cartilaginous end plates and become embedded in the bony trabeculae of the vertebral body, forming a strong, stable union.

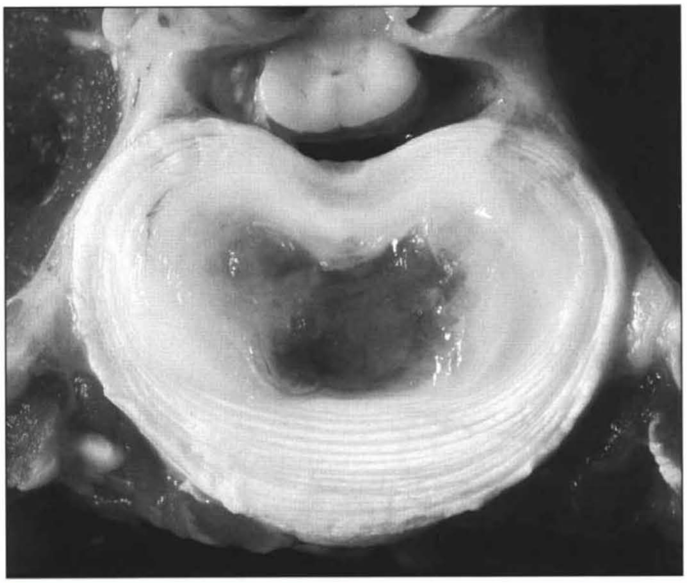

Figure 1.127 Intervertebral disk of a young dog. The gelatinous nucleus pulposus is surrounded by the annulus fibrosus, which consists of concentric layers of fibrocartilage.

Dorsally and ventrally, the intervertebral disks merge with the **dorsal and ventral longitudinal ligaments**, which run the length of the spinal column. The dorsal longitudinal ligament lies in the floor of the vertebral canal, merging with each disk as it passes, except between the second and tenth thoracic vertebrae. In this region, *conjugal ligaments* connecting the heads of the corresponding ribs cross the floor of the canal between the dorsal longitudinal ligament and the dorsal portion of the annulus fibrosus. The extra support provided by the conjugal ligaments is no doubt responsible for the low incidence of disk protrusions between the second and tenth thoracic vertebrae in dogs.

Intervertebral disks are designed to allow limited movement between adjacent vertebral bodies when the vertebral column is subjected to a wide variety of different loading conditions, including compression, tension, bending, shear forces, and torsion. Degenerative changes occurring in the nucleus pulposus and/or annulus fibrosus as part of the aging process or in disease states can markedly alter the ability of intervertebral disks to withstand such forces.

Synovial joints

Synovial or **diarthrodial** joints are found predominantly in the appendicular skeleton and allow considerable movement between adjacent bones. The bone ends in these specialized joints are covered by *hyaline articular cartilage* and an *articular capsule* surrounds a central cavity filled with *synovial fluid*. Some synovial joints are supported by ligaments, while others, such as the femorotibial joint, contain fibrocartilaginous menisci. Because of the importance of these joints, and the frequency with which they are involved in disease processes, the individual components of synovial joints will be discussed in more detail.

Articular cartilage is the key component of synovial joints, being required to withstand the compressive forces associated with weight bearing in addition to the shear forces that occur during motion. Grossly, it is smooth, bluish-white, and turgid in young animals but, with advancing age, it becomes yellow, opaque, and less elastic. The thickness of articular cartilage varies between and within joints, tending to be thickest at points of maximum weight bearing.

The matrix of articular cartilage is approximately 70–80% water. *The organic component consists largely of proteoglycans, type II collagen, and lesser quantities of types V, VI, IX, X, and XI.* Although not apparent in routine histologic preparations, the type II collagen fibrils are arranged in loops with either end firmly embedded in the calcified zone. Therefore, the fibrils located in the superficial zone are oriented parallel to the articular surface, while those in the radial zone are more vertical. This arrangement presumably enhances the ability of articular cartilage to withstand the range of shear and compressive forces to which it is exposed. In addition to covalent cross-links between chains of type II collagen in articular cartilage, there are intermolecular links between type II and type IX collagen. Type IX collagen is a small, nonfibrillar molecule, comprising only 1–2% of articular cartilage, but appears to be important in anchoring proteoglycan molecules to collagen and stabilizing the network of collagen fibers within the matrix.

The *proteoglycan subunits of articular cartilage* consist of a core protein with the glycosaminoglycan molecules chondroitin-6-sulfate, chondroitin-4-sulfate, and keratan sulfate attached. A small peptide referred to as *link protein* links the amino-terminal end of the core protein in proteoglycan subunits to hyaluronan (hyaluronic acid) filaments, thus forming massive, stable proteoglycan aggregates. The term *aggrecan* is applied to the proteoglycan monomers that link with hyaluronan, and the complex is referred to as an aggrecan aggregate. The glycosaminoglycan molecules in these aggregates are negatively charged because of the presence of many carboxyl and sulfate groups and therefore remain separated when attached to the core protein. Water molecules are trapped and immobilized by the negative charges and the meshwork of large, hydrophilic molecules, resulting in the *formation of a gel* supported by a delicate reticular arrangement of collagen fibrils. Water can move only slowly within this meshwork, thus allowing articular cartilage to maintain its turgidity when subjected to a compressive load. This flow of water during movement is important in promoting the transport of nutrients to chondrocytes within the articular cartilage and providing lubricant for the joint. Small quantities of nonaggregating proteoglycan monomers, including decorin and biglycan, are also found in articular cartilage. The role of these proteoglycans, which consist of chondroitin sulfate and dermatan sulfate, is not clear.

Histologically, the cellular concentration of articular cartilage is low, especially in adults, and the chondrocytes are not distributed randomly. In the *superficial or gliding zone*, the chondrocytes are relatively small and flattened, with their long axis parallel to the articular surface. Beneath this layer, is an *intermediate (transitional) zone* in which the chondrocytes are round or ovoid, then a *radial zone*, in which large, round chondrocytes line up vertically in short columns reminiscent of those in the physis. The proteoglycan content of the transitional and radial zones is greater than that of the superficial zone. The fourth recognizable zone in mature articular cartilage is the *calcified zone*, which is separated from the radial zone by an irregular basophilic line, referred to as the "*tidemark*." Although collagen fibrils do not cross from the calcified zone of articular cartilage into subchondral bone, the undulating nature of this osteochondral interface provides a strong attachment with considerable resistance to shearing forces. In immature animals, endochondral ossification beneath the articular cartilage contributes to the growth in size of the epiphysis. The metachromasia of cartilage matrix with stains such as toluidine blue is due to its glycosaminoglycan content. When proteoglycans are lost, metachromasia is reduced, the intercellular substance stains positively by the periodic acid-Schiff (PAS) method, and collagen fibers are more prominent.

Although the collagen component of articular cartilage is relatively stable, the *proteoglycan macromolecules are constantly being degraded and replaced*, perhaps as part of an internal remodeling system mediated by autodegradative enzymes. Various zinc-dependent metalloproteinases are secreted by the chondrocytes and cleave the core protein, link protein, and hyaluronan molecules at specific locations. The fragments diffuse into the synovial fluid then into the synovial membrane, where they are removed by lymphatics. Overactivity of these proteases may be responsible for cartilage degradation in degenerative joint disease and immune-mediated arthritis. Chondrocytes in articular cartilage must continually synthesize new matrix components in order to replace those that are degraded and lost. They respond to various soluble mediators, including synovial cytokines, such as tumor necrosis factor and interleukin-1, in addition to mechanical loading, changes in hydrostatic pressure and even to electric fields. A serine proteinase inhibitor and various collagenase inhibitors have been isolated from human and bovine articular cartilage. These are probably important in the regulation of extracellular matrix degradation.

Articular cartilage is devoid of blood vessels and nerves. The chondrocytes within articular cartilage therefore depend on diffusion of nutrients from synovial fluid through the extracellular matrix, except in immature animals where a proportion of the nutrients entering articular cartilage may diffuse through the relatively permeable subchondral bone. Because of the absence of nerve endings, damage to articular cartilage does not cause pain unless there is concomitant injury to the subchondral bone and/or joint capsule, both of which are well supplied with nerves. The surface of the cartilage appears to be porous, at least in macromolecular dimensions, and the diffusion of nutrients into cartilage is aided by the massaging effect of normal movement. It appears that the integrity of the cartilage is preserved only if joint movements are physiological in their range and pressure. *Sustained excesses of pressure and prolonged disuse accelerate degeneration.* The latter is of particular relevance in animals with limb fractures, where one or more joints may be immobilized by casting or external fixation. Such fixators should be left in place for the shortest time possible and, ideally, allow up to 10 degrees of joint motion.

The chemical composition of articular cartilage alters with advancing age. Although the collagen content remains relatively stable throughout life, the proteoglycan content slowly decreases from birth. The protein core and glycosaminoglycan chains are longer in immature animals than in adults and there is a rapid decline in the concentration of chondroitin-4 sulfate with aging. This is accompanied by a corresponding increase in the concentration of keratan sulfate.

The thin plate of **subchondral bone**, to which the articular cartilage is attached, is approximately *ten times more deformable than cortical bone.* This is important in allowing more even distribution of the load between the articular cartilage and the bone at times of peak loading. In chronic degenerative joint diseases, the subchondral bone may become denser. In such cases, the articular cartilage is required to bear an increased proportion of the burden and the degenerative process is accelerated. There is some debate as to whether thickening of the subchondral bone precedes degeneration of the articular cartilage in degenerative joint diseases, or occurs as a sequel, but it is likely that the two processes occur concurrently.

In some joints of cattle, horses, and pigs, nonarticulating depressions known as **synovial fossae** (Fig. 1.128) are present near the midline. These normal structures are bilaterally symmetrical and are acquired during the first months of postnatal life as a consequence of joint modeling. During skeletal growth, acquired incongruities in central areas of certain joints cause progressive loss of contact between apposing articular surfaces. While the superficial or gliding layer of the articular cartilage in these areas persists, chondrocytes in the deeper zones of the subarticular growth cartilage are not maintained and gradually disappear. Gradually, synovial fossae appear as central depressions having distinct borders and a smooth, blue to pink surface, reflecting the proximity of the subchondral capillary bed. A study in 50 swine found that synovial fossae were not present at birth, but were present commonly after 4–5 months of age on the articular surfaces of the scapula, distal humerus, proximal radius, distal radius, and distal surface of the intermediate carpal bone. *It is important that synovial fossae are not mistaken for lesions in the articular cartilage or as indicators of collapsed subchondral bone.* In general, they are of no significance, although in horses they may be structural points of weakness where infection can be passed between the joint cavity and the subchondral bone. In diseased joints, synovial fossae may become more prominent due to hyperemia of the synovium or the underlying epiphyseal bone.

An **articular capsule** surrounds each synovial joint and consists of an outer fibrous capsule and an inner synovial membrane. The **fibrous capsule** consists of parallel bundles of dense, fibrous connective tissue and merges with the periosteum of the bones on either side of the joint. This strong capsule restricts the range of movement possible between articulating bone ends and is supported in some areas by focal thickenings or **ligaments**. Intra-articular ligaments, such as the cruciate ligaments of the stifle, add further support in some joints. **Tendons** may also attach to the articular capsule, adding strength to areas that require it. Collagen fibers from ligaments and tendons may be attached to the fibrous capsule or may attach to bone at sites referred to as **entheses**. At these sites, collagen fibers from the tendon merge with zones of unmineralized then mineralized fibrocartilage, before becoming incorporated into bone as **Sharpey's fibers**. Entheses are well served by anastomosing blood vessels originating within the peritenon, perichondrium, and periosteum, and have a prominent nerve supply. Excessive tension on ligaments may lead to rupture of the ligament, or to an avulsion fracture, where a fragment of bone is detached with the enthesis intact. The latter is not uncommon in animals with rickets or fibrous osteodystrophy. The fibrous capsule is well supplied with blood vessels, lymphatics, proprioceptive nerves, and pain receptors. Thickening of the fibrous capsule in animals with chronic joint diseases leads to reduced motion or stiff joints but may be difficult to appreciate clinically or at necropsy.

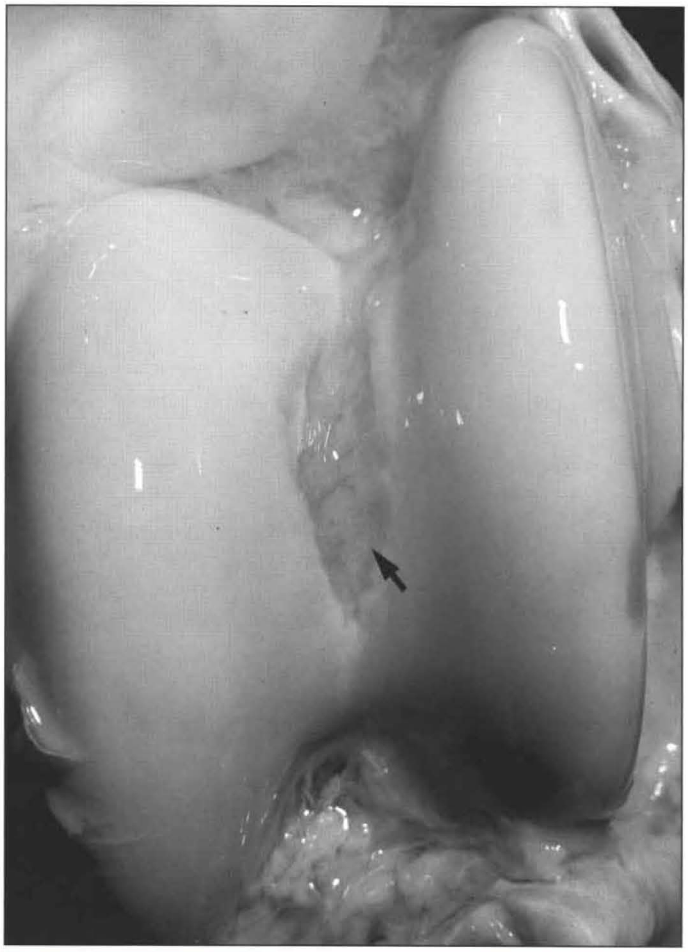

Figure 1.128 Synovial fossa (arrow) in the groove between articular condyles of the talus in a horse.

In the *femorotibial joints* of domestic animals, *semilunar fibrocartilaginous disks, or* **menisci**, provide additional stability. These structures are firmly attached to ligaments, or to the fibrous layer of the joint capsule, and extend into the joint space between the articulating bone surfaces. Menisci are not lined by a synovial membrane but are innervated and have a blood supply. Similar, but more circular or oval structures, referred to as **articular disks**, *are present in the temporomandibular joint.* Articular disks may possess a central perforation. Intrameniscal calcification and ossification in the stifle joint occurs uncommonly in humans and has been reported in cats. Such lesions must be differentiated from intra-articular avulsion fractures or loose bodies in clinical radiographs.

The **synovial membrane** is a smooth, glistening, highly vascular layer that lines the inner surface of the fibrous capsule. It also covers any intra-articular ligaments or tendons and is reflected on intra-articular bone where it merges with the periosteum or the perichondrium, as the case may be. In the transition zone, it merges with the articular margins and spreads for a short distance over the non-weight-bearing articular cartilage. In some areas, particularly in recesses of the joint, the synovial membrane has many *small, villus projections*, which presumably permit expansion of the synovial membrane in association with joint movement or changes in intra-articular pressure. These synovial villi are not easily discerned macroscopically in normal joints but may become enlarged, hyperemic, and more numerous in some chronic inflammatory or degenerative diseases of joints. In addition, thickened folds of synovial membrane, often containing adipose tissue, extend into the joint cavity. These *fat pads* generally occupy depressions on the articular surface and are displaced during motion. Synovial membranes lining tendon sheaths and bursae are structurally similar to those lining diarthrodial joints.

The *synovial membrane generally consists of two layers*, a thin, cellular **intima** on the inner surface and a **subintima**, which contains variable quantities of areolar, adipose, and fibrous tissue. The loose fibrous connective tissue of the subintima merges with the dense fibrous capsule. The subintima is richly vascular, and contains many lymphatics and nerves, together with a small number of histiocytes. Dendritic cells similar to the antigen-processing Langerhans cells of skin have been identified in the synovium and have been shown to interdigitate with T-lymphocytes. Specialized post-capillary venules with cuboidal endothelial cells, referred to as *high endothelial venules*, allow lymphocytes to migrate easily from the blood into the subintima of the synovial membrane in certain inflammatory conditions. In areas where the synovial membrane lines intra-articular ligaments or tendons, the subintimal layer is usually attenuated or inapparent.

The synovial intima consists of *synoviocytes* forming an ill-defined layer, one to three cells deep. The cells vary in shape from fusiform to polygonal. No basement membrane exists between the synovial intima and subintima and the *synoviocytes are of mesenchymal rather than epithelial origin*. In some areas, the synoviocytes are closely packed, while elsewhere they are relatively sparse and the subintimal layer may be directly apposed to the joint cavity. Two types of synoviocytes, referred to as type A (macrophage-like) and type B (fibroblast-like) cells, are recognized on the basis of their morphology, function, and immunochemical staining. *Type A synoviocytes originate from the bone marrow and have phagocytic and antigen-processing functions*. Ultrastructurally, they resemble tissue macrophages, possessing a dense, heterochromatin-rich nucleus, many cytoplasmic vacuoles and poorly developed rough endoplasmic reticulum. They are primarily responsible for removing and degrading particulate matter from the joint cavity and possess antigen-processing properties. *Type B synoviocytes are probably of fibroblastic origin*. They have a well-developed Golgi apparatus, prominent rough endoplasmic reticulum and are responsible for the synthesis of hyaluronan in addition to matrix components, including collagen. They are also equipped with various enzymes capable of degrading cartilage and bone. Both cell types produce cytokines and other mediators. Cells with ultrastructural characteristics intermediate between types A and B synoviocytes, so-called *intermediate or type C cells*, have also been described.

The synovial membrane is freely permeable in either direction to molecules of small dimension, which may be removed by the capillaries and lymphatics. Larger particles are phagocytosed by type A synoviocytes. The removal of particulate matter from the joint and its deposition in the subintimal layer is a continuous process. Because of the long life span of type A synoviocytes, estimated to be from 3–6 months, phagocytosed particulate matter may persist in the synovium for long periods. When the volume is large, as may occur in diseased joints, its presence in the synovial membrane stimulates fibrosis of the capsule, contributing to the swelling and fixation of diseased joints. *The synovial membrane proliferates markedly in certain disease states*, and has considerable powers of regeneration following injury or synoviectomy. *In chronic synovitis, lymphocytes and plasma cells diffusely infiltrate the synovial membrane, and may accumulate in hypertrophic synovial villi*. The lymphocytes are sometimes arranged in follicles.

The transitional zone of the synovial membrane is characterized by a gradual merging of the synovial membrane with the periosteum and cartilage margin. The intima is well vascularized where it extends onto the cartilage surface and it is in this area that erosion, or alternatively lipping and osteophyte formation, often occurs in chronic arthritis and degenerative arthropathy. The transitional zone of the synovial membrane is also the initial site of synovial proliferation and development of the *vascular granulation tissue or* **pannus,** which sometimes spreads across the articular cartilage in chronically inflamed joints. Pannus may also develop from the marrow spaces of subchondral bone and extend onto the articular surface through defects in the cartilage. *This layer of granulation tissue interferes with the normal nutrition of articular cartilage and is capable of eroding and destroying cartilage through the activity of cytokines and collagenases*. Collagenases may be synthesized by cells in diseased synovial membranes, by granulation tissue, and by neutrophils in the synovial fluid. The collagens of the synovial membrane itself are generally resistant to these collagenases because of their cross-linking. Adhesion of pannus to opposing articular surfaces *may cause fibrous ankylosis* and, if bone is formed in the connective tissue, bony ankylosis results. Few animals are permitted to survive to the stage of bony ankylosis, but fibrous ankylosis occurs occasionally in pigs with mycoplasma arthritis and in other chronic arthritides. Bony ankylosis sometimes involves the intercarpal joints of racing horses.

Synovial chondromatosis (osteochondromatosis) is a syndrome characterized by the presence of *many nodules of hyaline cartilage, some of which may undergo ossification, in the synovial membrane* (Fig. 1.129). It is widely believed that these nodules develop by metaplasia, or even benign neoplasia, of mesenchymal elements in the synovium. An alternative hypothesis is that, at least in some cases, they are derived from fragments of cartilage eroded from a damaged articular surface as part of a pre-existing joint disease. Such fragments are capable of surviving, and growing, in the synovial fluid, which provides a nutritious culture medium. Some may attach and become embedded in the synovial membrane, where survival and proliferation of chondrocytes within fragments would also be expected. Some of these bodies then become vascularized and undergo endochondral ossification. Some human patients and animals with synovial chondromatosis also have either few or multiple loose bodies free within the synovial fluid. These could represent nodules that have developed within the synovial membrane and become detached, but it seems more likely that they are of articular cartilage origin and have grown within the joint space, as occurs in some animals with osteochondrosis. However, synovial

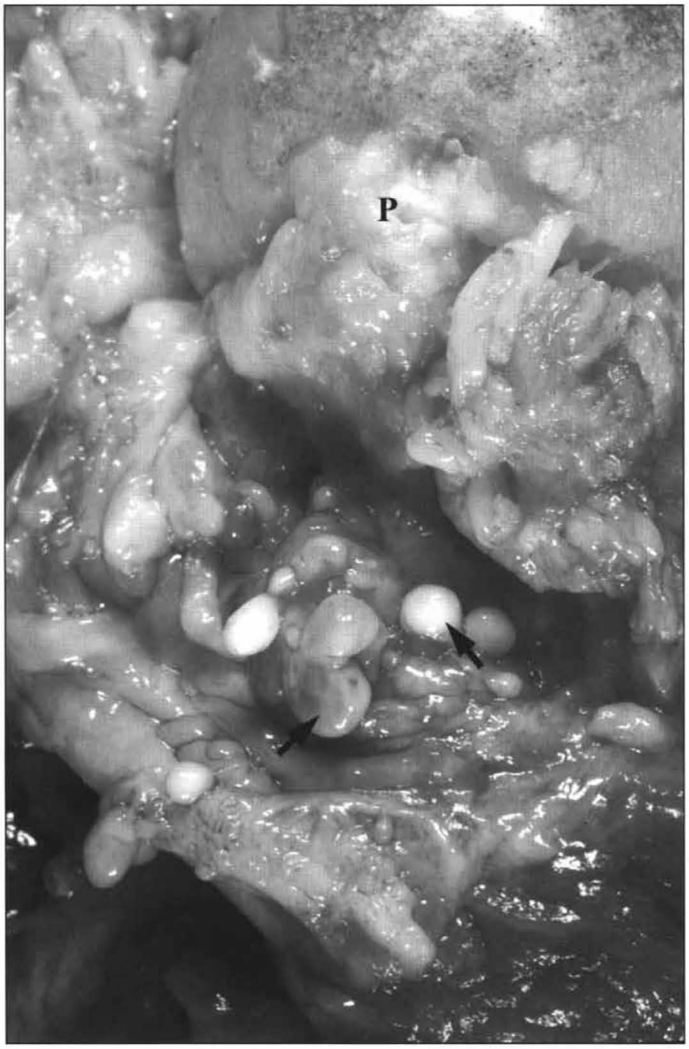

Figure 1.129 Synovial chondromatosis associated with degenerative joint disease in the hip of a dog. Several smooth, oval, cartilaginous nodules (arrows) are present within or attached to the synovium. Also note the villus hypertrophy, pannus formation (P), and eburnation of the femoral head. (Courtesy of RA Fairley.)

chondromatosis sometimes occurs in the absence of an underlying articular disease, or involves extra-articular structures such as bursae or tendon sheaths. Such cases, referred to as **primary synovial chondromatosis**, are more likely to be due to chondroid metaplasia of subsynovial fibroblasts, although the possibility that they are seeded by microscopic fragments of cartilage released from mildly damaged articular surfaces should be considered.

Synovial fluid is a viscous, clear, colorless or slightly yellow fluid, and is the main source of nutrients for articular cartilage. Essentially, *it is a dialysate of plasma, modified by the addition of hyaluronan, glycoprotein, and various other macromolecules by synoviocytes and other cells in the synovial membrane.* Electrolytes and small molecules such as glucose, lactate, and some small plasma proteins are able to move freely into and out of the synovial fluid through the synovial membrane, but large proteins such as fibrinogen are excluded. The viscous nature of synovial fluid reflects its high concentration of hyaluronan and varies between joints, as does the volume of fluid.

Hyaluronan is believed to function as a lubricant for the synovial membrane and periarticular tissues, but it probably plays little, if any part, in lubricating the motion between opposing cartilage surfaces. Lubrication of synovial joints under relatively light loading relies on the presence of the glycoprotein **lubricin**, which adheres to the surface of articular cartilage and binds a highly insoluble, **surface-active phospholipid** with strong lubricating properties. Recent studies have demonstrated that *it is the surface-active phospholipid, rather than lubricin, that actually lubricates the joint.* This is referred to as boundary lubrication. *Lubrication of articular surfaces under heavier loads depends on hydrostatic (weeping) lubrication*, which involves the seepage of water from the matrix when the cartilage is compressed. The water is squeezed onto the articular surface just ahead of the contact area and accumulates in the many minute depressions that are normally present. Once the compressive force is removed, the fixed charges within the cartilage attract the water and small solutes back into the matrix, and the cartilage returns to its original shape.

Normal diarthrodial joints contain only a very small volume of synovial fluid but the volume generally increases greatly in response to injury or inflammation. This is most likely due in part to increased vascular permeability in the synovial membrane following the release of inflammatory mediators such as prostaglandins and cytokines. The resulting increase in protein concentration of synovial fluid alters the normal oncotic balance and therefore fluid volume. In damaged joints, increased lymphatic drainage accelerates the clearance of proteins and cartilage breakdown products from synovial fluid.

Synovial fluid normally contains a small number of mononuclear cells and occasional free synoviocytes. Neutrophils and erythrocytes are uncommon unless the joint has been damaged, the synovial membrane is inflamed, or the sample has been contaminated with blood during collection. *The number of neutrophils increases markedly in both septic and nonseptic inflammatory diseases of the joint.* The synovial fluid may become turbid and less viscous depending on the number of neutrophils that are present.

Response of articular cartilage to injury

Because of its avascular nature and the absence of undifferentiated cells with the ability to respond to injury, *articular cartilage has only limited powers of regeneration.* The chondrocytes of mature articular cartilage show little if any sign of mitotic activity and have limited capacity for increasing matrix synthesis. Furthermore, their encasement in lacunae restricts their capacity to migrate to areas of damage. The regenerative potential of articular cartilage decreases even further with advancing age as the number of chondrocytes declines and the size of matrix proteoglycans decreases.

The response of articular cartilage to injury varies with the nature of the insult and with the depth of the lesion. *Superficial lacerations that do not penetrate the tidemark, and therefore fail to cause hemorrhage or inflammation, do not heal.* Chondrocytes adjacent to the lesion may proliferate, forming small clusters (*chondrones*), and may produce new matrix, but they do not migrate into the lesion. Within a few weeks of injury the chondrocyte response subsides, the lesion persisting for long periods but without progressing to chondromalacia or degenerative joint disease.

The repair of injuries that involve the full depth of the articular cartilage and penetrate subchondral bone differs markedly from the repair of superficial lesions. Hemorrhage occurs from blood vessels in the subchondral bone and the lesion becomes filled with a hematoma. Inflammatory cells and primitive mesenchymal cells invade the hematoma, probably under the influence of local growth factors, such as PDGF and TGF-β, derived from platelets and from the damaged bone. Within approximately 2 weeks of injury, some of the mesenchymal cells in the lesion have features of chondrocytes and begin to produce a matrix rich in proteoglycans, but also containing type II collagen. By 6–8 weeks, the defect is filled with fibrocartilage, which is firmly bonded to the adjacent hyaline articular cartilage. New bone formation occurs at the base of the lesion, restoring the subchondral bone plate, but the new bone does not extend into the area previously occupied by articular cartilage, remaining well below the articulating surface. The fibrocartilage repair tissue is analogous to the fibrous scar that repairs most other tissues and although it is an adequate replacement for articular cartilage at sites of deep injury, it does not perform as well when subjected to mechanical loading. In general, *most large defects in articular cartilage will eventually progress to degeneration after being filled with fibrocartilaginous repair tissue.* Early signs of degeneration may be present within a year of injury, although in some situations the repair tissue appears to function satisfactorily for a prolonged period and may become remodeled to more closely resemble normal articular cartilage. Interestingly, continuous passive motion of articular surfaces subjected to full-thickness injury has been shown to stimulate more rapid and successful healing of the articular cartilage than either complete immobilization or intermittent active motion.

Subchondral cystic lesions in horses are considered a manifestation of osteochondrosis, but in a recent study, similar lesions were induced experimentally by creating full-thickness defects in the articular cartilage and extending them 4 mm into the subchondral bone. Histologically, the lesions consisted of variable quantities of fibrous connective tissue, fibrocartilage, and bone. This study suggests that *trauma to weight-bearing surfaces, in addition to osteochondrosis, may predispose to subchondral cystic lesions in horses.*

DEVELOPMENTAL DISEASES OF JOINTS

Osteochondrosis

Osteochondrosis is a common and important disease of pigs, horses, and large breeds of dog, but also occurs in cattle, sheep, and farmed deer. Young, fast-growing animals are most susceptible to osteochondrosis, especially breeds selected for rapid growth. The disease is most likely analogous to human osteochondrosis and to tibial dyschondroplasia in chickens and turkeys. It is characterized by multifocal abnormalities in endochondral ossification involving articular–epiphyseal cartilage complexes (the immature cartilage covering the ends of growing long bones) and growth plates. As such, osteochondrosis is not strictly a disease of joints, but since the clinical and pathological manifestations relate primarily to lesions in articular cartilage, it is included in this section. **Dyschondroplasia** is a more appropriate name for this disease as the initial lesion is in the growing cartilage, but the term osteochondrosis has become entrenched in the literature and a change in nomenclature is now unlikely to gain widespread acceptance. Other synonyms for the disease are **osteochondrosis dissecans** and **osteochondritis dissecans**. Such differences in terminology are due, at least in part, to the variation in lesions when examined at different stages. Severe degenerative joint disease is a common sequel to osteochondrosis and is one of the most common causes of lameness in domestic animals, especially in swine, horses, and certain large breeds of dog.

The *etiology and pathogenesis of osteochondrosis are poorly understood* and have been the subject of considerable recent debate, but valuable clues have emerged from studies in swine, horses, and dogs. The etiology is multifactorial, but most likely involves the effect of trauma or biomechanical factors on cartilage that has been weakened by nutritional or hormonal imbalances, vascular disruption, or genetic factors. Whatever the cause, the initial lesion in the articular–epiphyseal cartilage complex of each species where detailed studies have been performed are remarkably similar, *suggesting a common pathogenesis, most likely involving ischemic damage to the growing cartilage.*

In adult animals articular cartilage is avascular, relying on diffusion of nutrients from synovial fluid, but the articular–epiphyseal cartilage complex of immature animals depends on the presence of viable blood vessels within cartilage canals, at least for the first few months of life. These vessels, which appear to arise from the perichondrium, gradually disappear as the lumens of cartilage canals become filled with hyaline cartilage in a process referred to as *chondrification.* Investigation of the vascular supply to the femoral condyles of swine

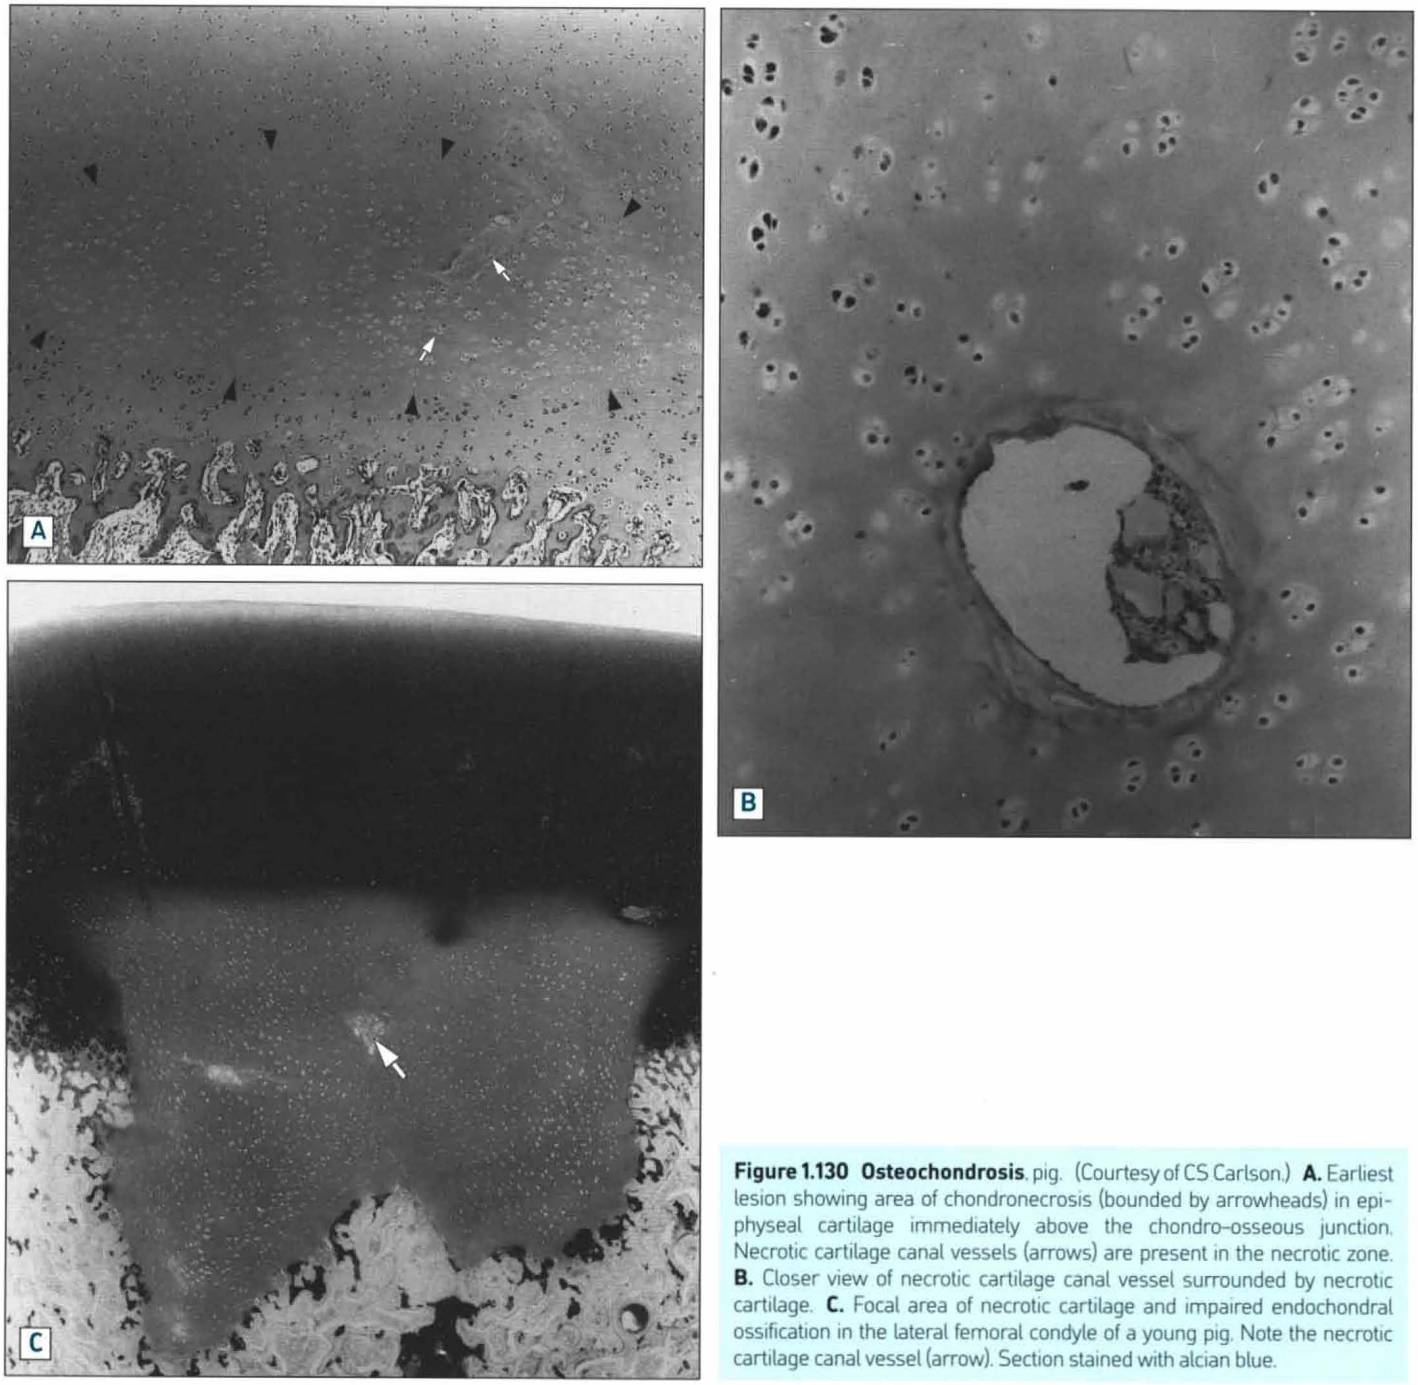

Figure 1.130 Osteochondrosis, pig. (Courtesy of CS Carlson.) **A.** Earliest lesion showing area of chondronecrosis (bounded by arrowheads) in epiphyseal cartilage immediately above the chondro-osseous junction. Necrotic cartilage canal vessels (arrows) are present in the necrotic zone. **B.** Closer view of necrotic cartilage canal vessel surrounded by necrotic cartilage. **C.** Focal area of necrotic cartilage and impaired endochondral ossification in the lateral femoral condyle of a young pig. Note the necrotic cartilage canal vessel (arrow). Section stained with alcian blue.

revealed that the cartilage of both condyles is fully vascularized at 2 weeks of age but that the blood supply recedes with maturity. By the time the pigs are 4–5 months of age the condyles are virtually avascular. In horses, cartilage canal blood vessels have disappeared from the articular–epiphyseal cartilage complex of the distal tibia by 3 months of age, and from the femoral condyles by 5 months.

Surgical interruption of the cartilage canal vascular supply in growing pigs at approximately 2 months of age results in necrosis of subarticular epiphyseal cartilage, but not of the overlying articular cartilage. This closely resembles the earliest lesion of osteochondrosis identified in the articular–epiphyseal cartilage complex of pigs and horses, wherein focal areas of cartilage necrosis and chondrolysis associated with necrotic cartilage canal blood vessels are confined to the epiphyseal cartilage and do not involve either the overlying articular cartilage or the subchondral bone (Fig. 1.130A, B). Similar early lesions have also been recognized in dogs and calves. These observations suggest that there is a risk period during which the epiphyseal cartilage of the articular–epiphyseal cartilage complex is dependent on the blood supply delivered by cartilage canal vessels. Disruption of the blood supply during this period in a young, rapidly growing animal may be the initial event in osteochondrosis. Local ischemia to this zone of developing cartilage would lead to necrosis, delayed endochondral ossification, and an extension of necrotic cartilage into the subchondral bone. Such lesions would not be expected to occur once the cartilage canals have closed and the cartilage is deriving its nutrients by diffusion from synovial fluid.

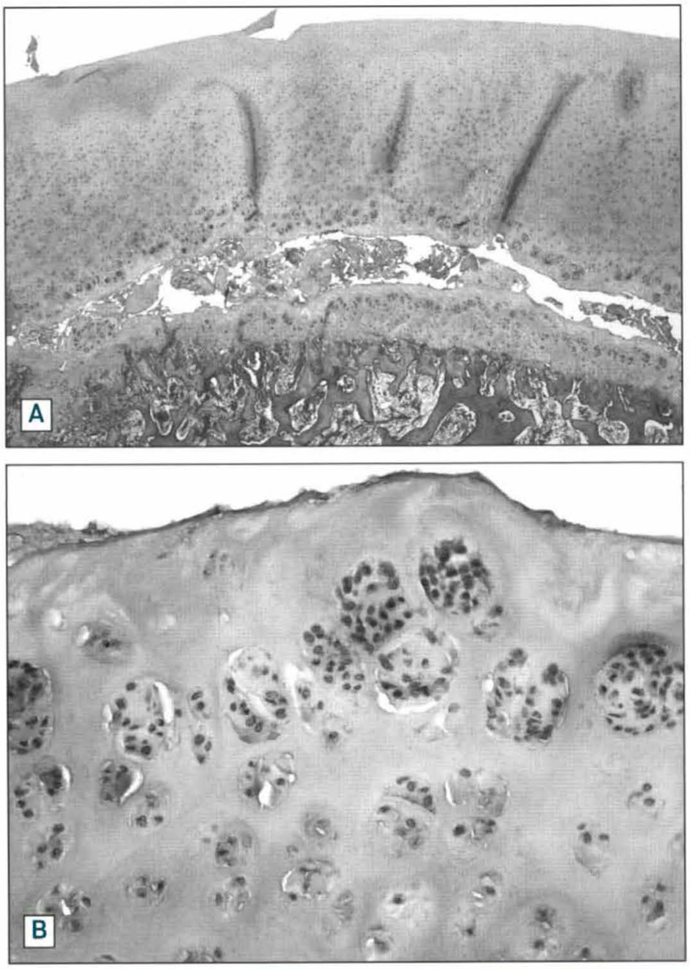

Figure 1.131 Osteochondrosis, foal. **A.** Horizontal cleft in deep layer of necrotic cartilage. **B.** Higher power of cartilage lining the cleft, showing acellular areas of chondronecrosis and many clusters of proliferating chondrocytes (chondrones) indicating a response to injury.

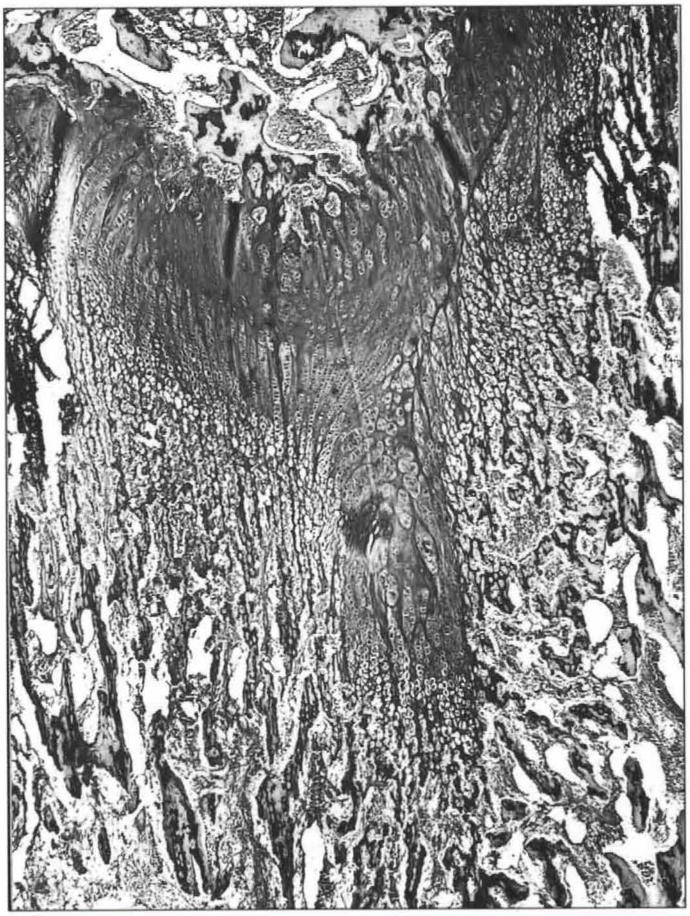

Figure 1.132 Focal retention of physeal cartilage (**metaphyseal dysplasia**) in osteochondrosis in a pig.

The presence of necrotic cartilage in the articular–epiphyseal cartilage complex induces *localized failure of endochondral ossification*. The necrotic cartilage does not mineralize or become invaded by blood vessels from the epiphyseal bone, and extends into the subchondral bone as ossification continues in adjacent, unaffected areas of cartilage (Fig. 1.130C). Small defects are unlikely to cause problems and no doubt heal spontaneously. Islands of necrotic cartilage left behind in the subchondral bone of the epiphysis are often found incidentally in various stages of repair. If the lesion is sufficiently large, clefts form in the deep layers of necrotic cartilage (Fig. 1.131A, B), presumably due to the trauma of weight bearing. The cleft may cause extensive underrunning of the articular cartilage and eventually join with the articular surface, creating a flap, which either remains attached or becomes separated, *forming a loose body or "joint mouse."* Loose bodies may survive and enlarge within the joint space, deriving their nutrients from the synovial fluid, and may even undergo endochondral ossification. Some become attached to the synovial membrane. At this advanced stage, the lesion is accompanied by inflammatory changes in the synovium and is often referred to as osteochondritis dissecans.

Another potential sequel of osteochondrosis involving the articular–epiphyseal cartilage complex is the *formation of subchondral cystic lesions* consisting initially of degenerate or necrotic cartilage, which is eventually replaced with fibrous tissue. This lesion, which appears to be most common in horses, will be discussed in more detail later in this section.

The physeal lesions of osteochondrosis differ morphologically from those involving the articular–epiphyseal cartilage complex, suggesting the possibility of a different pathogenesis. *Early lesions in the growth plate consist of cone-shaped foci of retained cartilage extending into the metaphysis* (Fig. 1.132), but rather than containing necrotic cartilage, these foci of metaphyseal dysplasia consist of viable hypertrophic chondrocytes. This does not exclude the possibility of an ischemic origin as experimental vascular disruption has been shown to induce similar changes in the growth plate of young pigs and lesions identical to tibial dyschondroplasia in chickens. It has also been suggested that these retained wedges of hypertrophic cartilage may be secondary to the development of trabecular microfractures in the primary spongiosa near the chondro–osseous interface. Such fractures would interfere with vascular invasion of the mineralized cartilage during endochondral ossification leading to persistence of hypertrophic zone chondrocytes. A similar mechanism has been proposed for the multifocal physeal thickening observed in Alaskan Malamute dogs with chondrodysplasia.

Although several possible causative factors have been incriminated in osteochondrosis, *there seems little doubt that the etiology is multifactorial*, and it is likely that differences between species exist. A *genetic predisposition* to osteochondrosis appears to exist in most species. This is at least partly related to the *predisposition for rapid growth*, as the prevalence is greatest in species and breeds where this attribute has been emphasized. Furthermore, in species other than pigs, the prevalence is higher in males than females, presumably due to their more rapid growth. The occurrence of many familial cases of osteochondrosis in humans, and the apparent increase in prevalence within certain genetic lines in animals, suggests that there is *also a direct genetic component to the disease*, at least in some cases. A heritability coefficient of 0.24–0.27 has been estimated from a study of Standardbred horses in Sweden.

Trauma almost certainly plays an important role, as supported by the increased prevalence of articular lesions at sites of greatest weight-bearing force. Furthermore, pigs housed on hard surfaces appear to have increased incidence and severity of the disease. Whether trauma alone is capable of causing osteochondrosis is questionable, but the forces associated with weight bearing and motion, when inflicted on large foci of degenerate or necrotic cartilage, would be expected to predispose to cleft formation and separation of cartilage flaps from subchondral bone. The role of trauma in the etiology of physeal lesions is difficult to determine, but compressive forces acting vertically on articular surfaces inevitably are transmitted through epiphyseal bones to the growth plate. This could damage the vascular supply to the physis, especially in young animals still dependent on transphyseal blood vessels within cartilage canals.

Rapid growth and optimal nutrition are considered necessary for the development of osteochondrosis in most animal species, but contradictory evidence has been obtained from experimental studies and *the exact role of nutritional factors in the etiology of osteochondrosis remains to be determined*. A comparison of weanling swine fed either 12% or 16% protein in their ration demonstrated a reduced growth rate in the former group but no reduction in the incidence of osteochondrosis. This does not however exclude the possibility that further reduction in growth rate may have been beneficial, as in this study all pigs in both groups developed lesions. In another study, swine fed a balanced ration at 70% of that of controls grew more slowly, and had less severe lesions of osteochondrosis than controls when slaughtered at the same weight (90 kg). However, a comparison of lesions in pigs from both groups when they were slaughtered at the same age (208 days) revealed that the lesion score was highest in pigs on the restricted ration. These data suggest that although restricted growth rate did not reduce the severity of osteochondrosis, there was some resolution of the lesions in pigs on the restricted ration by the time they reached slaughter weight.

Experimental prolonged excess of dietary calcium is reported to increase the prevalence and severity of osteochondrosis in susceptible breeds of dog but does not appear to influence the disease in pigs and its relevance to the naturally occurring disease is questionable. Increased dietary calcium is believed to result in hypercalcemia and hypergastrinemia, both of which would be expected to induce hypercalcitoninemia and impaired bone resorption, but suggestions that osteochondrosis results from this mechanism are speculative and unproven. Of more significance is the apparent link between primary or secondary copper deficiency and osteochondrosis in horses, pigs, and deer. *Low dietary copper or high dietary levels of copper antagonists, including zinc and molybdenum, have been associated with both experimental and natural osteochondrosis*. Calcium is also a copper antagonist thus providing a possible explanation for the reported effect of high dietary calcium on osteochondrosis in dogs. As a component of the enzyme lysyl oxidase, copper is involved in strengthening collagen molecules in articular cartilage, and other connective tissues, by the formation of intermolecular cross-links. Copper deficiency could therefore weaken articular cartilage and the walls of small blood vessels in cartilage canals, rendering them more susceptible to the forces of weight bearing or other trauma.

Various hormones have been implicated in the etiology of osteochondrosis. Growth hormone and somatomedins stimulate the activity of chondrocytes both in vitro and in vivo and have been shown experimentally to increase the severity of osteochondrosis lesions in the articular–epiphyseal cartilage complex of pigs. Furthermore, high levels of growth hormone are present in young dogs of large breeds at the stage where they are most susceptible to the development of osteochondrosis. Insulin and insulin-like growth factors I and II are also mitogenic for chondrocytes and may provide an explanation for the apparent link between osteochondrosis and the feeding of high-energy diets, which would be expected to induce hyperinsulinemia. Lesions resembling osteochondrosis with extensive underrunning of cartilage have occurred in horses following the administration of glucocorticoids. A possible link between copper and hormone levels has been suggested and warrants further investigation. Several hormones, including glucocorticoids, insulin, insulin-like growth factor-I, interleukin-1, estrogen, and progesterone have been shown to alter metallothionein synthesis and are therefore capable of altering copper metabolism. Furthermore, growth hormone has been shown to reduce copper retention in pigs. This may help to explain the increased incidence of osteochondrosis in rapidly growing young animals.

Thrombosis of small blood vessels within cartilage canals has been suggested as a possible cause of ischemia to the articular–epiphyseal cartilage complex and to physeal cartilage. Lipid emboli were observed in the lumen of these vessels in one study, but their origin and significance is not known. Fibrin thrombi occurring in association with bacteremia or septicemia could also cause thrombosis of cartilage canal vessels. It is unlikely however that the majority of cases of osteochondrosis occur by this mechanism.

Because of differences between species in the nature and distribution of lesions, and their sequelae, it is appropriate to consider each species separately.

1. **Swine** As in other species, *microscopic lesions of osteochondrosis in swine are far more common than clinical signs or gross examination at necropsy would suggest*. In some studies, up to 100% of rapidly growing young pigs had microscopic changes of osteochondrosis in their growth plates or articular–epiphyseal cartilage complexes. Clearly, the vast majority of such lesions heal uneventfully and only those that are sufficiently large, or subjected to excessive trauma, progress to become clinically significant. At this stage, gross lesions are likely to be present in one or several joints. *Predilection sites in pigs* are the joint surfaces of the medial humeral and femoral condyles, anconeal process, lumbar vertebrae, mediodistal part of the talus, humeral head, glenoid cavity of the scapula, distal ulna, and dorsal acetabulum. *Physeal lesions* occur most commonly in the distal ulna, distal femur, costochondral junctions, femoral and humeral heads, thoracolumbar vertebrae, and the ischial tuberosity.

   The articular lesions of osteochondrosis are often bilateral, and may be symmetrical. It is important to distinguish them from synovial fossae, which are present as normal structures in some joints. *Early articular lesions* appear as thickened, white or cream foci of articular cartilage, which are sharply demarcated from adjacent normal areas of cartilage. In some cases the articular cartilage, which is not directly affected in osteochondrosis, will be depressed or wrinkled due to collapse of necrotic cartilage in the underlying articular–epiphyseal cartilage complex. *In more advanced lesions, the affected cartilage usually shows evidence of separation and underrunning* (Fig. 1.133), and there may be nodules of cartilage reflecting attempts at repair. In other cases, *underrun segments of articular cartilage may be detached completely, leaving a deep ulcer with exposure of subchondral bone* (Fig. 1.134). Lesions of this type are referred to as **osteochondritis dissecans** and occur most frequently on weight-bearing surfaces of the medial condyles of the humerus and femur in pigs of 5–7 months of age. In such cases, large fragments of articular cartilage may be present within the joint space. Since these so-called loose bodies or joint mice obtain nutrients by diffusion from synovial fluid, they can survive and grow within the joint, and may be larger than the defect from which they originated. The dissecting lesion does not involve bone but sometimes flaps of cartilage contain osseous tissue. This probably develops by endochondral ossification following invasion of vessels and cells from the area of attachment. The defect in the articular surface is initially filled with vascular connective tissue, which eventually is converted to fibrocartilage. Even if a dissecting lesion does not result, hemorrhage and fibrosis may occur in the subchondral bone and the resulting localized radiolucent area may be the basis for one type of "bone cyst" in osteochondrosis. *Degenerative arthropathy is common in the late stages of the disease*, but evidence that osteochondrosis was involved may no longer be apparent grossly. Even histologically, the changes may be too altered by secondary changes to reflect the initial lesion. Synovial villi may be enlarged and mild lymphoplasmacytic inflammation with scant fibrinous exudate may be present in the synovium, but these changes are nonspecific.

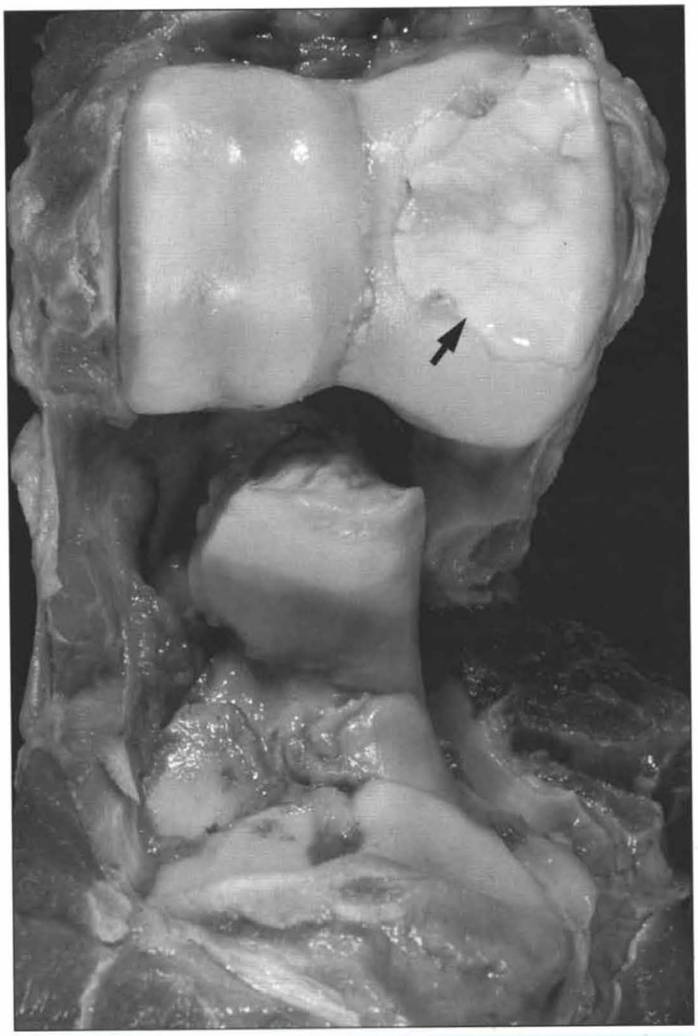

Figure 1.133 Osteochondrosis, pig. Elbow joint. Large area of thickened, underrun articular cartilage (arrow) on the medial humeral condyle, sharply demarcated from adjacent normal cartilage. (Courtesy of RA Fairley.)

Severe **growth plate lesions** associated with osteochondrosis may appear grossly as thickened foci. *Microscopically these foci, which are sometimes referred to as metaphyseal dysplasia, consist of persistent hypertrophic chondrocytes* (Fig. 1.132) and are associated with delayed mineralization. *Such lesions are similar to those of rickets* and may present a diagnostic challenge to the pathologist, especially since trabecular microfractures in the primary spongiosa may also occur in osteochondrosis and imply an underlying metabolic bone disease. In osteochondrosis, the mineralization failure is transient

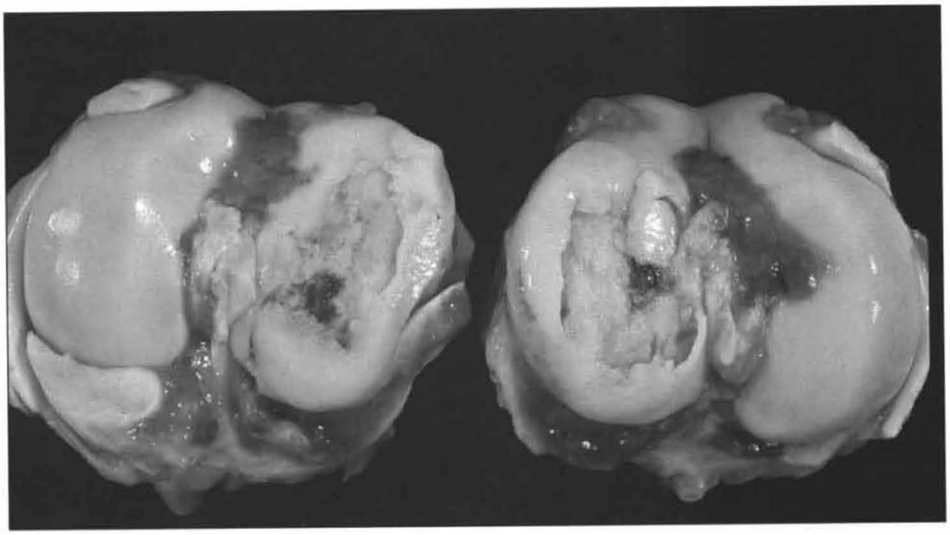

Figure 1.134 Osteochondrosis, pig. Bilateral detachment of articular cartilage on medial femoral condyles with exposure of subchondral bone. Lesions of this type are referred to as **osteochondritis dissecans**. (Courtesy of RA Fairley.)

and focal, and there is no evidence of delayed mineralization of osteoid, as occurs in rickets. The fate of these metaphyseal lesions is varied. Some undergo relatively normal ossification, others persist as nodules of cartilage in the metaphysis, while many degenerate and are replaced by fibrous tissue in which woven bone or fibrocartilage develops.

Irregular eosinophilic streaks, associated with areas of disorganized growth plate architecture, also occur in osteochondrosis (Fig. 1.135A). These may reflect either vestiges of cartilage canals or infraction lines occurring as a sequel to growth plate trauma. Similar eosinophilic streaks are normally present in the growth plates of young animals but are usually parallel to cartilage columns. In osteochondrosis they are often stellate and may subdivide the physeal cartilage into disorganized, sometimes degenerate, lobules. *Bony bridges*, uniting the epiphysis and metaphysis and effectively closing the growth plate at that location, may develop at sites of physeal degeneration (Fig. 1.135B). *Angular limb deformity* resulting from premature closure of a growth plate on one side and continued growth on the other is a potential sequel to this lesion but appears to be less common in pigs than in other species.

Another manifestation of osteochondrosis in swine is **epiphysiolysis**, *the separation of an epiphysis from metaphyseal bone*. This is a traumatic lesion, predisposed to by a defect in growth cartilage of the physis, and probably develops either from an extended eosinophilic streak or from areas of necrosis in the growth cartilage, rather than from foci of metaphyseal dysplasia. *The common sites for epiphysiolysis are femoral head* (Fig. 1.136*), ischiatic tuberosity of females, and lumbar vertebrae.* The distal epiphysis of the ulna and the anconeal process may also be involved, although strictly speaking the lesion involving the latter should not be called epiphysiolysis. In pigs, unlike dogs, the anconeal process does not develop from a separate ossification center, so **apophysiolysis** is a more appropriate term. Separation may be complete, as is often the case with the ischiatic tuberosity, or partial, as occurs in the head of the femur, which sometimes remains attached at its lateral margin. Separation probably occurs when the process of endochondral ossification reaches or approaches the cartilage defect. The resulting fracture may extend in a jagged crack through primary and secondary spongiosa.

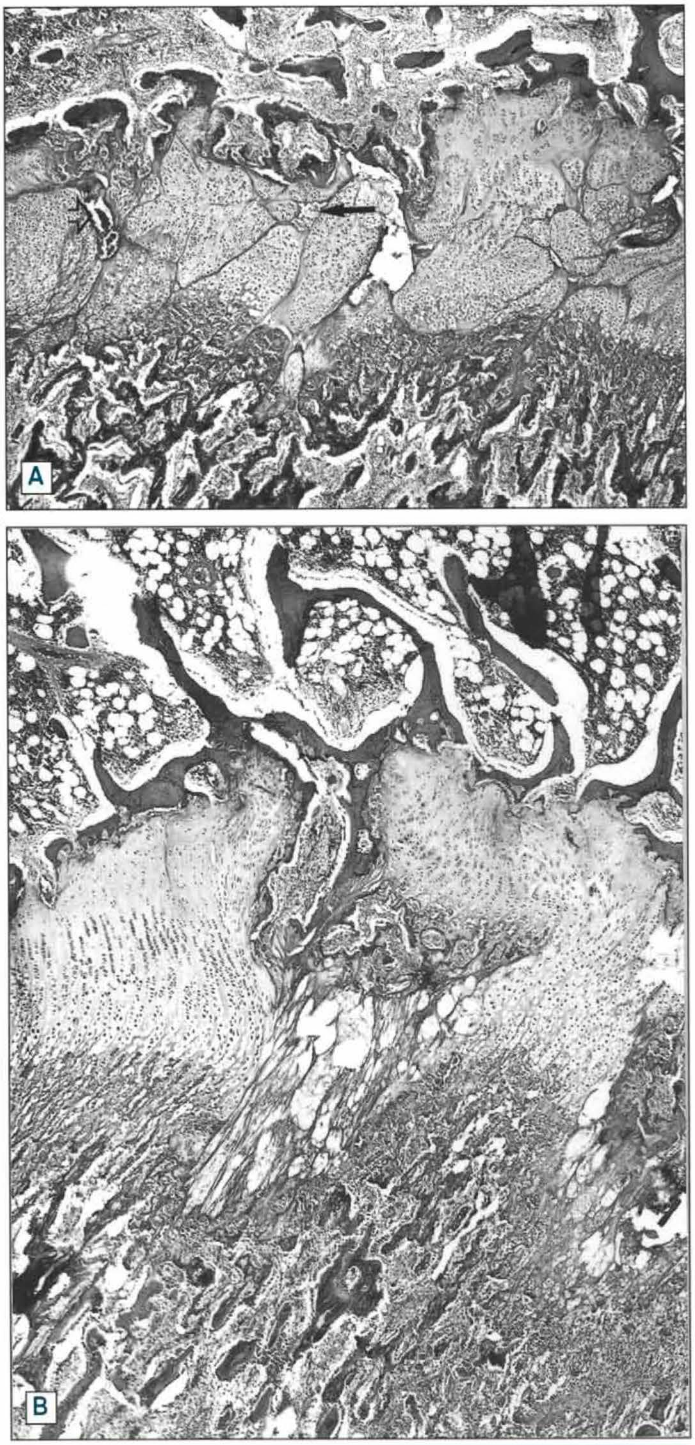

Figure 1.135 Osteochondrosis, pig. **A.** Eosinophilic streaks and focal cavitation (arrow) in a disorganized physis. **B.** Focal degeneration of the physis with formation of a bony bridge between the epiphysis and metaphysis.

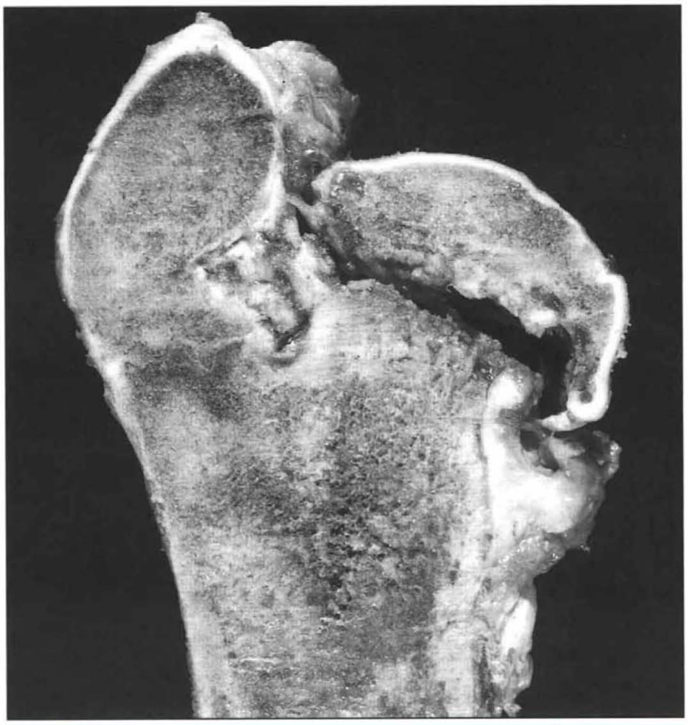

Figure 1.136 Osteochondrosis, pig. Epiphysiolysis of the femoral head.

2. **Dogs** *Osteochondrosis in dogs includes several orthopedic diseases, usually occurring in young fast-growing males of large and giant breeds.* Osteochondritis dissecans of the shoulder joint is the classic presentation of the disease, but similar lesions may also occur in other major joints. In addition, *ununited anconeal process and fragmented coronoid process* are believed to be manifestations of osteochondrosis in dogs.

The major predilection site for **osteochondritis dissecans** *in dogs is the caudal aspect of the humeral head.* In susceptible breeds, lesions are common between 4 and 8 months of age and are bilateral in approximately 70% of cases. Many lesions resolve spontaneously but others progress to cause severe lameness due to degenerative joint disease. As in pigs, *early lesions* are visible grossly as discrete gray/white or cream foci in the articular surface representing areas of thickened or underrun cartilage (Fig. 1.137A, B, C). Flaps of cartilage often detach from these sites and form loose bodies, leaving large ulcers that are gradually filled with fibrocartilage. Healing of such defects is never perfect and partly healed lesions of osteochondritis dissecans are often detected several months, or even years, later in the shoulder joints of dogs with chronic degenerative joint disease (Fig. 1.138). Such lesions may also be found incidentally, reflecting their high prevalence in certain breeds and the fact that they are not always symptomatic.

Osteochondritis dissecans also occurs in several other locations in dogs, including the medial aspect of the humeral condyle, the lateral, and less frequently the medial, condyle of the femur, and the medial trochlear ridge of the tibial tarsal bone. Lesions at these sites can be bilateral and may either cause lameness at a young age when the lesion are active, or predispose to degenerative joint disease.

Lesions in the humeral condyle form part of the **elbow dysplasia syndrome,** *which also includes ununited anconeal process and fragmented (ununited) medial coronoid process of the ulna.* The latter two conditions may also occur separately (see below), or in other combinations. Together the three lesions, which are often bilateral, cause foreleg lameness in young, usually large, growing dogs and often lead to arthropathy associated with periarticular osteophytes. The elbow dysplasia syndrome is characterized by incongruity of the joint caused by a step between the cranial margin of the proximal ulna and the caudal margin of the proximal radius. An increase in length of the proximal ulna is responsible for the incongruity and results in disruption of the normal continuous curve made by the profile of the trochlear notch of the ulna and the articular cartilage of the radius. Trauma from normal use most likely precipitates lesions.

Ununited anconeal process, which develops as an *epiphysiolysis,* is most common in the German Shepherd, but also occurs in other large and giant breeds. The ossification center of the anconeal process develops at about 11–13 weeks and expands for about 6 weeks until osseous union with the ulna is achieved by 4–5 months. If extensive fissures develop in the bipolar growth cartilage between the process and the ulnar diaphysis, normal plate closure does not occur and a fibrocartilaginous or fibrous union results.

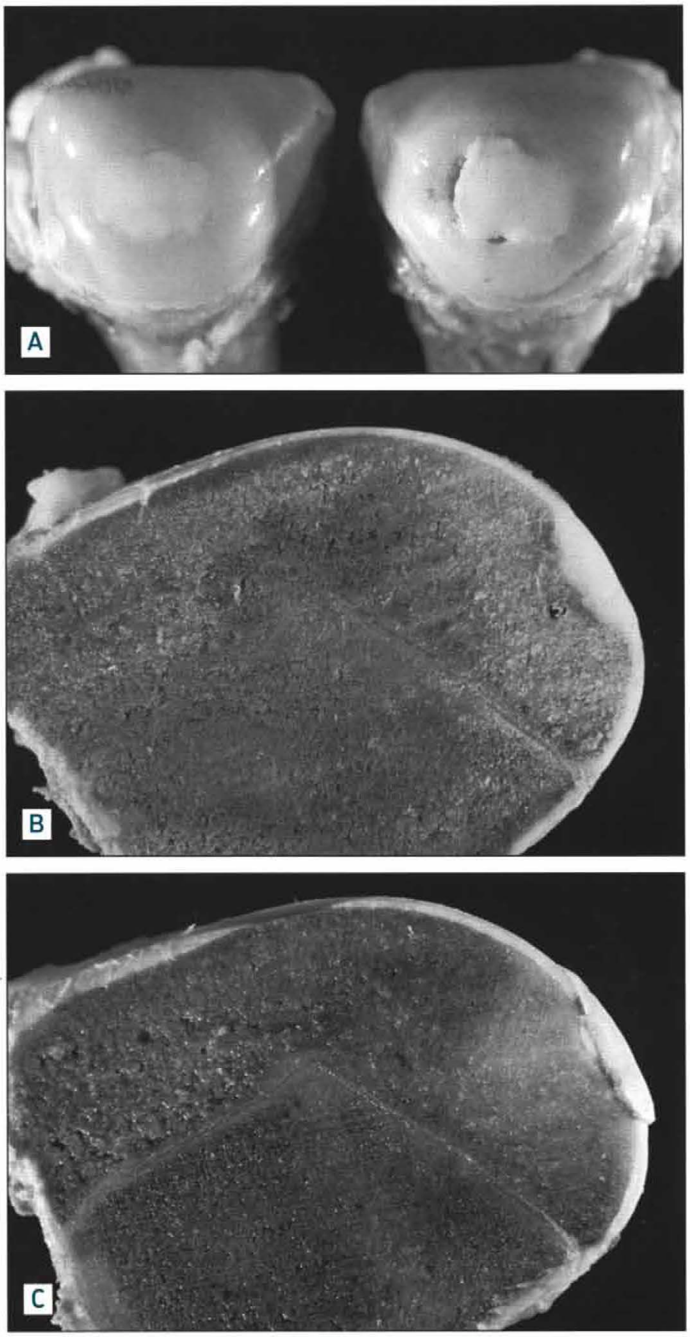

Figure 1.137 Osteochondrosis, dog. **A.** Early, bilateral lesions involving the caudal aspect of the humeral head in a 5-month-old Irish Wolfhound. **B, C.** Sagittal sections of the lesions shown in **(A)**. In **(B)** the articular cartilage is thickened, while in **(C)** the thickened cartilage has become detached from the subchondral bone.

Ununited (or fragmented) medial coronoid process of the ulna is less well known, but apparently more common, than ununited anconeal process. The coronoid process does not develop from a separate ossification center and is not easily seen in radiographs. Usually the first indications of disease are osteophytes around the anconeal process and the medial epicondyle of the humerus. Golden and Labrador Retrievers and Rottweilers are particularly prone to this condition. *In affected dogs, the medial coronoid process consists of one or several fragments, which may be in their normal position or completely separated from the articular surface of the proximal ulna as joint mice.* Lesions begin as vertical fissures in the proximal face of the articular cartilage and extend into the subchondral bone. They may reach the vertical joint surface or the area of insertion of the annular ligament.

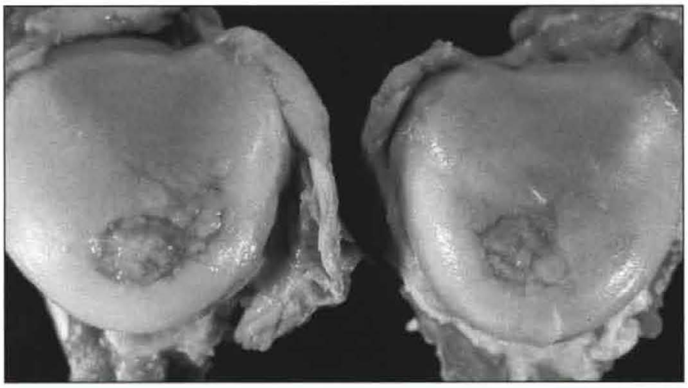

Figure 1.138 Partly healed lesions of **osteochondritis dissecans** in both humeral heads of a 4-year-old Great Dane with degenerative joint disease of both shoulder joints.

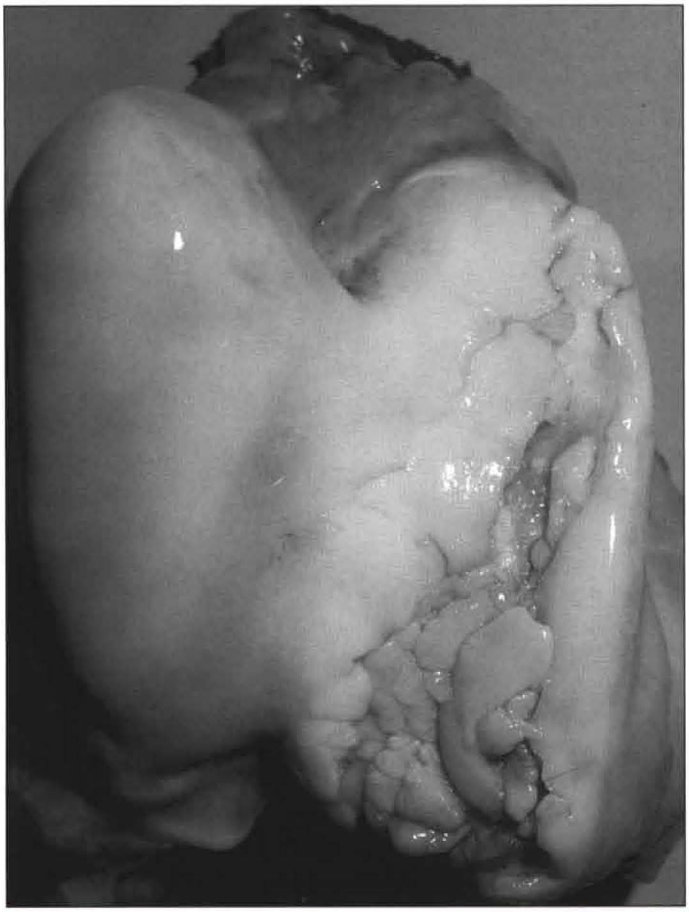

Figure 1.139 Osteochondrosis, horse. Extensive underrunning and displacement of articular cartilage on the lateral trochlear ridge of a 6-month-old foal. The many small cartilage nodules represent attempts at repair.

When complete separation of the fragment or fragments does not occur, the walls of the fissure become lined by fibrocartilage.

Other conditions in dogs, which are probably manifestations of osteochondrosis, include *retained cartilage core of the distal ulna* (Fig. 1.55A, B), and *slipped capital femoral epiphysis*. Retained cartilage cores also develop in the other long-bone metaphyses and may lead to growth deformities of the distal femur and proximal tibia. Canine hip dysplasia has been suggested as a possible manifestation of osteochondrosis but because of doubts over this classification, the disease is considered separately.

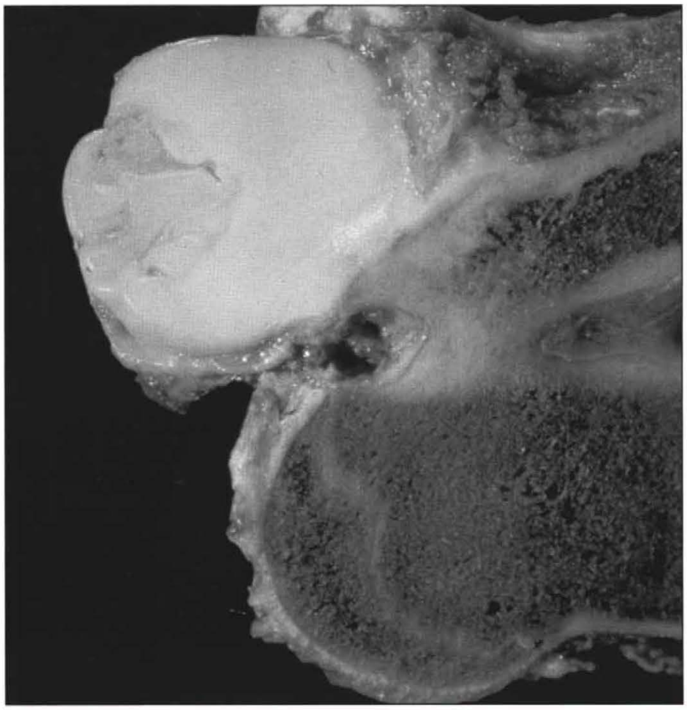

Figure 1.140 Osteochondrosis, horse. Flaps of detached cartilage on an articular facet of a cervical vertebra in a foal.

3. **Horses** Osteochondrosis is an important skeletal disease in horses of several breeds, and its incidence worldwide appears to be increasing. The term **developmental orthopedic disease** has been used to group osteochondrosis with several other skeletal diseases of young horses, some of which may occur as a sequel to, or as different manifestations of osteochondrosis. *These include osteochondritis dissecans, physitis, subchondral bone cysts, angular limb deformities, and wobbler syndrome.*

Although the lesions of osteochondrosis in horses may be widespread, there are several *predilection sites*, including the lateral trochlear ridge (Fig. 1.139) and medial condyle of the femur, the patella, the dorsal edge of the sagittal ridge of the distal tibia, and various sites in the tarsal and fetlock joints. In these locations, the pathogenesis of lesions is probably similar to that described earlier. Ossification of attached cartilage flaps seems to be more common in the horse than in other species. Lesions of osteochondrosis may also involve articular processes of cervical vertebrae (Fig. 1.140). Healing of such lesions may be characterized by formation of exostoses, which encroach on the spinal canal, or create asymmetry of articular facets, thus predisposing to wobbler syndrome.

Osteochondrosis in horses has been incriminated as a *predisposing lesion in the development of* **subchondral cystic lesions**, which are most common on the distal aspect of the medial femoral condyle (Fig. 1.141), distal aspect of the metacarpus, in addition to the carpus, elbow, and phalanges. It is suggested that subchondral cysts may develop from invaginations of articular cartilage, remnants of necrotic cartilage derived from the articular–epiphyseal cartilage complex, or in response to leakage of synovial fluid into subchondral bone through defects in articular cartilage. Such

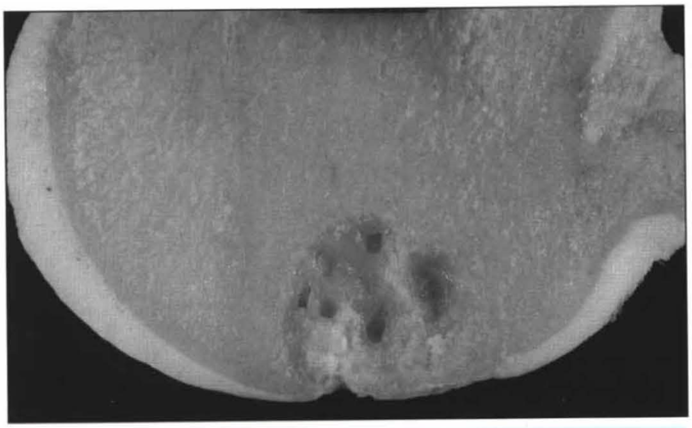

Figure 1.141 Osteochondrosis, horse. Subchondral cystic lesion in the medial femoral condyle. (Courtesy of NC State University.)

lesions have also been reproduced experimentally in young horses following traumatic damage to the articular cartilage and its supporting subchondral bone, suggesting that not all subchondral cysts are related to osteochondrosis. Histologically, the cysts usually consist of variable quantities of fibrous tissue and fibrocartilage, and are surrounded by sclerotic bone trabeculae.

Focal thickening of the growth plate, similar to metaphyseal dysplasia of pigs, is recognized as a manifestation of osteochondrosis in young foals. **"Physitis"** *or* **"epiphysitis"** *are commonly used clinical terms to describe these lesions, but both are misleading as the lesions are not inflammatory in origin*. The latter term is particularly inappropriate since the epiphysis is not involved. The lesions are thought to predispose to premature closure of growth plates and therefore *may induce angular limb deformity*. Epiphysiolysis is seldom reported in horses as a manifestation of osteochondrosis but has been described recently involving the physes of all cervical vertebrae from C3 to C7 in a 16-month-old filly.

Foals with congenital and neonatal angular limb deformities sometimes have concomitant hypoplasia of carpal bones and osteochondritis dissecans. These early lesions may both be manifestations of defective growth and maturation of cartilage. Lesions consistent with osteochondrosis were found at necropsy in the tarsal joints of 36 of 50 young horses with *spavin*, suggesting that osteochondrosis may be an important cause of this condition, at least in young animals.

Lesions of the palmar surface of the distal end of the metacarpal in adult racing Thoroughbreds are often discussed with the osteochondroses. These defects develop on the articular surface in contact with the proximal sesamoids. The *initial lesion* consists of fracture and necrosis of the subchondral bone, probably secondary to the trauma of hard running. With rest, *the fracture may heal* since articular cartilage above the fracture, nourished by synovial fluid, remains viable and probably holds the bone fragment in place. Collapse of subchondral tissues causes depression of the intact articular cartilage, but revascularization and healing may occur. On occasion, the complete fragment breaks free and this type of osteochondritis dissecans is analogous to some of the lesions described in man. The fact that horses so affected are adults, and are athletes in hard training, suggests that these lesions of the palmar surfaces of metacarpals *should be classified with stress fractures* rather than with osteochondrosis.

The relationship between copper deficiency and osteochondrosis in horses is compelling. Lesions indistinguishable from naturally occurring osteochondritis dissecans were reproduced experimentally in foals weaned from their dams at birth and fed on copper-deficient milk. Furthermore, there are several reports of similar lesions occurring in different parts of the world in foals grazing either copper-deficient pasture or pasture contaminated with the copper antagonists zinc and cadmium. Neonatal foals obtain copper primarily from milk, and yet mare's milk normally contains low copper concentrations and does not respond to supplementation. Foals born with inadequate hepatic copper reserves may therefore develop copper deficiency at an early age unless supplemented. Interestingly, supplementation of mares during late pregnancy and of their foals from 90 to 180 days of age appeared to reduce the prevalence and severity of osteochondrosis, even though unsupplemented control animals were fed at a level slightly above National Research Council recommended levels. There are also claims that copper supplementation has a palliative effect on established lesions of osteochondrosis. Possible mechanisms by which copper deficiency might predispose to osteochondrosis were discussed earlier in this section. Clearly, further work is needed in order to determine the precise role of copper in the etiology of osteochondrosis in horses and other species.

4. **Cattle** There are only occasional reports of osteochondrosis in cattle, but *the disease is likely to be much more common in this species than is currently recognized*. Due to financial constraints and difficulties in detailed radiologic examination, many lame cattle are sent for slaughter without definitive diagnosis. In a survey of middle-aged bulls slaughtered for nonmedical reasons, lesions of osteochondrosis were detected in the stifle joint of three of 25 animals in the absence of clinical lameness. Degenerative joint disease was detected in the stifle of 14 of the 25 bulls and although these lesion were too advanced to accurately determine their origin, the fact that the lesions identified as osteochondrosis, and those of degenerative joint disease both had a predilection for the lateral trochlear ridge, suggested that at least some cases of degenerative joint disease in this population of bulls were secondary to osteochondrosis. Other predilection sites for osteochondrosis in cattle are the humeral head, distal radius, elbow joint, and the tibial tarsal and occipital condyles.

Lesions characterized by focal thickening and chondrolysis are described in the growth cartilage of the articular–epiphyseal cartilage complex in young calves, *suggesting that the pathogenesis of the articular lesions in cattle is the same as in other species*. An association has been made between high-energy concentrate feeding and osteochondrosis in cattle, but the syndrome has also been reported in unsupplemented beef cattle grazing pasture. A possible genetic predisposition was suggested in the latter report.

Physeal lesions similar to those in pigs with osteochondrosis are described in the metacarpal and metatarsal bones of fast-growing, grain-fed, housed calves. In many cases, radiographic lesions characterized by focal thickening of the growth plate are accompanied by lameness and postmortem examination has revealed eosinophilic streaks and focal persistence of the hypertrophic zone. Disruption of the growth plate with bony bridging between the metaphysis and epiphysis is also recorded in affected calves. Hard floors apparently increase the number and severity of lesions, supporting the role of trauma in susceptible animals.

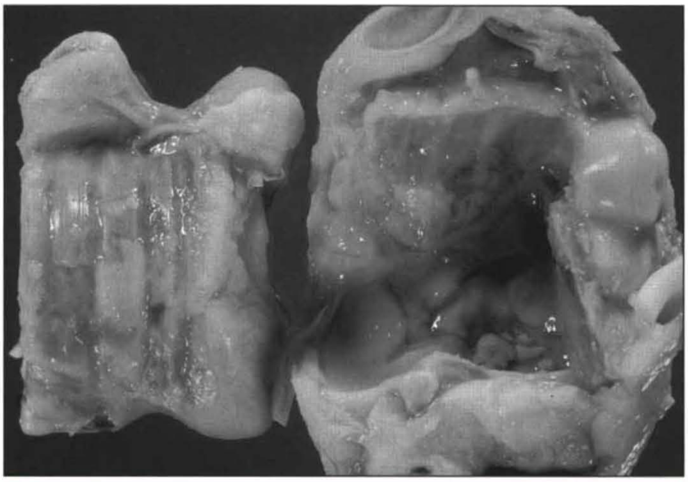

Figure 1.142 Osteochondrosis associated with copper deficiency in a farmed red deer. Extensive erosion of articular cartilage on the plantar surface of the talus and its opposing articular surface. Only small islands of cartilage remain and there are deep linear grooves in the exposed subchondral bone.

5. **Deer** *A strong association is recognized between osteochondrosis and copper deficiency in farmed red deer and wapiti x red deer hybrids in New Zealand.* On some farms, more than 30% of the fawns are affected. Lameness may be noticed as early as 1 month of age, but more commonly, the problem is not noticed until weaning at around 4 months of age. *Epiphysiolysis of the femoral head* is a common manifestation of the disease and may be bilateral. Animals with this lesion are severely lame and may adopt a "bunny-hopping" gait or "cow-hocked" stance. Other predilection sites are the carpal, hock (Fig. 1.142), and stifle joints. The lesions are usually bilateral. Affected deer invariably have low serum and/or liver copper concentrations and the disease can be prevented by copper supplementation of pregnant hinds.
6. **Sheep** Osteochondrosis appears to be *rare* in sheep, but has been reported as a cause of lameness in young, rapidly growing, Suffolk ram lambs. It is likely that the incidence of osteochondrosis in sheep will increase with continued selection for rapid growth. Microscopic lesions are common in growth plates of fast-growing lambs, but few of these progress to gross lesions. Valgus and varus limb deformities are common in ram lambs in feedlots and test stations in the USA and also occur in other countries. Grossly, some affected rams have thickening of the distal radial physis, similar to the growth plate lesions of osteochondrosis but joint changes are absent. Vascular and growth plate lesions mimicking osteochondrosis can be produced experimentally in lambs by procedures that increase weight bearing. Epiphysiolysis of the distal radial growth plate, associated with deformity of the forelimbs, is reported in 3-month-old lambs, supporting the concept that the physeal lesions of osteochondrosis may be one cause of angular limb deformity in sheep.

Hip dysplasia

Hip dysplasia is the most common skeletal disease of large and giant breeds of dogs, but may occur in all dog breeds and is occasionally reported in cats, cattle, and horses. *The disease is characterized by a lack of conformity between the femoral head and acetabulum, resulting in subluxation and, invariably, degenerative joint disease.* A polygenic mode of inheritance is postulated in dogs, and estimates of heritability have varied from 0.2 to 0.6. Environmental effects are believed to play a significant role in the severity of lesions. In particular, growth rate during the first few weeks of life appears to be important; faster-growing dogs having more severe lesions. Overfeeding young pups of susceptible breeds has been shown to shorten the time to first appearance of hip dysplasia and increase its severity. In another study, limiting the food consumed by Labrador Retrievers between 6 weeks and 1 year of age reduced both the incidence and severity of the disease.

1. **Dogs** Increased joint laxity is a common feature in dogs with hip dysplasia and appears to have a hereditary basis. *Although the cause of joint laxity is not clear, it is well established that dogs with hip dysplasia generally have low pelvic muscle mass.* The hip joint, probably more than any other joint, depends on muscle action to maintain the relationships between articulating surfaces during weight bearing and motion. Breeds such as Greyhounds, which do not get hip dysplasia, have a much greater muscle mass than German Shepherd Dogs, in which the disease is common. Hypotrophy of pectineal muscles, due to a developmental neuropathy, has also been suggested as a predisposing cause of hip dysplasia in dogs. Spasm or shortening of the pectineal muscle would be expected to create an upward force by the femoral head on the dorsal rim of the acetabulum. Such a force during early postnatal development of the hip joint could result in abnormal modeling and a dysplastic joint.

   It is possible that the basic defect in hip dysplasia is intrinsic to the hip joint, rather than to its supporting structures. It has been suggested that hip dysplasia is a manifestation of osteochondrosis but this hypothesis does not appear to be widely supported.

   Radiographic evidence of hip dysplasia in affected pups is usually not apparent until about 6 months of age, but may be detected earlier in severe cases or much later in dogs with mild lesions. *A radiographic diagnosis of hip dysplasia is based on the presence of subluxation of the joint or evidence of degenerative joint disease, or both.*

   The *gross lesions* of canine hip dysplasia vary with the stage of the disease. In the early stages, acetabula appear shallow, there is subluxation of the femoral head, and the articular cartilage may be dull or roughened. *The lesions are most prominent in weight-bearing areas of the femoral head and the dorsal rim of the acetabulum.* As the disease progresses, the articular cartilage becomes yellow or gray and erosion leads to fibrillation, then eburnation, with sclerosis of the subchondral bone. Osteophytes may develop at chondro-osseous margins. The shape of the femoral head may be altered due to the abnormal forces associated with subluxation and the femoral neck may become thickened as enthesiophytes develop at the attachment of the joint capsule. The joint capsule may be thickened with fibrous connective tissue and granulation tissue developing within the synovial membrane may extend over part of the articular surface as a pannus. In advanced stages, evidence of hip dysplasia may be masked by the manifestations of severe, degenerative joint disease. In some cases, the formation of osteophytes around the acetabular rim may disguise its original shallowness. In dogs with severely dysplastic joints, advanced changes of degenerative joint disease may be present by one year of age.

   Microscopic changes in hip dysplasia are those of degenerative joint disease (see below) and contribute nothing specific to the diagnosis. Early lesions include edema and tearing of collagen fibers in the ligament of the head of the femur and hypertrophy and hyperplasia of synoviocytes in the synovial membrane. Later in the disease, synovial villi may be infiltrated with mononuclear cells, the joint capsule is thickened with fibrous tissue, and the eroded articular cartilage contains clusters of proliferating chondrocytes.

2. **Cats** *Hip dysplasia is much less common in cats than in dogs*, but its frequency in the general cat population is probably underestimated. Many cats with radiographic evidence of hip dysplasia are asymptomatic and *the diagnosis is often incidental.* In a survey of 648 cats representing 12 breeds, the overall frequency of hip dysplasia was about 6.6%. Persians and Himalayans had a higher prevalence rate (15.8% and 25.0%, respectively) but only small numbers of these purebreds were included in the study and the results may be misleading. Other studies have indicated a very high prevalence of hip dysplasia in the Maine Coon breed of cat, which, like the Persian and Himalayan breeds, has a larger body size and a relatively small gene pool. As in dogs, no sex predilection is apparent in cats.

   The role of joint laxity in the pathogenesis of feline hip dysplasia is uncertain and requires further investigation. A consistent observation in cats with hip dysplasia is an *abnormally shallow acetabulum*, rather than subluxation of the joint, which is a feature of the disease in dogs. The shallow acetabulum predisposes to degenerative joint disease but the distribution of lesions in cats differs from that in dogs. The most extensive remodeling and proliferative changes in affected cats involve the craniodorsal acetabular margin, whereas in dogs the dorsal rim of the acetabulum is most severely affected. A further difference is the lack of remodeling of the femoral neck in cats with hip dysplasia.

3. **Cattle** *Hip dysplasia in cattle is best known in Herefords* but also occurs in the Aberdeen Angus, Galloway, and Charolais breeds. An inherited component is suspected but too few cases are reported to allow confirmation or characterization of the mode of inheritance. The disease is largely confined to males. Although some calves may be affected at birth, clinical lameness usually commences from 3 months to 2 years of age. Since lame bulls are more often sent for slaughter than subjected to postmortem examination, the true prevalence of hip dysplasia in cattle may be much higher than is realized. The lesions are generally bilateral and are characterized by shallow acetabula and degenerative arthropathy involving both the femoral head and acetabulum. *Rapid growth and mineral deficiencies appear to exacerbate the condition*, and it is likely that at least some cases of hip dysplasia in cattle represent manifestations of osteochondrosis.

Luxations and subluxations

Congenital luxations are rare in animals but **atlanto-axial subluxations** are reported in dogs, goats, cattle, and horses. In dogs, miniature and toy breeds are usually affected. *The underlying lesion appears to be failure of fusion of the odontoid process to the body of the axis.* Clinical signs vary from neck pain to tetraplegia, with age of onset varying from a few months to several years. *Absence or hypoplasia of the odontoid process occurs in calves*, often in conjunction with atlanto-occipital fusion. Tetraplegia may be present at birth or develop at several months of age. In both dogs and calves, *fusion of the odontoid process with the axis* normally occurs in the early months of life and it is possible that in some cases postnatal influences are responsible for the condition.

Atlanto-axial subluxations occur in some *Arabian foals* with a familial, probably inherited, syndrome involving occipitalization of the atlas and atlantalization of the axis. Affected foals may be dead or tetraparetic at birth, or develop progressive ataxia within a few months. They have atlanto-occipital fusion and atlantal condyles that articulate with a malformed axis, thereby displacing the cranio-vertebral articulation caudally. *Congenital atlanto-occipital fusion with a wedge-shaped vertebral piece and cervical scoliosis* also occurs in horses as a sporadic defect unrelated to the Arabian condition. Subluxations of cervical vertebrae in horses and dogs are discussed with cervical vertebral stenotic myelopathy ("wobbler syndrome") earlier in this chapter.

Temporomandibular subluxation is reported in Basset Hounds and Irish Setters. Clinically, open-mouth locking of jaws occurs when the zygomatic arch interferes with the normal movement of the coronoid process of the mandible. Developmental abnormalities in the condyloid process of the mandible and the mandibular fossa of the temporal bone are responsible for subluxation but the *cause of the dysplasia is unknown.* The lesions are bilateral. A similar condition in American Cocker Spaniels may be bilateral or unilateral. In these animals, temporomandibular subluxation may be elicited by manipulation but is not associated with spontaneous clinical signs. Dysplasia of the mandibular fossa and hypoplasia or aplasia of the retroglenoid process are responsible for the excess joint mobility.

Subluxation of the carpus is reported as a sex-linked recessive trait in a colony of dogs in which hemophilia A also existed, although the two disorders do not occur in the same animals. Signs of carpal subluxation first appear when the animals begin to walk. Most carpal subluxations and luxations are secondary to trauma.

Patellar luxations and **subluxations** are common in dogs, less so in horses, and rare in other species. In **dogs**, most are associated with anatomical defects and are probably inherited as polygenic traits. Females are affected 1.5 times as often as males. The condition may be unilateral or bilateral and luxations of variable severity may occur either medially or laterally. Occasionally they occur in both directions. Medial luxations account for about three-quarters of the cases and are *most common in small dogs*, especially Pomeranians, Yorkshire Terriers, Chihuahuas, Miniature and Toy Poodles and Boston Terriers. Lateral luxations tend to occur in larger dogs including some giant breeds, such as Great Dane, St. Bernard, and Irish Wolfhound. Clinical signs commonly develop within the first few months of life, but may be present at birth. Various anatomical defects involving the femorotibial joint, and sometimes the entire limb, are present in affected dogs and may be adaptational deformities. Patellar luxation in **horses** almost always occurs in a lateral direction and is associated with hypoplasia of the lateral ridge of the femoral trochlea. It is sometimes congenital and bilateral in both foals and calves. The condition probably is inherited in ponies, and perhaps also in horses. Patellar luxation is rarely reported in **cats** and most cases appear to have a traumatic origin. A genetic predisposition has however been suggested in the Abyssinian and Devon Rex breeds.

The *consequences of luxations and subluxations* vary with the species of animal and the joint involved. In general, subluxations, whether they are genetic or traumatic in origin, *predispose to degenerative joint disease* due to instability of the joint. Luxations are more likely to damage periarticular soft tissues and, if the articular cartilage remains in persistent contact with soft tissues, it degenerates and is replaced by fibrous tissue and bone. If movement is minimal, a *fibrous or bony fixation* may develop, but continued movement may result in the formation of a new joint. Fibrous tissue about the dislocated bone ends sometimes becomes organized into an articular capsule with a synovial lining, but the articular surfaces are covered with fibrous tissue rather than articular cartilage.

Abnormal positioning of joints in terms of overextension or overflexion occurs in animals with **arthrogryposis**, but only in the most severe cases are the articular surfaces deformed. The primary lesion is in the central nervous system, where the congenital absence of motor neurons supplying selected muscles results in muscular atrophy and overextension or overflexion of the opposing unaffected muscle groups. **Congenital torticollis**, whether or not it is associated with a branchiocephalic fold, is associated with articular abnormalities of the cervical vertebrae in sympathy with the concertina-like compression that occurs on the concave side of the deviation.

DEGENERATIVE DISEASES OF JOINTS

Synovial joints

Degenerative diseases involving the major weight-bearing joints of the limbs are very common in humans and domestic animals. In human medicine, the term **"osteoarthritis"** is preferred for this group of diseases although it incorrectly implies an inflammatory origin. **Degenerative joint disease** is a more appropriate term, based on the putative pathogenesis, and will be used in this chapter. Other commonly used *synonyms include osteoarthrosis and degenerative arthropathy*.

Degenerative joint disease is not a specific entity, but a common sequel to various forms of joint injury and involves an interaction between biologic and mechanical factors on the articular cartilage, subchondral bone, and synovium. It can be either *monoarticular or polyarticular* and may be classified as either *primary or secondary*. **Primary** *degenerative joint disease refers to those cases where there is no apparent predisposing cause and generally occurs in older animals*. Such cases may reflect an acceleration of the normal aging changes that occur in joints. Mild degenerative changes in weight-bearing articular surfaces, including yellowing and fibrillation of cartilage, are common incidental findings in adult dogs at necropsy. In the absence of clinical signs of lameness it is difficult to justify a diagnosis of degenerative joint disease in such cases, but it is likely that these represent the early manifestations of the disease and probably account for the mild lameness and stiffness seen in many old dogs.

Secondary *degenerative joint disease is associated with an underlying abnormality in the joint or its supporting structures, predisposing to premature degeneration of the cartilage. Any condition that causes direct damage to the articular cartilage, creates instability, or results in abnormal directional forces can predispose to degenerative joint disease.* For example, secondary degenerative joint disease is an inevitable consequence of the joint laxity in dogs with hip dysplasia, due to the effect of abnormal mechanical forces on articular cartilage. Traumatic injuries to ligaments may also create joint instability leading to degenerative joint disease. Incongruity of opposing articular surfaces, as occurs in many animals with osteochondrosis, is a common cause of degenerative joint disease involving the shoulder, elbow, stifle, and hock joints of dogs and other species. Other disorders that may predispose to secondary degenerative joint disease include malaligned limb fractures, angular limb deformities, aseptic necrosis, or metabolic bone diseases with collapse of subchondral bone, inherited defects in cartilage or collagen formation, septic arthritis, and hemarthrosis. Persistent hemarthrosis, as occurs in animals with hemophilia or other coagulopathies, may lead to chronic, proliferative synovitis with accumulation of hemosiderin-containing macrophages in the synovium. Invasive pannus may develop from the hyperplastic synovial tissue and spread out over the articular surface.

The *gross lesions* of degenerative joint disease are similar whether the disease is primary or secondary in origin, although the lesions of secondary degenerative joint disease are generally more severe by the time an affected animal comes to necropsy. *The earliest gross lesion is roughening of the articular cartilage in areas of weight bearing* (Fig. 1.143) due to loss of proteoglycans from the matrix and unmasking of the collagen fibrils. This is referred to as **fibrillation**. Initially, only the superficial layers are involved but, with continued abrasion of the degenerate cartilage, vertical fissures develop in deeper layers in the direction of collagen fibril alignment and may extend to the subchondral bone. In hinge-type joints, such as the hock, fetlock, and elbow, *linear grooves (wear lines)* may be present in the cartilage in the direction of joint movement (Fig. 1.144). These are found relatively commonly in the joints of adult horses. Their cause is uncertain and they are not necessarily associated with progressive lesions. Progressive erosion of fibrillated cartilage is accompanied by sclerosis of the subchondral bone. In advanced lesions, *the articular cartilage may be*

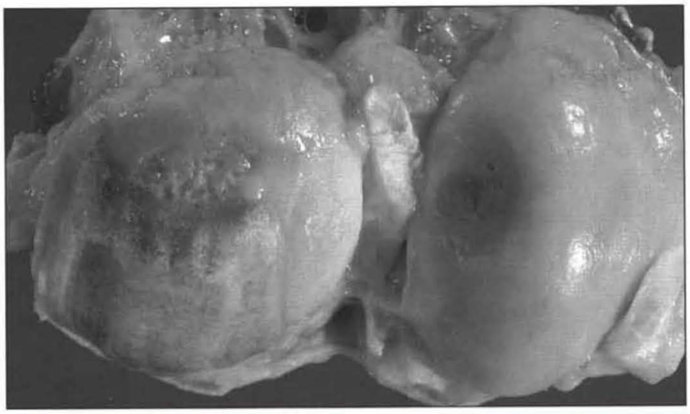

Figure 1.145 Chronic degenerative joint disease of the stifle joint in a cow. Loss of articular cartilage on the medial condyle with eburnation of the exposed subchondral bone. A smaller lesion is present on the lateral condyle.

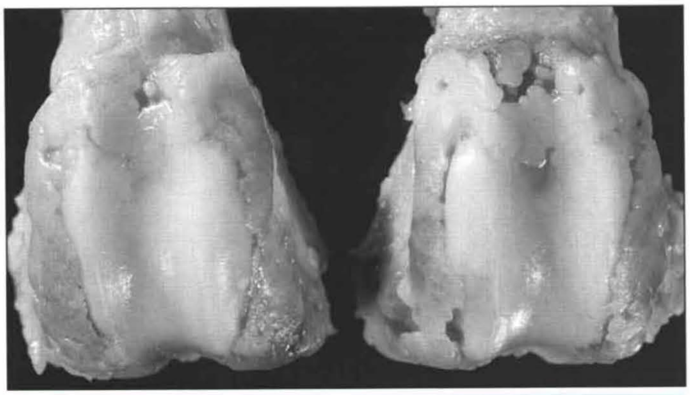

Figure 1.146 Degenerative joint disease, dog. Extensive osteophyte formation along the chondro-osseous margins of both stifles.

completely ulcerated in areas of maximum weight bearing and the exposed bone worn smooth, a process referred to as **eburnation** (Fig. 1.145). Increased stiffness of the sclerotic subchondral bone may accelerate the loss of the overlying cartilage due to reduced flexibility during weight bearing. In fact, some investigators have proposed that sclerosis of subchondral bone may be the initial lesion in degenerative joint disease. More likely, this is just one of a combination of factors involved in progression of the disease. Cystic lesions are often present beneath eburnated surfaces in human patients with degenerative joint disease but are seldom seen in domestic animals. *Another consistent gross feature of degenerative joint disease is the formation of* **osteophytes** *at the margin of articular cartilage and bone* (Fig. 1.146). These small, nodular, outgrowths of bone, covered by a thin layer of hyaline cartilage may surround the articular surface and either distort its shape or obscure the boundary between the articular surface and the supporting bone. Osteophytes develop rapidly following joint injury and can be detected as early as 7 days after a joint has been unstable experimentally. Changes also occur in the synovium and joint capsule of animals with degenerative joint disease. The joint capsule is thickened with fibrous connective tissue and there is likely to be hypertrophy of synovial villi.

A variety of *histologic changes* have been reported in the articular cartilage of animals and humans with degenerative joint disease. *Reduction in metachromatic staining of the superficial cartilage matrix*, presumably associated with the loss of proteoglycan, is a common early change and may be accompanied by necrosis of chondrocytes in the tangential layer. *Clusters of proliferative chondrocytes (brood capsules or chondrones) may be present*, especially adjacent to fissures in areas of fibrillation (Fig. 1.147A). Elsewhere, the density of chondrocytes is

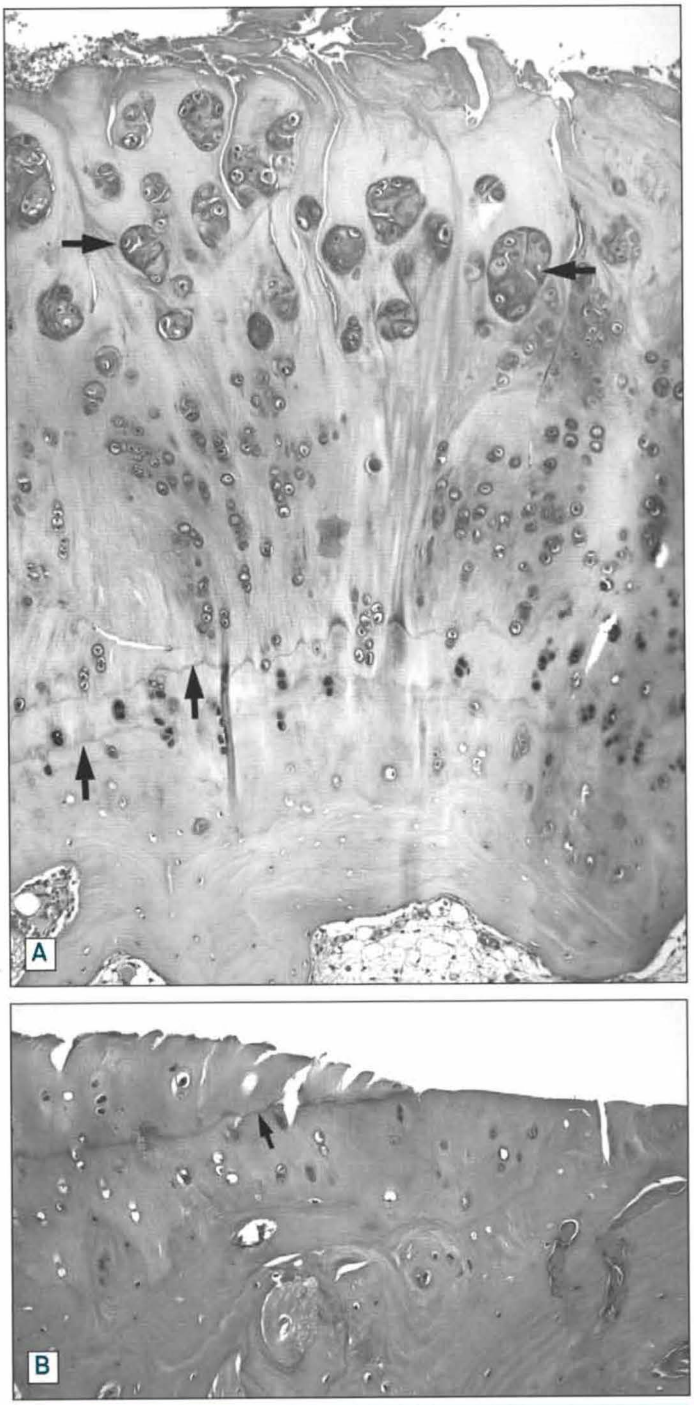

Figure 1.147 Degenerative joint disease, dog. **A.** Fibrillated articular cartilage with irregular surface, eosinophilic matrix and disorganization of chondrocytes. Several chondrones (horizontal arrows) are adjacent to clefts in superficial layers. The tidemark is duplicated in some areas (vertical arrows). **B.** Junction between areas of fibrillation and eburnation. The frayed cartilage becomes eroded to the level of the tidemark (arrow) at which stage it is replaced by an articular surface comprised of mineralized cartilage then sclerotic bone.

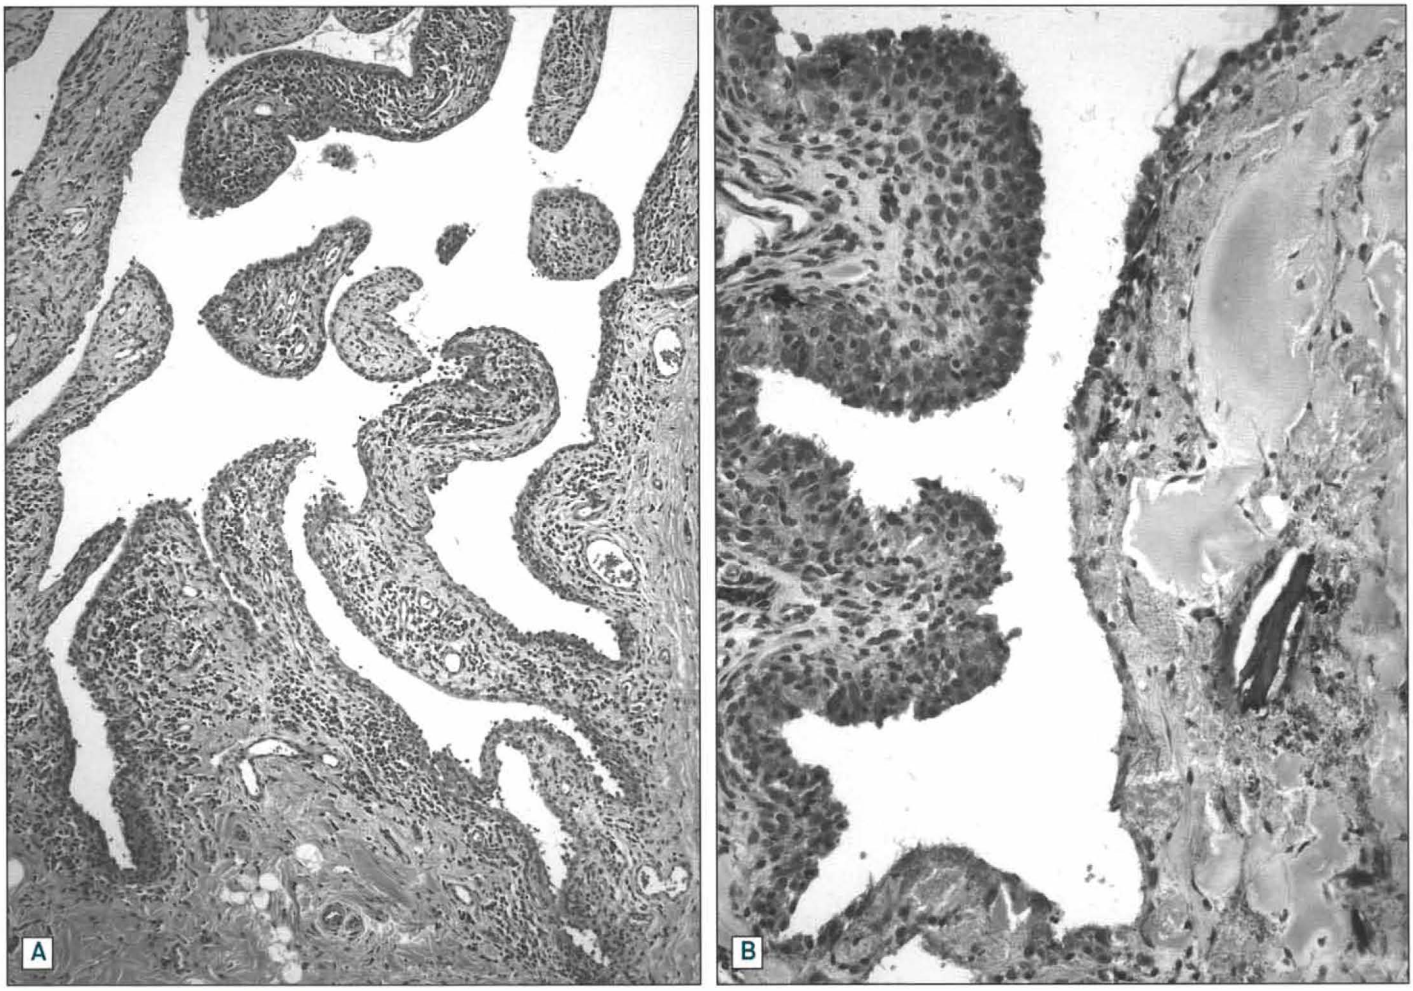

Figure 1.148 Chronic degenerative joint disease. A. Hypertrophic villi lined by plump synoviocytes and infiltrated with mononuclear inflammatory cells. **B.** Fragments of degenerate cartilage and occasional spicules of bone, most likely derived from the eroded articular surface, embedded in the synovium. The adjacent villi are lined by hyperplastic synoviocytes.

often reduced but remnants of degenerate cells may still be apparent. In advanced lesions, *the overall thickness of the degenerate cartilage may be markedly reduced*, the surface is irregular, and deep clefts may be present. Collagen fibrils within the matrix appear more prominent. The tidemark is often duplicated or disrupted, and may be penetrated by blood vessels. *Fibrillated cartilage merges with areas of eburnation* (Fig. 1.147B), where the articular cartilage is absent and the trabeculae of subchondral bone show variable degrees of thickening and/or remodeling. In chronic degenerative joint disease, *synovial villi are hypertrophic*, sometimes branching and are lined by plump, hyperplastic synoviocytes (Fig. 1.148A). Small to moderate numbers of *mononuclear inflammatory cells*, predominantly lymphocytes, in addition to hemosiderin-containing macrophages are often present. *Fragments of degenerate cartilage*, presumably derived from the eroded articular surface, may be embedded in the synovium or attached to its surface (Fig. 1.148B). Such fragments may enlarge through proliferation of surviving chondrocytes and may be an early stage of secondary osteochondromatosis (see p. 134).

The *pathogenesis of degenerative joint disease is complex* and continues to be debated in human medicine, even after many decades of research and observation. Although there are differing hypotheses on the exact sequence of events, most investigators conform to the view that the disease is *primarily degenerative in nature and that the accompanying inflammatory changes are secondary*. It must be recognized however, that lesions of degenerative joint disease will also develop as a sequel to chronic inflammation in many primary inflammatory conditions of man and domestic animals. There is convincing evidence that the *chondrocytes* of articular cartilage play an important role in the early stages of disease development. These post-mitotic cells normally survive throughout the life of the individual and maintain a balance between degradation and repair of the cartilage matrix under the influence of cytokines, growth factors, and direct physical stimuli. Disruption of this balance in favor of matrix catabolism occurs in the early stages of degenerative joint disease and is reflected by depletion of the proteoglycan aggregates, aggrecan, which are a major component of cartilage matrix. Continued reduction in the proteoglycan content of the matrix, together with damage to collagen fibrils, interferes with the viscoelastic properties of articular cartilage. As a result, progressive loss of cartilage occurs under the influence of normal biomechanical forces.

The early loss of matrix components in degenerative joint disease is mediated by degradative enzymes, including metalloproteinases, serine proteinases, cysteine proteinases, and aggrecanase. Many of these enzymes are derived from chondrocytes, but synoviocytes and inflammatory cells may also produce them. Natural inhibitors of these enzymes are normally present in articular cartilage but are deficient in degenerative joint disease. Several zinc-dependent metalloproteinases are recognized but the collagenases, stromelysins, and gelatinases appear to be the most important in cartilage degradation. Collagenase and stromelysin are synthesized as latent enzymes in cartilage and can be activated by plasmin and plasminogen activator or inhibited by plasminogen activator inhibitor-1. Collagenase breaks down the scaffolding of type-II collagen, while stromelysin cleaves aggrecan in addition to some types of collagen. Degradation products of aggrecan and type-II collagen may remain in the cartilage matrix or diffuse into the synovial fluid, where they can be detected. Proteoglycan fragments in synovial fluid may be either phagocytosed by synovial cells or enter lymphatics in the synovium.

Various cytokines and growth factors are also believed to be involved in the pathogenesis of degenerative joint disease, particularly in the generation of the inflammatory response. Most attention has focused on the role of the cytokines interleukin-1, interleukin-6, and tumor necrosis factor-α. Interleukin-1 and tumor necrosis factor-α have been shown to increase the synthesis of metalloproteinases and plasminogen activators, and to induce the resorption of cartilage both in vitro and in vivo. Interleukin-1 also stimulates fibroblasts to synthesize collagen type I and type II, and may therefore contribute to fibrous thickening of the joint capsule in degenerative joint disease. The role of interleukin-6 is less clear but it is released in vitro by chondrocytes from normal and degenerate cartilage and may be involved in autocrine stimulation of chondrocyte proliferation. It has also been detected in the synovial fluid of human patients with various arthropathies and may be an important intermediate signal for the activities of interleukin-1 and tumor necrosis factor-α. Growth factors, such as insulin-like growth factor-1 and transforming growth factor-β, have an anabolic effect on connective tissues and have been shown to stimulate proteoglycan and collagen synthesis. They can also inhibit or reverse some of the catabolic effects of interleukin-1. Similarly, the cytokine γ-interferon inhibits the action of interleukin-1 on metalloproteinase production and proteoglycan depletion from cartilage. These observations support the concept of a complex interaction between cytokines and growth factors in the pathogenesis of degenerative joint disease.

Inflammatory changes in the synovium of humans and animals with degenerative joint disease are most likely secondary to the stimulation of interleukin-1 and tumor necrosis factor-α by synoviocytes following the release of degraded collagen and proteoglycan fragments from degenerate cartilage. The neuropeptide, substance P, may also be involved. This peptide has been detected in the synovial membrane and fluid of human patients with degenerative joint disease and has been shown to activate both inflammatory cells and synoviocytes, in addition to stimulating the secretion and action of interleukin-1.

Primary and secondary degenerative joint diseases are common in most domestic animal species, but in dogs, horses, and cattle, certain types are either sufficiently common or important to warrant discussion as separate entities.

Degenerative joint diseases of horses

Although degenerative joint diseases may affect a wide range of synovial joints in horses, those involving the *interphalangeal, metacarpophalangeal, and hock joints* are of particular importance. *These joints are subjected to considerable biomechanical loading during motion*, especially in performance horses, and are therefore predisposed to traumatic injury to the articular cartilage, subchondral bone, or supporting structures. *In joints subjected to considerable motion, such as the metacarpophalangeal joints, the changes of degenerative joint disease are usually characterized by gradual erosion of articular cartilage, sclerosis of subchondral bone, chronic synovitis, and gradual stiffening of the joint due to fibrous thickening of the joint capsule.* In low-motion joints, such as the proximal and distal interphalangeal, distal intertarsal, and tarsometatarsal joints, maximum loading during motion is focused on a restricted area. In these joints, the lesion typically is characterized by full-thickness necrosis of the articular cartilage with limited wearing, focal damage to subchondral bone, and bony ankylosis. Degenerative changes involving the navicular bone and the adjacent deep digital flexor tendon, referred to as *navicular syndrome*, probably have a similar pathogenesis and will be discussed here, although they are more appropriately classified as a form of bursitis rather than with degenerative joint diseases.

Metacarpophalangeal (fetlock) joints

Traumatic and degenerative diseases of the metacarpophalangeal (fetlock) joints of the foreleg are *more common than similar lesions affecting any of the other limb joints.* This susceptibility to injury presumably reflects the relatively small surface area of this joint in comparison to most others and the considerable range of motion expressed by the joint. Furthermore, during racing, the entire weight of the animal is transmitted to the ground through this joint during one phase of the stride. *Poor conformation and excessive training of horses at a young age no doubt contribute to the development of lesions in this and other joints.* **Traumatic synovitis** of the dorsal joint capsule often results from repeated overextension of the fetlock joint in the racehorse. At the point of maximum extension, the *proximodorsal margin of the proximal phalanx traumatizes the fibrous synovial pad* covering the dorsal surface of the distal end of the cannon bone. In response to constant trauma, the fibrous pad becomes enlarged due to hyperemia, edema, and fibroplasia, and extends across the adjacent dorsal articular margin of the cannon bone. Degeneration of the underlying articular cartilage occurs as a result of impaired access to synovial fluid and release of inflammatory mediators from the inflamed synovium. In cases where the inflammation resolves and the synovial pad retracts, the degenerate, pitted articular surface remains as evidence. In other cases, hemorrhage from the traumatized synovial pad and the insertion line of the joint capsule results in the formation of an organizing hematoma. *The firm yellow/brown lesion on the dorsal surface of the distal cannon bone is referred to as* **villonodular synovitis**. The histological features of these lesions vary with their duration. In the subacute stages, they include a mixture of hemosiderin-containing macrophages and well-ordered granulation tissue. Chronic lesions consist of dense, poorly vascularized fibrous tissue infiltrated by mononuclear inflammatory cells and covered by a layer of synoviocytes.

Another common change involving the metacarpophalangeal joint in performance horses is the *formation of a periarticular lip along the dorsal articular margin of the proximal phalanx*. Initially, the lip consists of an overgrowth of articular cartilage, but its deeper layers undergo endochondral ossification, creating an *osteophyte* that can be detected radiographically. With repeated trauma, microscopic or macroscopic chip fractures may develop in the bony support of the lip. The repair of such fractures is often compromised by the continued trauma of racing or training, and loosened chip fractures, attached to the adjacent bone by granulation tissue, may cause synovitis and acute clinical signs.

Traumatic osteochondrosis

Small, ovoid, "bruised" defects about 2–4 mm in diameter are relatively common incidental findings in the palmar articular surface of the condyle of the cannon bone in racehorses at necropsy. More severe lesions of this type are symptomatic and are characterized by apparent collapse of the articular cartilage into a defect in the subchondral bone. These lesions are referred to as traumatic osteochondrosis. They typically occur in highly trained, mature racehorses and are believed to result from focal sclerosis of subchondral bone, leading to microfractures and bone necrosis. During the repair process, the lesion is susceptible to displacement or collapse, particularly if strenuous exercise persists during this period.

Transverse ridge arthrosis

This is a degenerative lesion involving the transverse ridge of the condyle of the cannon bone, particularly in the foreleg. The lesions vary from mild fibrillation to the development of deep ulcers extending into the underlying bone. The transverse ridge develops between the dorsal articular surface of the condyle, which articulates with the proximal phalanx, and the palmar surface of the condyle, which articulates with the proximal sesamoid bones. If the fetlock joint is overextended during racing, the base of the proximal sesamoid bone overrides the transverse ridge, exposing it to shearing forces and eventually leading to degeneration.

Instability of the metacarpophalangeal joint created by experimental transection of the medial collateral and the lateral collateral sesamoidean ligaments in horses has been used to induce lesions similar to those of naturally occurring degenerative joint disease. The lesions included scoring lines (linear erosions) in the articular cartilage and osteophyte formation along the lateral articular margin of the sesamoid bone and lateral aspect of the proximal phalanx.

Ringbone

Degenerative diseases of **interphalangeal joints** are commonly referred to as *ringbone*. *High* or *low* ringbone refers to involvement of the *proximal or distal interphalangeal joints* respectively. *The lesions are typically bilateral and primarily involve the forelimbs.* In young horses, subchondral cystic lesions associated with osteochondrosis are considered an important predisposing factor in high ringbone, although similar subchondral lesions can also be induced by trauma to the articular surface of young animals. In older horses, instability of the joint secondary to traumatic injuries to the joint capsule, ligaments, or tendons supporting the joint may be involved. Alternatively, repeated episodes of minor trauma from athletic activity, or mechanical stresses associated with faulty conformation, may place excessive strain on the insertion lines of the dorsal joint capsule. Degenerative disease of the proximal interphalangeal joint also occurs secondary to subluxation of the joint following fractures of the palmar or plantar eminences of the middle phalanx. High ringbone is found most often in adult horses used for western events or polo, where horses running at high speed make abrupt stops, turns, and twisting motions.

The severity of the articular and periarticular lesions of high ringbone varies markedly between individuals. In the *early stages of the disease*, affected joints may be partly immobilized by fibrous thickening of the dorsal joint capsule and there may be early cartilage degeneration of one or both condyles of the distal first phalanx and the apposing glenoid cavity of the proximal second phalanx. Joint fluid is normal and the synovium is not congested. The periarticular response, which includes fibrous thickening of the dorsal joint capsule and bone formation beginning in the joint capsule insertion line, is a much more prominent feature than the cartilaginous changes. *The periarticular bony response on the dorsal surface of the joint gives the lesion its name.* In *advanced lesions*, full-thickness necrosis of the articular cartilage, followed by erosions in the subchondral bony plate, may lead to *ankylosis*. In cases where there is residual joint motion, there is eburnation of the ulcerated articular surfaces, thickening of the subchondral bony plates and inhibition of ankylosis.

Degenerative disease of the distal interphalangeal (coffin) joint

This occurs most often in racehorses, probably as a result of repeated minor trauma. *The Quarter Horse breed appears predisposed to problems of this joint*, possibly because their relatively small hoof diameter, short, upright pasterns, and large body size place greater stress on the joint during racing at high speeds. Periarticular osteophytes and enthesiophytes involving the distal aspect of the middle phalanx or the extensor process of the distal phalanx, characteristic of low ringbone, are present in some, but not all cases of degenerative joint disease of the coffin joint. In other cases the disease is less obvious clinically and radiographically and may be confused with navicular syndrome.

Bone spavin

This is a degenerative disease of the tarsus of the horse and occasionally the ox. Structural changes in this disorder are essentially the same as those occurring in high ringbone and presumably have a similar pathogenesis, initiated by sustained loading and joint immobilization. The *major lesions develop on the medial side of the tarsus*, primarily involving the distal intertarsal joint and, less commonly, the tarsometatarsal and proximal intertarsal joints. Examination of early cases of bone spavin, centered in the distal intertarsal joint, indicates that periarticular fibrosis initially immobilizes the dorsomedial side of the joint. "Kissing lesions" subsequently develop in articular cartilage adjacent to the dorsomedial margins of the apposing articular surfaces of the central and third tarsal bones. *Early lesions* show full-thickness necrosis of the apposed cartilage surfaces and intense bone remodeling within the thickened subchondral bony plate. *Intermediate lesions* show penetration of the necrotic cartilage by granulation tissue from the areas of intense subchondral bone remodeling. As the *lesion progresses*, granulation tissue extends across the joint space through areas of necrotic cartilage and establishes a *fibrous ankylosis*, which later gives way to a more stable *bony ankylosis*.

Navicular syndrome (navicular disease)

This is a degenerative disorder involving the distal half of the flexor surface of the navicular bones of the forelegs of mature horses. Various theories for its etiology have been proposed, but a biomechanical origin, associated with the combined effect of abnormal forces and poor conformation, is currently favored. An alternative hypothesis, whereby thrombosis of arterioles supplying the distal region of the navicular bone leads to ischemic necrosis of the bone, has failed to gain support.

Horses having *abnormal foot conformation*, i.e., bone and joint alignments at either end of the spectrum for the breed, are predisposed to navicular syndrome. At one end of this spectrum are *racing Thoroughbreds with very long toes and low heels*. In horses with this conformation, the deep digital flexor tendon places sustained pressure against the distal border of the flexor surface of the navicular bone. At the other end of the spectrum are those American Quarter Horses with an *extremely upright foot conformation*. In such animals, the deep digital flexor tendon exerts repetitive concussive forces on the distal border of the flexor surface of the navicular bone during exercise. Either sustained pressure or repetitive concussion can activate the remodeling processes in the subchondral region of the navicular bone in an attempt to adapt the flexor cortex to these biomechanical stresses. If pressure or concussive forces are of low intensity and of limited duration, the subchondral bone and spongiosa thicken sufficiently to absorb, diffuse, and redistribute the load. In such horses, the navicular bones are sclerotic and the fibrocartilage of the flexor surface of these horses often shows degenerative changes, but there is no clinical lameness.

When the sustained load or concussive forces acting on the distal border of the flexor surface of the navicular bone exceeds the physiologic limit, an exaggerated bone remodeling response is initiated. This eventually creates *lytic lesions in the subchondral bone beneath the flexor surface of the navicular bone*. Granulation tissue arises within these sites of intense bone remodeling in the same manner as it does in high ringbone and bone spavin. The granulation tissue eventually penetrates the overlying layer of degenerate fibrocartilage and forms fibrous adhesions to the apposing dorsal surface of the deep digital flexor tendon.

Bone marrow fibrosis and distended veins can be demonstrated in the marrow spaces of the subchondral bone and spongiosa located in the distal halves of the navicular bones of horses with navicular syndrome. It appears that vessels participating in the intense bone remodeling response leak edema fluid into the marrow spaces of the subchondral spongiosa supporting the flexor surface of the bone. This fluid is organized by fibrous tissue, which forms at the drainage angle in the medullary cavity of the distal border of the navicular bone. Blood vessels in this area are entrapped in the fibrous tissue, which retards venous drainage, resulting in distended veins, venous hypertension, and pain.

Enlarged vascular channels can often be seen radiographically in horses with navicular syndrome. As the tiny nutrient arteries enter along the floor of the synovial fossae, which are located on the distal border of the navicular bone, each main artery sends off small branches to the synovial lining of each of the respective synovial fossae. As part of the hyperemia associated with the remodeling process, the synovial lining of the fossae also undergoes active hyperemia. Osteoclasts are attracted to the site and activated to resorb bone, thus enlarging the synovial fossae and eventually eroding into the navicular bone. The *resorptive process* follows the pathway of the nutrient artery into the medullary cavity of the distal border of the navicular bone, creating deep synovial invaginations that are recognized on radiographs as enlarged vascular channels.

Degenerative joint diseases of dogs

Primary and secondary degenerative joint diseases are relatively common in adult dogs, particularly medium and large breeds, and usually involving the major weight-bearing joints. Secondary degenerative joint disease in dogs most often occurs as a sequel to joint instability or incongruity following dysplastic diseases of the hip or elbow or to the various manifestations of osteochondrosis. These are discussed in more detail elsewhere in this chapter.

Primary degenerative joint disease is sufficiently common in aged dogs to be regarded by many as an *inevitable consequence of aging*. Gross lesions are often found incidentally at necropsy in animals that had shown no clinical evidence of lameness. In one study, 31 (21%) of 150 randomly selected dogs had degenerative lesions in the *stifle joint* at necropsy. In 23 of these dogs, the lesions were bilateral. Degenerative joint disease of the shoulder and hip joints are also common in middle-aged and old dogs. The lesions are usually bilateral and develop slowly, starting at around 5–6 years of age as areas of softening and yellow discoloration on regions of articular cartilage subjected to maximum weight-bearing stress, then progress to fibrillation (see Fig. 1.143) and sometimes eburnation. Osteophytes frequently line the chondro-osseous junction (see Fig. 1.146) and may encircle the articular surface. In severe cases, the joint capsule is thickened and synovial villi are hypertrophic.

Degenerative joint disease of the *shoulder joint* may be related to joint laxity. Like the hip joint, the shoulder relies on muscular strength for stability. Atrophy of muscles with aging could therefore permit excessive joint mobility and persistent mild trauma to the articular cartilage. The fact that the dog bears 65–70% of its body weight on its forelegs may account for the development of lesions in shoulders more frequently than in hips. The shoulder lesions of primary degenerative joint disease may be difficult to distinguish from the degenerative lesions that occur as a sequel to osteochondrosis, especially in the advanced stages. Both typically affect the caudal aspect of the humeral head, and both are generally bilateral. However, as described earlier in this chapter, osteochondrosis develops at a much earlier age than primary degenerative joint disease and although healed lesions of osteochondrosis may be found incidentally in older dogs, they represent the repair of a cartilage defect, rather than progressive degeneration of articular cartilage from its superficial layers.

Degenerative joint diseases of cattle

Degenerative joint disease of the *stifle joint* occurs in mature dairy cows and is reported as a *possible inherited trait in Holsteins and Jerseys*. Clinical signs include lameness and muscle atrophy. The lesions are bilateral, and appear to develop in the conventional manner. Cartilage degeneration, erosion, eburnation, and osteophyte formation occur on the distal femur and are most severe on the medial aspect (see Fig. 1.145). Complementary lesions are present in the proximal tibia and shredding of the medial meniscus is common (Fig. 1.149).

Stifle arthropathy also occurs in stud dairy and beef bulls and may be secondary to poor conformation, ligament damage, or ruptured meniscus during fighting, or as a consequence of osteochondrosis. The latter may be an important cause of wastage of well-grown beef bulls that have been fed for optimal growth prior to sale or showing.

Degenerative joint disease of the *hock joints (spavin)* has been described as a problem in *tied Swedish dairy cows*. In one study, 37%

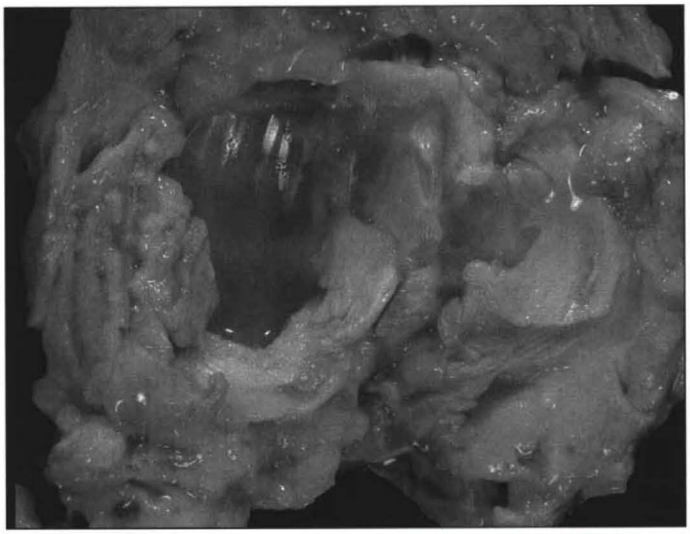

Figure 1.149 Degenerative joint disease, cow. Proximal tibia of same stifle joint as shown in Fig. 1.145. Shredding of medial meniscus, eburnation of medial articular surface (corresponding to medial condylar lesion), and marked fibrous thickening of joint capsule.

of animals were affected. The changes developed before the cows were 2 years old and increased in severity with age, sometimes progressing to ankylosis.

A lethal syndrome characterized by generalized degenerative joint disease and brachygnathia superior is reported in Angus calves. Affected calves have facial abnormalities, including reduced length of maxillary and palatine bones, together with abnormalities in all major joints. Macroscopic changes vary from reduced luster of articular cartilage to erosions and deep ulcers, eburnation of exposed subchondral bone, and thickening of joint capsules. Histologic lesions include degeneration of the articular cartilage matrix and necrosis of chondrocytes, in addition to fibrillation, chondrone formation, and chronic synovitis. Physeal abnormalities are also described. A genetic defect in the composition of cartilage matrix is suspected but the mode of inheritance is uncertain.

Cartilaginous joints

The most important degenerative diseases of cartilaginous joints are those affecting *intervertebral disks*. Such diseases are of particular importance in humans and dogs, but are rare in other species, as are degenerative diseases of other cartilaginous joints. **Degeneration of intervertebral disks** occurs in all dog breeds as part of the aging process, but there are significant differences between chondrodystrophic and nonchondrodystrophic breeds in the nature of the degeneration, and the age at which it occurs.

In **chondrodystrophic breeds**, such as the Dachshund, Pekingese, Poodle, Beagle and Cocker Spaniel, *the nucleus pulposus starts to degenerate early in life* and by one year of age, it has become largely replaced by dry, gray/white or yellow, cartilaginous material (Fig. 1.150A). The initial microscopic change is thickening of the delicate fibrocartilaginous septa between cellular clusters, dividing the nucleus pulposus into lobules. Chondrocyte proliferation within the nucleus leads to *replacement of the original structure with chondroid tissue* within the first year of life. No lesions are apparent in the annulus fibrosus at this stage. The change in the nucleus pulposus in chondrodystrophic dogs *occurs in all disks* throughout the length of the vertebral column and is accompanied by a decline in the glycosaminoglycan and water content, and an increase in the collagen content of the matrix. Beginning at the periphery, *the chondroid tissue in the nucleus pulposus degenerates and mineralizes*, eventually becoming a crumbly mass (Fig. 1.150B). At this stage, there is *degeneration of the inner lamellae of the annulus fibrosus*, probably due to the altered viscoelastic properties of the degenerate nucleus pulposus. Individual lamellae may tear and allow degenerate nuclear material to escape into the annulus. Meanwhile, degeneration of the annulus fibrosus continues until the outer lamellae are also involved.

In **nonchondrodystrophic dogs**, *the normal mucoid nature of the nucleus pulposus persists, at least until middle age*, and although it may become dry and more fibrous with advancing age, it seldom mineralizes. Occasionally, fibrous metaplasia of the nucleus pulposus occurs in relatively young dogs of nonchondrodystrophic breeds, but such changes are believed to be secondary to *focal disruption of lamellae in the annulus fibrosus*, presumably as a result of trauma. In support of this belief is the observation that these lesions are *generally confined to a single disk*, unlike the generalized changes that occur in the nucleus pulposus of chondrodystrophic dogs. Traumatic damage to the annulus fibrosus would be expected to alter the biomechanical properties of

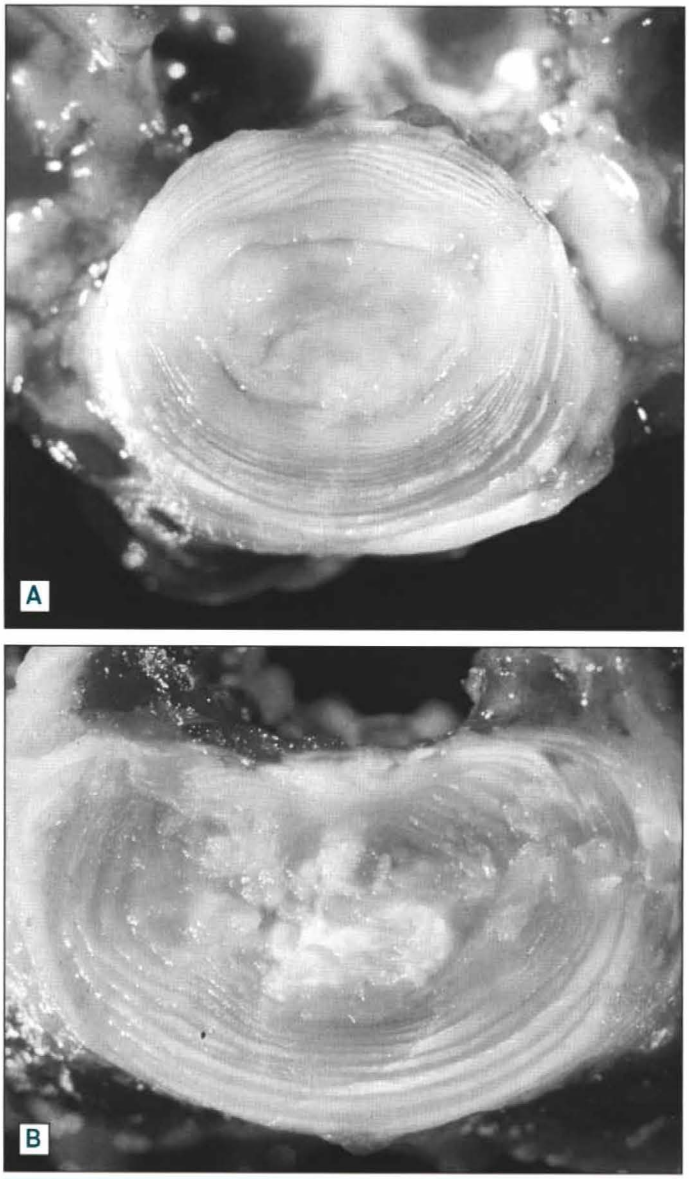

Figure 1.150 Intervertebral disk degeneration. **A.** Dry, gray/white nucleus pulposus (compare with Fig. 1.127) **B.** Chalky white foci of mineralization in the nucleus pulposus of a chondrodystrophic dog. Inner layers of annulus fibrosus are also degenerate.

the entire disk, leading to adaptive, and eventually degenerative, changes in the nucleus pulposus. Presumably, this same mechanism of intervertebral disk degeneration can occur in chondrodystrophic breeds, but the changes would be difficult to differentiate from the more severe, and more common, lesions outlined above.

Not surprisingly, *significant differences exist between chondrodystrophic and nonchondrodystrophic breeds of dog in the biochemical composition of their intervertebral disks.* At birth, the nucleus pulposus of chondrodystrophic disks contains up to 12 times more collagen than proteoglycan. The collagen composition increases rapidly with maturity, and by 11 months of age averages 25%. In nonchondrodystrophic breeds the collagen content of intervertebral disks remains below 5% for most of the animal's life. At all ages, the proteoglycan content of the intervertebral disk in chondrodystrophic breeds is significantly less than that of nonchondrodystrophic breeds.

The nucleus pulposus of *equine intervertebral disks* is more fibrous than that of dogs and its demarcation from the annulus fibrosus is less distinct. Although the nucleus pulposus of horses becomes less cellular with age, no chondroid or fibrous metaplasia occurs. In *cats*, macroscopic signs of intervertebral disk degeneration are not apparent until the animal is almost senile. Degenerative changes similar to those occurring in nonchondrodystrophic dogs are described in *adult sows and boars*, but dorsal herniation of the nucleus pulposus into the spinal canal has not been reported in this species. *Although disk protrusions are reported occasionally in cats and horses, discussion in the following section will concentrate on the syndrome in dogs*, for which there is a considerable volume of information.

Herniation of intervertebral disks

Because of their altered biomechanical properties, and their inability to withstand the normal range of forces associated with motion, *degenerate intervertebral disks are predisposed to complete or partial herniation or protrusion of nucleus pulposus material through the annulus fibrosus.* Many herniations are asymptomatic, but damage to adjacent structures, such as the spinal cord or peripheral nerve roots, is common and will be reflected by the clinical signs. Because of the eccentric location of the nucleus pulposus within the annulus fibrosus, most herniations occur through the narrower dorsal or dorsolateral regions of the annulus. In fact, *dorsal herniation of disk material into the spinal canal is considered the most common cause of paresis or paralysis in dogs.* Ventral herniation also occurs and may predispose to spondylosis (see below) and, on rare occasions, *nuclear material may herniate through the cranial or caudal cartilaginous end plate into a vertebral body, forming a so-called "Schmorl's node."*

Two types of dorsal herniation (types I and II) were recognized in classical descriptions of the disease in dogs by Hansen. **Type I herniations** *are characterized by a massive extrusion of degenerate nuclear material through the annulus fibrosus and dorsal longitudinal ligament into the spinal canal* (Fig. 1.151A). The sudden compression of the spinal cord, and/or peripheral nerve roots, typically causes *acute pain, paresis, or paralysis*, depending on the volume of extruded material and its location. Extradural hemorrhage may accompany laceration of longitudinal venous sinuses in the spinal canal. In some cases, severe damage to the spinal cord, or its vascular supply, results in *extensive hemorrhagic myelomalacia and ascending syndrome.* More commonly, the myelomalacia remains localized to a few cord segments. *The irritant nuclear material induces an inflammatory reaction* within the spinal canal and may become adhered to the dura.

Type II herniations generally develop slowly and are characterized by *partial herniation of the nucleus pulposus through ruptured annular fibers*, eventually resulting in bulging of outer lamellae and the intact dorsal longitudinal ligament into the spinal canal (Fig. 1.151B). Damage to the cord or peripheral nerve roots is much less than in type I herniations and clinical signs are generally mild.

Type I herniations of intervertebral disks are largely confined to chondrodystrophic dogs, particularly Dachshunds, and generally occur between 3 and 7 years of age. *Type II herniations are usually seen in nonchondrodystrophic dogs* between 6 and 8 years of age but can occur in any breed, as well as in humans, cats, and occasionally other species. Type I herniations are seldom reported in nonchondrodystrophic dogs.

Disk protrusions occur most frequently at sites of greatest vertebral mobility. In dogs, 70% of clinical cases of intervertebral disk disease are the

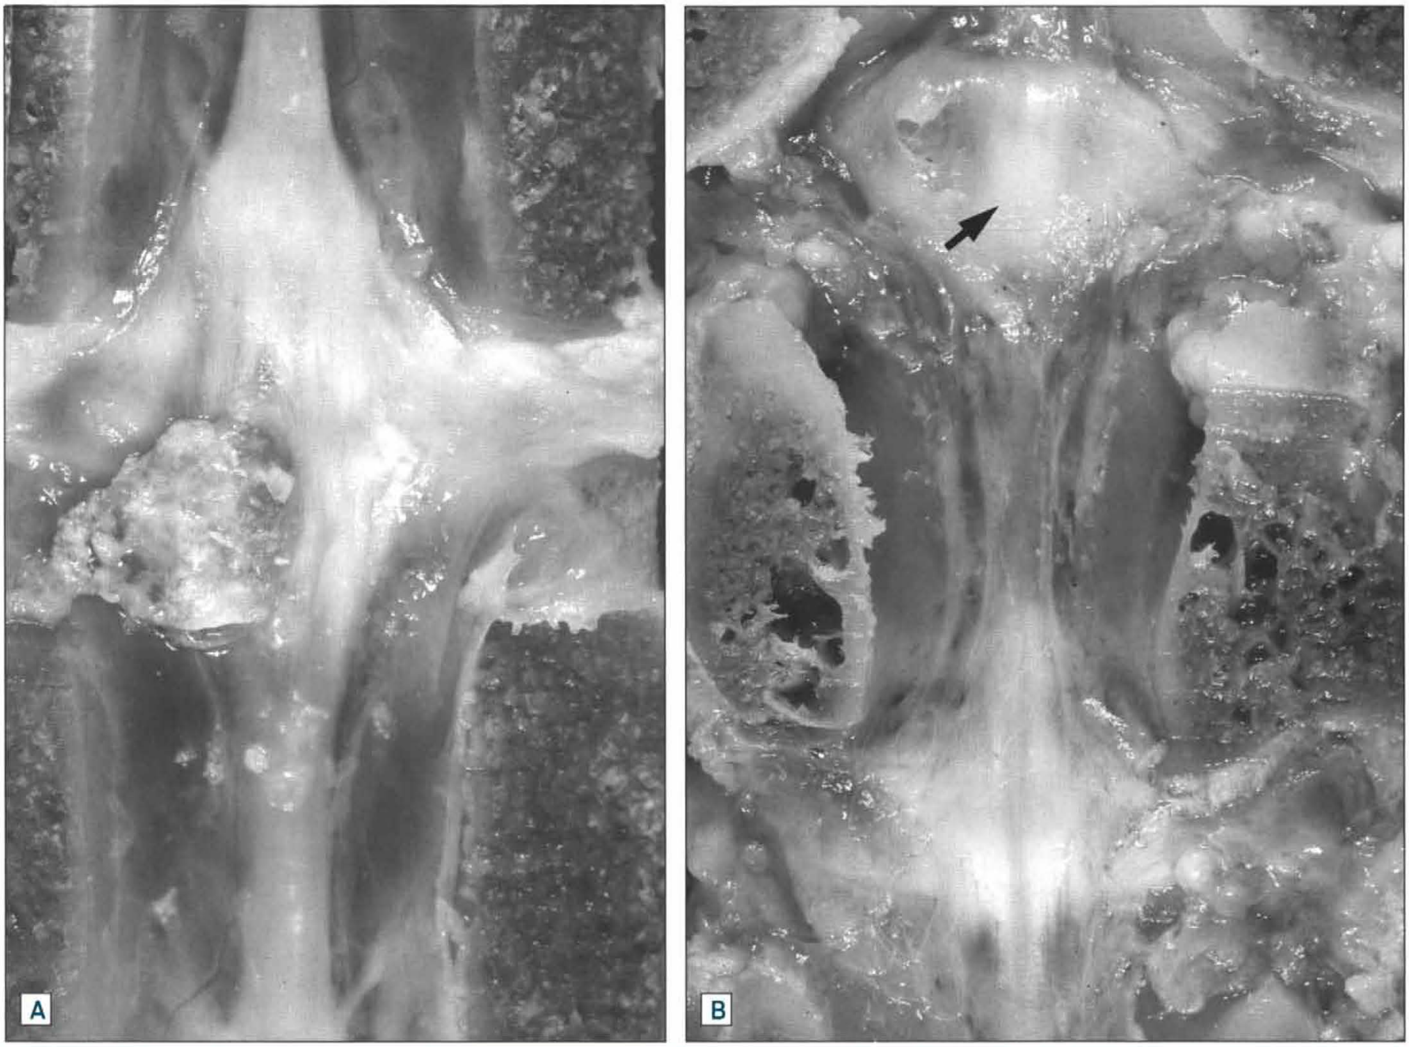

Figure 1.151 Degeneration and herniation of canine intervertebral disks. **A.** Herniation of a crumbly mass of degenerate disk material into the spinal canal through a tear in the dorsal longitudinal ligament (type I herniation). The adjacent disk is normal. (Courtesy of RA Fairley.)

result of herniations between the 12th thoracic and 2nd lumbar vertebrae. Approximately 15% of cases occur in the cervical region. Neurological signs associated with cervical disk protrusions are usually less severe than those involving the thoracolumbar region as the cervical cord occupies comparatively less space in the spinal canal, allowing more room for displacement before compressive damage occurs.

Herniations of intervertebral disks are *rare in horses* but occasionally are reported in the *cervical region*. Furthermore, in one study of cervical intervertebral disks in 17 clinically normal horses, partial extrusion of nuclear material through the annulus fibrosus, similar to type II lesions in dogs, was detected histologically in five horses. No intervertebral disk herniations have been reported in the thoracolumbar region of horses, probably because of the relative inflexibility of the equine spine in comparison to dogs and humans, and the strong longitudinal ligaments supporting the spine in this species. The mechanism of the cervical herniations in horses is not clear, but traumatic damage to the disk or adjacent vertebrae is a likely possibility, at least in some cases.

Ischemic myelopathy caused by **fibrocartilaginous embolism** *of spinal blood vessels is recognized as a possible sequel to degenerative disk disease in dogs.* Clinical signs relate to acute, severe, spinal cord damage similar to that associated with type I herniations of intervertebral disks, but the syndrome is *generally associated with type II herniations and is most common in nonchondrodystrophic dogs of large and giant breeds.* The spinal lesions may involve several vertebral segments and appear grossly as areas of swelling, malacia, and hemorrhage. Microscopically, fibrocartilaginous material, similar to that found in the degenerate nucleus pulposus, can usually be detected in the lumen of venules or arterioles (sometimes both) in areas of malacia. The mechanism by which embolic nuclear material enters the spinal vasculature is not clear. Venous emboli are probably caused by herniation of nuclear material directly into the overlying venous sinus, but arterial emboli are more difficult to explain. One suggestion is that they pass through arteriovenous communications from the venous circulation. Alternatively, they may directly penetrate arterioles in the degenerate annulus fibrosus and be extruded up to the radicular artery, from where they could gain access to the spinal cord. The possibility that such emboli develop following prolapse of the nucleus pulposus into the marrow cavity of an adjacent vertebral body has also been suggested, and is supported by experimental evidence. Demonstration of

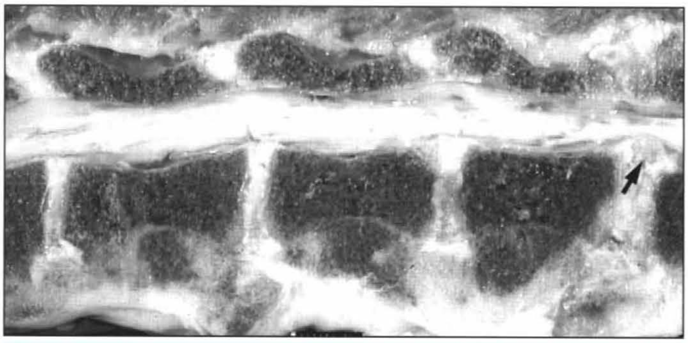

Figure 1.152 Ankylosing spondylosis, dog. Adjacent vertebral bodies united by thick, bony bridges along their ventral aspect. Also notice the type II disk herniation (arrow). (Courtesy of R. A. Fairley.)

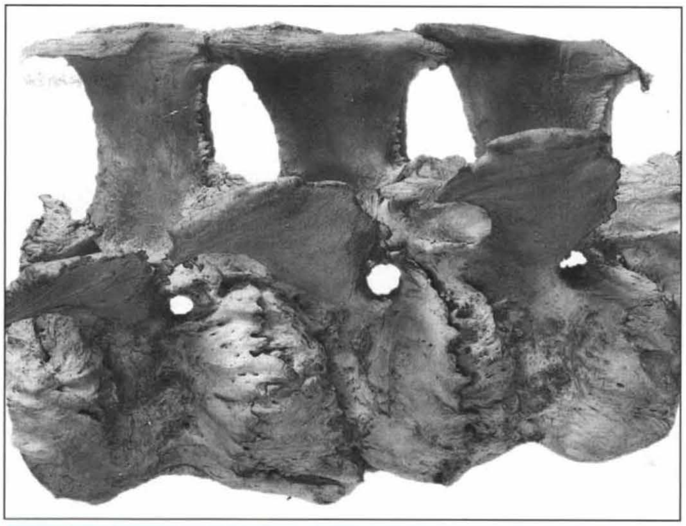

Figure 1.153 Ankylosing spondylosis, bull. Fusion of adjacent vertebral bodies by new bone deposited on ventral and ventrolateral surfaces.

Schmorl's nodes in vertebral bodies in the vicinity of spinal lesions would add further support to this hypothesis.

Fibrocartilaginous embolism has also been reported occasionally in pigs, cats, horses, and sheep. Of these species, pigs appear to be affected most frequently. The syndrome has occurred in weaner pigs as young as 45 days of age and, on one property, occurred in up to 25 of 1800 finishing pigs that had been sorted for slaughter at a weight of 126 kg. No degenerative changes in intervertebral disks, or other apparent predisposing factors, have been recognized in affected pigs. It is suggested that a *combination of heavy muscling and abrupt activity or excitement* may create increased pressure within intervertebral disks of young pigs and predispose to herniation of nuclear material into adjacent vertebrae or blood vessels. However, detailed dissection of disks and vertebrae in the vicinity of spinal lesions does not appear to have been performed.

Spondylosis

Spondylosis (spondylosis deformans, ankylosing spondylosis) is a common degenerative disease of the vertebral column characterized by the formation of osteophytes at the ventral and lateral margins of vertebral bodies adjacent to intervertebral spaces. The osteophytes may appear as spurs growing towards the adjacent vertebral body or as complete bony bridges with fusion of vertebrae (Fig. 1.152). Osteophytes also may be found dorsolaterally, projecting into the vertebral canal, but these are small and uncommon. In some cases, spondylosis is accompanied by degeneration of the synovial joints of the articular facets, and the reactive osteophytes may produce concurrent ankylosis of these articulations.

The *pathogenesis* of spondylosis is believed to involve an *initial degenerative change in the ventral annulus fibrosus*, probably secondary to trauma. Separation or tearing of the collagenous attachment of the annulus fibrosus from the adjacent vertebral body predisposes to mild ventral displacement of the annulus fibrosus and stretching of the ventral longitudinal ligament. This induces formation of bony outgrowths or spurs at the ventral margin of the intervertebral disk. As the disease progresses, further displacement of the annulus fibrosus and stretching of the ventral longitudinal ligament leads to more extensive osteophyte formation and eventually to bony bridging of the intervertebral space.

Spondylosis occurs most frequently in bulls, pigs, and dogs, and is seen less often in other domestic animal species. It is important in bulls kept in artificial breeding centers where it is presumably related to repeated traumatic damage to intervertebral disks during semen collection; *lesions are found in almost any bull past middle age.* Osteophytes develop mainly on the caudal end of thoracic vertebrae and the cranial end of lumbar vertebrae, and their incidence and size tends to decrease in either direction from the thoracolumbar junction. The greatest number and size of osteophytes is therefore in the area of greatest spinal curvature where maximum pressure on the disks during the thrust of service would be expected. The sequence of osteophyte development begins with severe degeneration of the annulus fibrosus, which may be present in bulls as young as 2 years of age. The osteophytes develop first in the outer annulus fibrosus and at its insertion to the rim of the vertebra. Growth is also in part by periosteal apposition and osseous metaplasia of ligaments. The trabecular bone of the osteophytes becomes continuous with that of the vertebral body and eventually is densely sclerotic. A thick layer of bone may be deposited along the ventral and ventrolateral aspects of the vertebral bodies (Fig. 1.153). In late stages, the heads of many ribs and the articular processes of the vertebrae bear large irregular osteophytes, which frequently cause ankylosis of the corresponding joint.

Although spondylosis is a *common incidental finding in breeding bulls, the disease is sometimes associated with mild or severe clinical signs.* Affected bulls may show caudal weakness and ataxia, or even paralysis, after dismounting from service. They may continue to be mildly ataxic or recover, only to be affected again later. The onset of signs is usually associated with fracture of the vertebral bodies and of the ankylosing new bone, which is dense, but tends to be brittle. The line of fracture tends to follow a large penetrating vessel to the intervertebral disk, which is frequently separated, and then to diverge across the dorsal corner of one or other vertebra. There is little displacement of the fractured ends in most cases, which accounts for the incomplete spinal syndrome. Trauma to the spinal cord is usually mild and paralysis is usually secondary to either hemorrhage or repeated trauma.

In *dogs*, the incidence of spondylosis increases with age after about the fifth year, and *vertebral osteophytes are a common incidental* *finding during radiography or at necropsy.* As in bulls, the primary morphologic change in dogs and cats with spondylosis is in the *annulus fibrosus*. In dogs, most lesions occur in the region of the first and second lumbar vertebrae, an area of relatively high mobility. The lumbosacral articulation is also often involved. The link between spondylosis and clinical signs in dogs is questionable, but it seems likely that severe lesions are responsible for spinal stiffness and pain, and reduced enthusiasm for physical activity.

Ankylosing spondylosis is a relatively common incidental finding in adult sows and boars. Although no specific predisposing factors have been identified, degenerate intervertebral disks or narrow disk spaces are often associated with the lesions. The osteophytes most commonly involve *lumbar vertebrae*, especially those in the lumbosacral region. Ankylosis, if present, may be confined to the ventral aspect of the vertebral bodies, but in some cases there is extensive new-bone formation in the vertebral arches, thus fusing the articular processes and encroaching on the spinal canal.

Spondylosis in *horses* is comparable to that in other species, but the evolution of the osteophytes has not been studied in detail. Vertebral ankylosis in *cats* with chronic vitamin A toxicity is discussed elsewhere.

INFLAMMATORY DISEASES OF JOINTS

Inflammatory diseases of joints are generally referred to as either **arthritis** or **synovitis**. Although these terms are sometimes used interchangeably, they have slightly different meanings. *Synovitis refers to inflammation of a synovial membrane, whereas arthritis implies inflammation of other joint components in addition to the synovial membrane.* Inflammation of *tendon sheaths* often accompanies inflammation of an adjacent synovial joint and is referred to as **tenosynovitis** (synonyms: tendosynovitis or tendovaginitis). Secondary inflammatory changes are a feature of many chronic degenerative joint diseases, hence the commonly used term *osteoarthritis*, but in this section discussion will be confined to joint diseases that are primarily inflammatory in origin.

Arthritis may be either *infectious or noninfectious*, depending on the etiology. *Infectious arthritis occurs most frequently in farmed livestock and horses*, especially in young animals where it is a common sequel to neonatal bacteremia. *Most cases of noninfectious arthritis occur in dogs or cats and are immune-mediated.* Further classification is based on the duration of the lesion, the nature of the exudate, and the host response.

Fibrinous arthritis

This is typical of many *acute inflammatory diseases* of synovial joints, particularly those caused by *bacterial infections*. The presence of fibrin within synovial fluid indicates increased permeability of blood vessels in the synovial membrane, as fibrinogen and other large molecules are normally excluded. *Fibrin clots* may be floating free within the joint fluid, attached to the synovial membrane or lodged within recesses of the joint (Fig. 1.154A). In some cases, *sheets of yellow fibrin* partially or completely cover the synovial membrane, which is often edematous and hyperemic or may be studded with petechiae (Figs 1.154B, 1.155). *Synovial villi*, which are barely noticeable in normal joints, may become prominent macroscopically due to the edema and hyperemia. The synovial fluid is increased in volume and is usually slightly *turbid and mucinous*. When the inflammatory reaction is severe, there may be *gross edema of the periarticular tissues*. At this early stage, microscopic changes in the synovial membrane consist of edema and vascular engorgement, with few inflammatory cells. *Serous fluid or serofibrinous exudate* often infiltrates the fibrous layer of the articular capsule and the adjacent periarticular tissue.

In arthritis of longer duration, edema of synovial tissues is less apparent but the joint capsule and synovial membrane are thickened due *to proliferation of stromal cells and synoviocytes*, the latter often becoming several layers thick. *Sheets of fibrin containing variable numbers of neutrophils and fibroblasts may be attached to the surface* (Fig. 1.156). Villi continue to enlarge as a result of the cellular proliferation and may become extensively branched, with increasing numbers of lymphocytes and plasma cells, but few neutrophils (Fig. 1.157). Extravasated neutrophils pass quickly into the synovial fluid but seldom in sufficient numbers to give the fluid a purulent character. *Hypertrophy of villi* is greatest in the transition zone, and the proliferating fibrous stroma is joined by proliferating perichondrium to produce a fringe of granulation tissue, which spreads across the articular cartilage as a pannus and causes degeneration of the underlying cartilage.

Early resolution of the infection in animals with fibrinous arthritis is common, especially in smaller joints. However, the extensive deposits of fibrin in severe cases cannot be effectively removed by fibrinolytic mechanisms. Instead, the fibrin, which is deposited on the synovial membrane and within the layers of the articular capsule and periarticular tissue, is progressively invaded by fibrous tissue, leading to enlargement and restricted movement of affected joints.

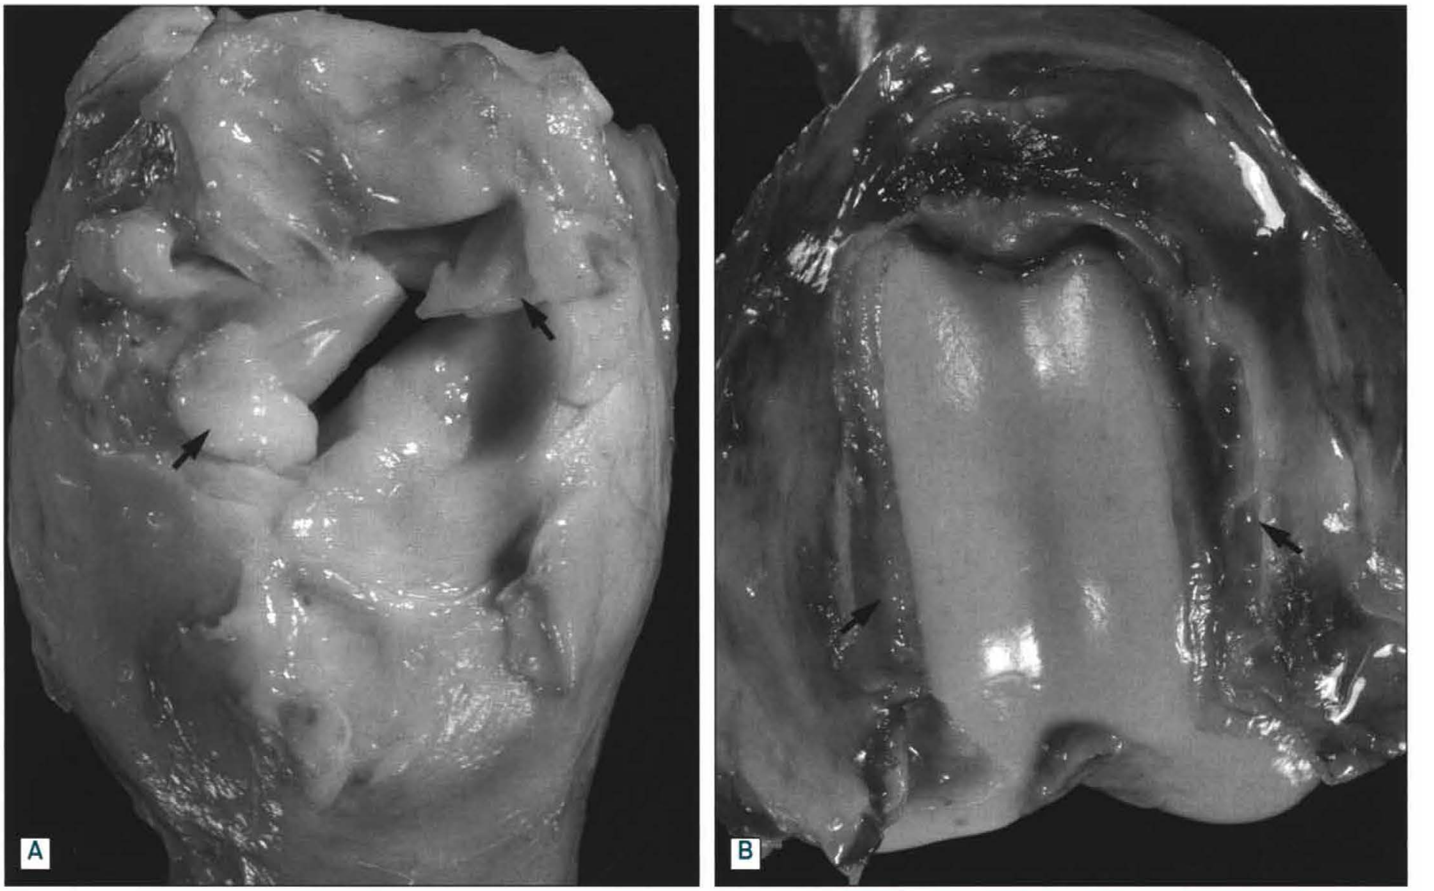

Figure 1.154 Fibrinous polyarthritis, calf. **A.** Large fibrin clots in the carpal joint (arrows). **B.** Stifle joint from the same calf showing an edematous, hyperemic synovial membrane covered by fibrin (arrows). The calf also had suppurative osteomyelitis (see Fig. 1.89A).

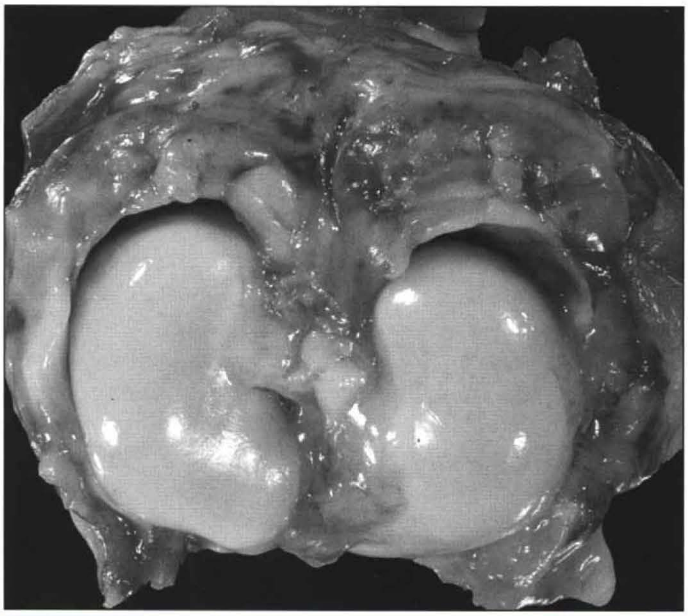

Figure 1.155 Fibrinous arthritis, pig. *Staphylococcus aureus* infection. The synovial membrane surrounding the femoral condyles is markedly thickened due to edema and an adherent layer of fibrin. Many petechiae are present in some areas.

The synovial lining is repaired by proliferation of synoviocytes. *Articular cartilage generally remains intact* in fibrinous arthritis, except in areas where it is covered by pannus. Pannus formation in joints with restricted movement may result in adhesions between apposed articular surfaces, leading to ankylosis.

Low-grade inflammation, with intense lymphocytosis, may persist in the synovial membrane, even in cases where the infection has apparently resolved. This may be due either to the persistence of an infectious agent that cannot be cultured or to ineffective removal by macrophages of the peptidoglycan components of microbial cell walls. For example, the cell wall of group A streptococci is relatively resistant to degradation by mammalian lysosomal enzymes, and is capable of provoking *persistent inflammation* in synovial tissues. Cell wall peptidoglycans from various other organisms, including *Erysipelothrix rhusiopathiae* also have this ability. All bacterial cell walls contain peptidoglycans, but there is considerable structural heterogeneity between bacterial species, and the types of side chain on the molecules probably determine their arthritogenic potential.

Purulent (suppurative) arthritis

This is characterized by the presence of *significant numbers of neutrophils in the synovial fluid, synovial membrane, and sometimes in adjacent structures*. When caused by bacterial infection, the neutrophils are usually abundant and may show *degenerative changes* in cytologic preparations of joint fluid. This is often referred to as **septic**

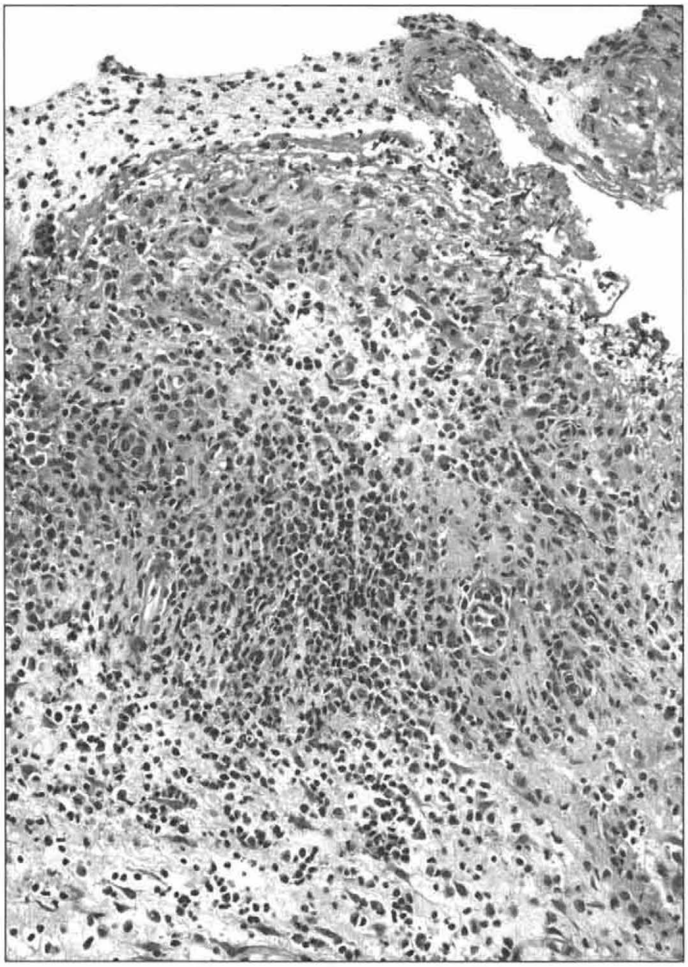

Figure 1.156 Subacute fibrinous arthritis, pig. *Streptococcus suis* type 1 infection. Edema, early proliferation of stromal cells and mixed cellular infiltration of synovial membrane. Fibrinous exudate containing moderate numbers of neutrophils is attached to the surface.

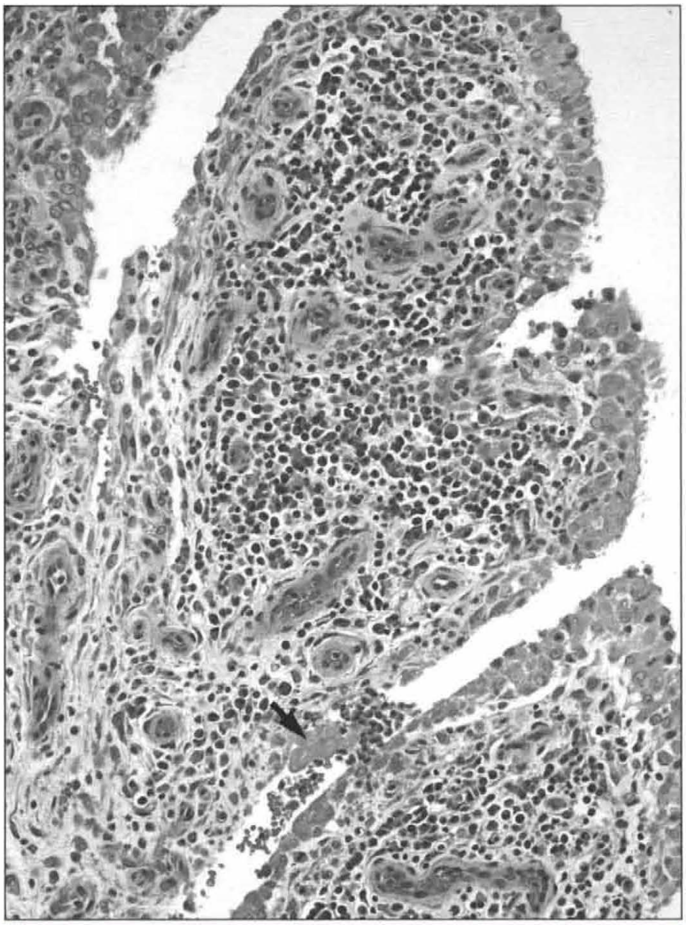

Figure 1.157 Chronic fibrinous arthritis, pig. *Streptococcus suis* type 2 infection. Hypertrophic villi infiltrated with mononuclear cells and lined by hypertrophic synoviocytes. A small fibrin tag and a cluster of neutrophils are trapped between two villi (arrow).

arthritis. Neutrophilic inflammation is a feature of arthritis caused by *Mycoplasma* spp., *Borrelia burgdorferi*, and certain viruses, but in these infections the neutrophils in synovial fluid are *nondegenerate*. Noninfectious, *immune-mediated arthritis* is also characterized by the presence of nondegenerate neutrophils in synovial fluid and differentiation from infectious arthritis is often difficult. *Bacteria are seldom observed in synovial fluid in animals with septic arthritis and false negatives on bacterial culture are common.*

Septic arthritis is often monoarticular and is *potentially a much more destructive process than fibrinous arthritis.* The synovial fluid is initially thin and cloudy but may resemble frank pus after a few days. *Destruction of articular cartilage* is much more likely to occur in septic arthritis than in fibrinous arthritis. *Lysosomal enzymes*, particularly collagenase, released from degenerating neutrophils probably play an important role in the cartilage destruction. Cytokines of macrophage origin, such as interleukin-1 and tumor necrosis factor-α, have also been shown to induce the resorption of cartilage both in vitro and in vivo and are most likely involved in chondrocyte-mediated cartilage degradation by stimulating the synthesis of metalloproteinases and plasminogen activators.

Complete resolution of septic arthritis is possible if the infection is eliminated spontaneously or by antibiotic therapy before erosion of cartilage occurs, but if the inflammatory process persists, the joint and adjacent structures will be severely altered. Cartilage degeneration occurs mainly at sites of weight bearing or at the articular margins, the latter in association with pannus formation. *Erosion of the degenerate cartilage may allow infection to enter the subchondral bone, resulting in purulent osteomyelitis* with extensive underrunning and separation of the articular cartilage. In such cases, it may be difficult to determine whether the arthritis preceded the osteomyelitis or vice versa, or whether the infectious agent gained access to both sites independently. Granulation tissue originating in the subchondral bone may grow out over the degenerate articular surface and predispose to ankylosis.

The suppurative process may extend to *involve adjacent tendon sheaths* and outwards from the synovial membrane of the articular capsule to *produce cellulitis in periarticular tissues.* The articular region is then greatly enlarged and the proliferation of fibrous tissue in response to inflammation, or during the healing process, results in permanent joint stiffness. In some cases, localization of the cellulitis into a periarticular abscess may be followed by *fistulation to the skin.* Fistulation to the skin surface may also result directly from empyema of the joint. Adhesions between tendons and tendon sheaths frequently occur in cases where tenosynovitis has developed in association with septic arthritis.

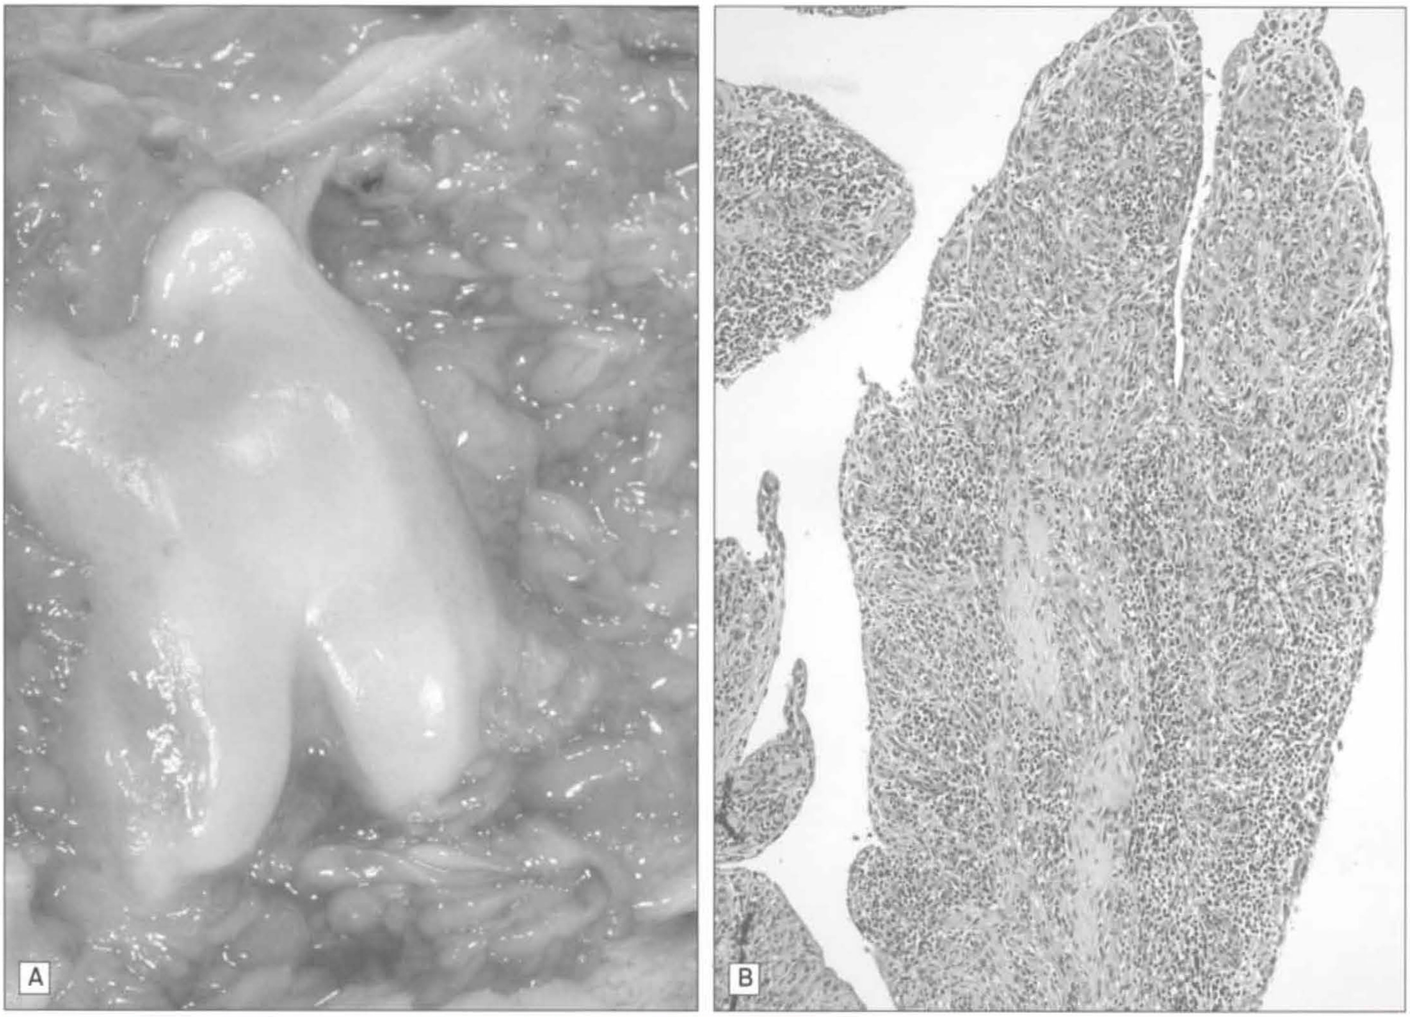

Figure 1.158 Proliferative arthritis, pig. **A.** Marked hypertrophy and hyperplasia of synovial villi in the stifle joint. (Courtesy of RA Fairley.) **B.** Hypertrophic villus in a pig with chronic *Erysipelothrix rhusiopathiae* infection. Note the stromal cell proliferation, mononuclear infiltration, and prominent synoviocyte layer.

Fibrinopurulent arthritis

Although it is convenient to classify inflammatory diseases of joints as fibrinous or purulent on the nature of the exudate, in reality, *many diseases would be better classified as* **fibrinopurulent arthritis**, *because the exudate consists of both fibrin and neutrophils.* In the chronic stages of many infectious and noninfectious forms of arthritis, lymphocytes and/or plasma cells are the major cell types infiltrating the synovial membrane (see Figs 1.148; 1.157). In such cases, **lymphocytic/plasmacytic synovitis** is a more appropriate morphological diagnosis. The term **proliferative arthritis** is often used to describe *chronic inflammatory diseases of joints where hypertrophy and hyperplasia of synovial villi is a prominent feature* (Fig. 1.158A, B).

An accurate etiologic diagnosis in animals with inflammatory diseases of joints may be crucial to a successful clinical outcome. In particular, failure to differentiate infectious and noninfectious causes of purulent arthritis can lead to inappropriate treatment and significantly alter the prognosis. *It is also important for septic arthritis to be recognized early and treated with an appropriate antibiotic in order to prevent degeneration of articular cartilage.* In addition to clinical history, analysis of synovial fluid often provides useful information but seldom allows a definitive diagnosis. As mentioned elsewhere in this section, many infectious and noninfectious forms of arthritis are characterized by increased numbers of neutrophils in synovial fluid. The neutrophils may show degenerative changes in bacterial infections but this is often difficult to appreciate in synovial fluid where the high concentration of hyaluronan prevents the cells from flattening out on the slide. Furthermore, not all bacteria induce such changes in neutrophils. Culture of bacteria or other agents from an inflamed joint allows a definitive diagnosis but false negatives are common. Culture of synovial membrane has been considered more sensitive but, in one study, *incubation of synovial fluid in a blood culture medium prior to culture yielded better results than either direct culture of the synovial fluid or culture of synovial membrane biopsies.* Microscopic examination of *synovial membrane biopsies* provides information on the nature of the inflammatory response and may be useful in differentiating chronic inflammatory and degenerative diseases of joints. Further information on diagnostic methods and details of laboratory results in specific diseases are discussed below.

Infectious arthritis

A variety of infectious agents, including *bacteria, viruses, and fungi*, are capable of infecting diarthrodial joints in humans and domestic animals. *In many, if not most situations, the arthritis is but one manifestation of a systemic infection*, with inflammatory lesions involving several tissues. In other cases, the infection may appear to be confined to one or more joints, suggesting either an affinity for synovial membranes or persistence of the infection in joints after being cleared from other sites. *Certain infectious agents may initiate a sterile synovitis in response to primary inflammatory lesions at sites distant from joints*. The mechanism of this form of arthritis is not clear, but it most likely involves an *immune-mediated reaction to nonviable bacterial components*, such as the bacterial wall antigen peptidoglycan, deposited in the synovial membrane, rather than direct infection of the joint by the agent. These forms of arthritis are discussed later under the heading Noninfectious (immune-mediated) arthritis.

A list of microorganisms that are commonly associated with infectious arthritis in domestic animals is presented in Table 1.4. Many agents other than those included in the list are capable of causing arthritis, but usually in isolated cases. Cats are not included in the list as infectious arthritis in this species is rare.

Some generalizations may be made about the prevalence of these infections relative to age. In *sheep*, with the exception of infection by *Mycoplasma* spp., infectious arthritis is primarily a disease of lambs. In *cattle*, streptococcal and coliform polyarthritis are neonatal, whereas infections due to *A. pyogenes* and *Salmonella* spp. may occur at any age. Streptococcal polyarthritis in *swine* is often a neonatal disease but the other infections are usually observed in weaned pigs. In *horses*, the organisms listed, other than *Salmonella* spp., generally cause intrauterine or neonatal infections.

Table 1.4 Common causes of infectious arthritis in domestic animals

Sheep
- *Chlamydophila pecorum*
- *Erysipelothrix rhusiopathiae*
- *Escherichia coli*
- *Histophilus somni*
- *Mycoplasma* spp.
- *Staphylococcus* spp.
- *Streptococcus* spp. (including types 1 & 2)

Goats
- *Mycoplasma* spp.
- Retrovirus

Swine
- *Actinobacillus suis*
- *Arcanobacterium pyogenes*
- *Brucella suis*
- *Erysipelothrix rhusiopathiae*
- *Escherichia coli*
- *Haemophilus parasuis*
- *Mycoplasma* spp.
- *Salmonella* spp.
- *Staphylococcus aureus*
- *Staphylococcus hyicus* ssp. *hyicus*
- *Streptococcus* spp. (including groups C & L)
- *Streptococcus suis* (types 1 & 2)

Cattle
- *Arcanobacterium pyogenes*
- *Escherichia coli*
- *Histophilus somni*
- *Mycoplasma bovis*
- *Salmonella* spp.
- *Streptococcus* spp.

Horses
- *Actinobacillus equuli*
- *Escherichia coli*
- *Klebsiella* spp.
- *Rhodococcus equi*
- *Salmonella* spp.
- *Streptococcus* (Group C)

Dogs
- *Blastomyces dermatitidis*
- *Borrelia burgdorferi*
- *Ehrlichia ewingii*
- *Escherichia coli*
- *Staphylococcus* spp.
- *Streptococcus* spp.

Bacteria

Bacterial arthritis is common in horses and food animals, usually as a sequel to neonatal bacteremia following omphalophlebitis ("navel ill"), or infections of the gastrointestinal tract or lungs. In many cases, the origin of the infection is not apparent either clinically or at necropsy, but inadequate transfer of colostral immunoglobulins is a common predisposing factor. The richly vascular synovial membrane appears to be a favored site for localization of bloodborne bacteria. Experimental studies have shown that viable bacteria injected intravenously lodge in the synovial membrane and gain access to synovial fluid more readily than to spinal fluid, aqueous humor, and urine.

Hematogenous bacterial infections in neonatal animals typically cause *polyarthritis*. Infected joints are generally hot, painful, and swollen due to the hyperemia and edema of the synovial membrane and joint capsule, and the increased quantity of synovial fluid. Although the infection may resolve in some joints, it often persists in others, particularly the large joints of the limbs, causing severe septic arthritis with destruction of articular cartilage. *Many, if not most young animals with septic arthritis of hematogenous origin also have osteomyelitis in the epiphyses or metaphyses of adjacent bones* (Figs 1.89A, 1.154A, B). This may be due to concurrent localization of the organism in the bone and synovial membrane, or may reflect the close vascular relationship between the epiphyseal bone and synovial membrane in young animals, with spread of infection from one site to the other. Foci of osteomyelitis originating at sites of endochondral ossification in the epiphysis, immediately beneath the articular cartilage, may underrun and penetrate the cartilage, spreading the infection directly into the synovial fluid. In joints where the capsule attaches distal to the physis, inflammatory foci in the metaphysis may contaminate the synovial fluid by penetrating the cortex near the physeal margin. This region is relatively porous in young animals because of the intense structural modeling that occurs in the metaphyseal cortex during rapid growth. The prevalence of concurrent bone involvement should always be considered in animals with bacterial arthritis as even if the arthritis can be successfully treated, the animal may eventually succumb to the effects of chronic osteomyelitis.

The reason why certain organisms are more likely to localize in the synovial membrane than others during bacteremia is not clear, but experimental evidence suggests that it is not purely due to chance. Studies in mice have indicated that *adherence* of *Staphylococcus aureus* to collagen is likely to be involved in the pathogenesis of septic arthritis and osteomyelitis. Other organisms causing arthritis have also been shown to possess *collagen-binding components*.

Spread of infection to joints from adjacent soft tissues is uncommon as the dense, fibrous layer of the joint capsule provides an effective barrier, but it may occur in necrotizing disorders such as necrobacillosis and footrot in cattle.

Direct implantation of bacteria into a synovial joint may occur as a sequel to a *penetrating wound* from the skin surface. This is the most common cause of bacterial arthritis in *dogs and cats*, where the disease occurs more often in adolescent and adult animals than in neonates. The arthritis is *monoarticular* and a mixed population of opportunistic bacteria is likely to be involved, often resulting in a highly destructive inflammatory response. *Arthroscopic surgery* and collection of synovial fluid by *fine-needle aspiration* may also introduce bacteria to a joint.

Although many different bacteria have been associated with arthritis in domestic animals, some specific types of bacterial arthritis are sufficiently important to warrant discussion in more detail.

Erysipelas

***Erysipelothrix rhusiopathiae**, the cause of porcine erysipelas and erysipeloid in man, is a gram-positive bacillus with a wide geographic distribution and host range.* It causes outbreaks of disease in *pigs, lambs, and birds*, and sporadic disease in the other domestic species. The organism is widespread in nature and is capable of survival, and perhaps growth, in decaying material of animal origin. It may be present in the soil of pig pens and in pit slurry, and survives for 2–3 weeks on pasture spread with slurry. It is resistant to many disinfectants and is capable of infecting many species, some of them in epidemic proportions. In spite of these epidemiological features, *pigs are probably the principal source of infection for other pigs. Erysipelothrix rhusiopathiae* can persist for many months in the lesions of diseased pigs, and it is often carried in the tonsils, intestine, bone marrow, and gallbladder of healthy swine.

Porcine erysipelas occurs in pigs of all ages, but the most susceptible are those from 2 months to 1 year of age, and pregnant sows. The latter may abort or give birth to stillborn young, from which the organism can be cultured. The disease can be produced by ingestion of the organism, contamination of cutaneous wounds, or as a result of bites of infected flies. The manifestations of erysipelas in pigs vary from an *acute septicemic form*, which is usually fatal, to *mild and chronic forms* characterized by necrosis of the skin, endocarditis, and polyarthritis. *In epidemics, the septicemic form predominates, whereas in endemic areas the disease tends to be sporadic, with cases of septicemia, polyarthritis, or endocarditis occurring in varying proportions.*

The **acute disease** is a *febrile septicemia*, which usually develops within 24 h of exposure to virulent organisms and produces *disseminated intravascular coagulation*. Endothelial cells of capillaries and venules throughout the body swell, monocytes adhere to them, and by 2–3 days microthrombi are widespread. By 4 days, accumulation of fibrin within and around vessels, bacterial invasion of endothelium and diapedesis of erythrocytes are prominent. Perivascular fibrin incites connective tissue proliferation in sites such as synovial membranes. *Grossly*, there is *purple discoloration of the skin* due to congestion and, in some cases, thrombosis of dermal capillaries and venules. Lesions may not be specific in pigs that die at this stage. *Petechiae or ecchymoses* may be present on serous membranes, the *spleen is almost always swollen and red,* and there may be *congestion and infarction in the gastric mucosa*. The latter lesion occurs in many acute infections in pigs. Subsidence of the acute disease, or a milder initial course, often leads to swelling of joints, lameness, and characteristic erythematous lesions in the skin.

The *cutaneous lesions* of porcine erysipelas are *roughly rhomboidal* and slightly raised. They are readily visible in light-skinned pigs and palpable when not visible in dark-skinned pigs. The skin within the rhomboid may be uniformly *bright red or purple*, but in some lesions only the margins and center are discolored. The latter lesions may progress to complete discoloration, or may return to normal within a few days. The uniform, bright red lesions may also resolve, leaving only an area of scurfiness as a residue. The dark red or purple lesions undergo dry necrosis and may eventually peel off or, if forcibly detached, expose a raw base. Occasionally, the skin lesions coalesce over large areas and lead to extensive cutaneous necrosis. The *tip of the tail and ears* may also become dark, shrunken, and leathery due to *ischemic necrosis*. Microscopically, there is neutrophilic infiltration of the walls of small dermal arterioles, many of which contain *cellular thrombi*. Suppurative inflammation of sweat glands is also a consistent microscopic finding, but otherwise the reaction is most severe at the junction of dermis and subcutis. *Similar cutaneous infarcts occasionally occur in other septicemic bacterial diseases* and the lesions should not therefore be considered pathognomonic for erysipelas. Confirmation requires culture of the organism from the undersurface of skin lesions or from other tissues.

By the time the cutaneous lesions of porcine erysipelas develop, lesions also may be found in *visceral organs*. In addition to *splenic enlargement*, numerous *petechiae may be visible in the renal cortices* and there is sometimes intense interstitial hemorrhage in the medulla. The renal cortical petechiae arise in part from small venules, but mainly from glomeruli. The *characteristic glomerular lesion of erysipelas is focal fibrinoid necrosis of the tufts, with intracapsular hemorrhage*. Less specific changes that might also be present include diffuse glomerulitis, characterized by swelling or proliferation of the glomerular endothelium, and segmental sludging of erythrocytes in some glomerular tufts. The latter lesion probably precedes fibrinoid necrosis and intratubular hemorrhage. Occasionally, gram-positive bacterial colonies are found in the necrotic tufts or in intertubular capillaries, where they are associated with tiny, intense foci of neutrophils.

The articular lesions of acute erysipelas are typically those of *fibrinous polyarthritis* (see above). The volume of synovial fluid is increased and the synovial membrane is hyperemic. In some cases, the synovial arterioles show necrotizing inflammation and extensive plugging by cellular thrombi.

Lesions in other tissues are not specific. There is leukocytosis with many mononuclear cells in hepatic sinusoids. The *lungs show typical lesions of bacteremia*, with organisms sequestered in the pulmonary capillaries, but without the focal localization of embolic pneumonia. The alveolar capillaries are intensely hyperemic and contain numerous sequestered leukocytes. Later, the alveolar walls tend to thicken as a result of cellular infiltration, mononuclear cells predominating, and this is accompanied by alveolar flooding and increased alveolar macrophages. The *skeletal musculature often shows extensive degeneration*, although it may be too recent to be visible grossly. Whether the muscular degeneration is an example of the classic change described as Zenker's degeneration or is mainly due to peripheral arteriolitis is difficult to determine. Of the remaining tissues, the *brain and eyes* appear to harbor lesions most consistently. The organisms localize in the choroid and the ciliary process and provoke an intense neutrophilic inflammatory response. In the brain, there is cerebral leukocytosis and degeneration of blood vessels in the cerebral white matter. Embolic bacterial colonies, together with a tiny surrounding zone of neutrophils and a few eosinophils, may be found in small vessels of the brain and spinal cord. Such foci of inflammation are quite common and are not always associated with visible organisms. The neural lesions do not produce neurological signs.

Chronic erysipelas in swine is characterized by *vegetative valvular endocarditis and/or arthritis*. Localization of the organism in heart valves and joints occurs as a sequel to either acute, nonfatal septicemia or mild, perhaps inapparent, systemic disease. The *mitral valves* are most often involved and pigs that die of endocarditis have congestive heart failure and embolism. *Large infarcts in the spleen and kidneys* are particularly common. The valvular lesions may be very large, consisting of layers of fibrin with variable numbers of trapped inflammatory cells. During the active stage, masses of gram-positive bacteria can be found near the surfaces of the thrombi. In older lesions, the bacterial colonies are buried more deeply in the thrombi and usually cannot be cultured.

Arthritis is a common expression of chronic erysipelas in pigs and may be unassociated with earlier acute or subacute signs of infection. It can be reproduced experimentally by injections of the organism, and also occurs in vaccinated swine. *Although vaccination seems useful in preventing the acute syndrome and mortality, it appears to enhance susceptibility to polyarthritis.* The number of joints affected following experimental inoculation of susceptible pigs depends on the number of organisms used and the strain of organism. In pigs with acute arthritis, organisms may be isolated from grossly normal as well as inflamed joints, but isolation from affected joints may be difficult in the chronic disease. Persistence of the inflammation in such cases may be due to the presence in synovial tissues of bacterial antigens, rather than intact organisms. Antigens persist for up to 18 months in arthritic joints and specific antibodies found in synovial fluid may be produced by plasma cells in the synovial membrane. Culture of the sediment from centrifuged synovial fluid however, usually yields a few organisms, even in very chronic erysipelas.

The *lesions in chronic erysipelas arthritis* vary in severity. In mild cases, there is excess synovial fluid and villus hypertrophy, but the articular capsule may appear normal. In severe cases, there is extensive villus hyperplasia and hypertrophy over much of the synovial membrane (Fig. 1.158A), together with pannus formation and cartilage degeneration. The hypertrophic villi are hyperemic and infiltrated with mononuclear cells, including plasma cells (Fig. 1.158B). *Diskospondylitis* is also a feature of chronic erysipelas.

Acute and chronic arthritis, similar to that caused by *Erysipelothrix rhusiopathiae* infection, also occur in pigs in association with certain other bacterial and mycoplasmal infections and *in many cases, the etiology remains undetermined.* The development of molecular biological techniques capable of demonstrating the presence of small quantities of persistent antigen may improve our diagnostic success with such cases in the future.

Erysipelas in sheep is usually the result of *percutaneous infection*, entry being gained through the *umbilicus, docking and castration wounds, shear wounds, and cuts or abrasions acquired during dipping.* The lesion in sheep may be confined to the skin and subcutis at the point of entry, or there may be bacteremia with localization in joints. Rarely, death may occur from septicemia.

Fibrinopurulent polyarthritis, and osteomyelitis, is the usual form of erysipelas seen in young lambs after docking or castration, and sometimes following umbilical infections. The arthritis is subacute or chronic and the morbidity may be as high as 50%. Mortality is low, and is a consequence of severe lameness rather than a direct result of the infection. The main limb joints are involved. In the early stages, there is synovitis with an increased volume of turbid synovial fluid. Later, the fibrinous exudate may coagulate into firm pads. Articular cartilage is initially unaffected, but foci of osteomyelitis in the subchondral epiphyseal bone may lead to collapse of the overlying articular surface and formation of irregular pits or ulcers with a base of granulation tissue. In the chronic stages, the joints are stiffened and deformed by periarticular fibrosis and by periosteal and perichondral osteophytes.

Cutaneous infections following dipping are associated with contamination of nonbactericidal dips with *E. rhusiopathiae.* Lesions occur most often about the *fetlocks* but invasion may occur wherever the skin is injured and contaminated. Post-dipping infections, which mimic cutaneous erysipelas, are occasionally caused by both *Arcanobacterium pyogenes* and *Corynebacterium pseudotuberculosis.* Cutaneous erysipelas may also occur when sheep are confined in wet, contaminated pens.

Lameness is severe and out of proportion to the gross changes in affected feet. The disease is febrile in some animals and associated with rapid wasting, but recovery occurs in 2–3 weeks. The affected pasterns are hot and painful, and there is regional lymphadenitis. The coronary band may be swollen and the swelling, which is always slight, may extend to the metacarpal or metatarsal regions. The affected areas are progressively depilated. Incision reveals moderate erythema and slight edema of the subcutis.

Histologically, there is acute inflammation very similar to that seen in the cutaneous lesions of porcine erysipelas. There are superficial pustules in the epidermis. In the outer layers of the dermis, there is perivascular edema, accumulation of neutrophils and cellular thrombi within vessels. The reaction is more severe in the deeper layers of the dermis and is characterized by suppurative hydradenitis, necrotizing vasculitis, and vascular thrombosis. Similar changes occur in the *sensory laminae of the foot* and are responsible for the severe lameness. In the course of 2–3 weeks, the inflammatory reaction resolves completely, except for residual lesions in the larger blood vessels.

Streptococcal septicemia and polyarthritis

Streptococci cause a variety of infections in domestic animals, including *septicemia, meningitis, polyarthritis, bronchopneumonia, and endocarditis.* In **swine**, there are well-defined syndromes of streptococcal septicemia, with localization in synovial structures, meninges, and elsewhere, caused by ***Streptococcus suis***. This organism shares cell-wall antigens with streptococci of Lancefield's group D but is not genetically related to them. Over 30 serotypes have now been recognized but those most frequently associated with arthritis are types 1, 2, 7, and 14. *In general,* Streptococcus suis *serotype 1 infects suckling pigs and is not pathogenic for other species, whereas serotype 2 tends to cause disease in weaner and feeder pigs and also cause meningitis and septicemia in man.* Serotype 7 may also have zoonotic significance. Interestingly, some serotype 2 strains cause only nonfatal pneumonia in gnotobiotic pigs, even following dexamethasone treatment. Increased virulence may depend on certain high-molecular-weight, cell-wall proteins that are released by muramidase.

***Streptococcus suis* type 1** may cause disease in piglets from 2 to 10 weeks of age, but most cases occur in the *2–3-week age group.* The disease may occur in one or all pigs in a litter, and a number of litters may succumb over a period of weeks. The infection is initially *bacteremic or septicemic* and death may occur at this stage with little evidence of localization in visceral organs. The spleen is slightly enlarged and purple, petechiae may be present in the renal cortex, and the lungs are hyperemic with small pleural hemorrhages. There may be a slight excess of fluid in serous cavities. When the course of the disease is slightly longer, there are signs of *arthritis and meningitis*. All joints may be affected but the lesions are most obvious in the large limb joints. The synovial fluid is increased in volume, slightly mucinous, and turbid due to the presence of neutrophils. Occasional gram-positive cocci may be seen in smears. The meningitis is fibrinopurulent and affects mainly the basal meninges. Clumps of fibrin may be found floating free in lateral ventricles or attached to choroid plexuses. The cerebral aqueduct and/or foramina of Luschka may be occluded by exudate or by ependymal reaction, leading to internal hydrocephalus.

Streptococcus suis type 1 is most likely *carried in the nasopharynx of sows* and transferred to their offspring shortly after birth. The portal of entry is the palatine tonsil. Piglets infected experimentally may have bacteremia for 2–3 weeks, after which time, the developing immunity eliminates infection from the blood and internal organs. The organism is relatively harmless unless it becomes established in joints or meninges.

Disease caused by ***Streptococcus suis* type 2** may be clinically and pathologically similar, but often the range of lesions is greater. The organism is *carried in the palatine tonsils of pigs*, and *infection is probably by the respiratory route*. In infected herds, it is isolated from up to 80% of clinically normal pigs and is commonly found in nasal turbinates and pneumonic lungs, where it is probably a secondary invader. Limited outbreaks do occur but *sporadic, isolated disease is more common*. The incubation period varies from 1 to 14 days and the clinical course from 4 to 48 h. Affected pigs are usually about 10–14 weeks of age and the most significant lesion is *purulent meningitis*, which, along with *polyserositis*, is visible grossly in about 50% of pigs. The bacteria probably enter the cerebrospinal fluid within monocytes via the choroid plexuses. *Purulent arthritis* occurs in a few animals, usually those at the lower end of the age range. *Fibrinopurulent pericarditis, endocarditis, or hemorrhagic, necrotizing myocarditis* occur in some pigs. Endocarditis most often affects the mitral valve. The myocarditis grossly may resemble mulberry heart disease but *the histologic lesions of necrotizing vasculitis and diffuse inflammation associated with bacteria are distinctive*.

Occasionally, *Streptococcus suis* type 2 causes *septicemia in newborn piglets*. Pigs dying acutely may show few lesions other than marked congestion of lungs and meninges with perhaps a few strands of fibrin adherent to the pleura, but purple discoloration of the skin and other signs of septicemia are usually present. *Streptococcus suis* is occasionally isolated from suppurative lesions in ruminants.

Streptococcus equisimilis also has been isolated from the joints of pigs with purulent arthritis. In experimental infections, other streptococci, such as *Streptococcus pyogenes* (Lancefield's group A) and group C streptococci produce arthritis and osteomyelitis, in swine.

Streptococci also cause *polyarthritis and meningitis* in **calves**. Metastatic iridocyclitis occurs in many bacterial infections in which polyarthritis occurs, but in none is it so consistent or prominent as in the *streptococcal disease of neonatal calves*. The disease is probably secondary to *umbilical infection* in most cases but, because ocular lesions may be visible grossly by 24 hours of life, there is a possibility that some infections are intrauterine. The clinical signs are of *hypopyon, corneal opacity and meningitis* and because of the strong affinity of the organisms for the meninges and eyes, the disease is without a chronic phase. The arthritis is acute and there is no obvious joint swelling.

In **lambs**, *Streptococcus* spp. are probably second only to *Erysipelothrix rhusiopathiae* as a cause of polyarthritis, although in a UK study, *Streptococcus dysgalactiae* was easily the most common isolate from the joints of arthritic lambs. The *umbilicus* is accepted as the likely route of entry in most cases and this is supported by the high prevalence of the disease in sucklings. There is some variation in the combination of lesions seen at necropsy, probably due to differences in the species and strains of organisms involved. Specific typing of *Streptococcus* spp. is not a routine procedure.

Localization of *Streptococcus* spp. in the joints and other organs of lambs is a sequel to bacteremia. Some lambs die acutely of septicemia and show few gross lesions. *Localization* in various tissues occurs in the course of 1–2 days and may involve any one or a combination of sites, including *the uvea, cerebrospinal meninges, valvular endocardium, myocardium, kidneys, and joints*. Meningeal localization seldom occurs in the absence of polyarthritis, but the latter may not be clinically evident in cases with a short clinical course. Polyarthritis may however occur alone. The infection may subside in many joints, persisting only in the larger limb joints and causing chronic lesions of purulent arthritis. In approximately 20% of lambs with subacute or chronic polyarthritis, there is coincident valvular endocarditis.

Coliform polyarthritis

Escherichia coli *often localizes in the joints or meninges (or both) in farm animals, but is a rare cause of arthritis in dogs.* In septicemic colibacillosis of neonatal **calves**, polyarthritis and tenosynovitis are common, but are easily overlooked or overshadowed by other manifestations of acute septicemia, including meningitis and polyserositis. The organism may enter the blood from the gut, oropharynx, or umbilicus. The lesions in calves are similar to those of streptococcal infection although iridocyclitis, with grossly visible hypopyon, occurs less frequently in association with coliform polyarthritis. In some cases, the polyarthritis is chronic, with lesions restricted to one or two of the larger limb joints and tending to be symmetrical. Chronic coliform arthritis in calves is often coincident with interstitial nephritis (white-spotted kidney), which may develop into descending pyelonephritis.

Polyarthritis caused by *Escherichia coli* also occurs commonly in **horses** and **pigs**, but does not appear to be a common isolate from the joints of lambs with polyarthritis.

Staphylococcal arthritis

Staphylococcus aureus *is a relatively common cause of polyarthritis in farm animals and monoarticular arthritis in dogs.* In lambs, *Staphylococcus aureus* may occur as a sporadic infection or as a complication of tick pyemia. In the UK, the latter syndrome occurs in lambs born onto tick-infested ground, particularly during the spring when tick activity is at a peak. The agent gains entry to the blood through bites of the blood-sucking nymphal stage of the tick *Ixodes ricinus*, then localizes in the synovial membrane and various internal organs. Vertebral osteomyelitis is a frequent complication of *Staphylococcus aureus* septicemia in affected lambs, often leading to ataxia or paralysis following collapse of necrotic bone into the spinal canal.

In one study, ***Staphylococcus hyicus*** subspecies *hyicus* was an important cause of fibrinopurulent arthritis in **pigs** up to 12 weeks of age. Lesions were most common in the *elbow and tarsal joints*. The palatine tonsil is considered an important site of entry for this organism in pigs. *Staphylococcus hyicus* subspecies *hyicus* produces *protein A*, which aids in attachment of the bacteria, and *exfoliative factors*, which may promote epithelial erosion and assist in the invasive process. The altered epithelial environment created by *Staphylococcus hyicus* subspecies *hyicus* in tonsillar crypts may also facilitate the entry of other bacteria to the blood or lymph of young pigs.

Staphylococcus spp. were the most common bacteria isolated from the synovial fluid in a study of 19 cases of *septic arthritis* in **dogs**. Interestingly, although all dogs included in the study had increased numbers of neutrophils in their synovial fluid, the *neutrophils were nondegenerate* in all but one case. This reinforces the point that detection of toxic neutrophils in synovial fluid is not a reliable means of differentiating septic arthritis from noninfectious, immune-mediated arthritis in dogs.

Haemophilus and *Histophilus* septicemia and arthritis

Glasser's disease *is a fibrinous meningitis, polyserositis, and/or polyarthritis of* ***pigs****, caused by* ***Haemophilus parasuis***. The organism is part of the normal flora of the upper respiratory tract of conventional pigs but is often isolated from pneumonic lungs and regarded as a secondary invader. It is acquired from the dam shortly after birth but colostral antibodies usually protect young piglets against disease. Active immunity develops by 7–8 weeks. *Haemophilus parasuis* occasionally produces severe outbreaks of disease in animals aged around 5–12 weeks, usually following transportation or other management stress. Cesarian-derived pigs are susceptible at any age and often develop Glasser's disease after introduction to a boar test-station or a conventional herd.

Glasser's disease is defined on an etiological basis, as there are other organisms, such as *Streptococcus suis*, which produce similar lesions and similar diseases. *Mycoplasma* spp. also produce serositis and arthritis in swine but the diseases are more chronic, and meningitis is either absent or lymphocytic, depending on the species of mycoplasma involved.

Glasser's disease is peracute, with high fever, lameness, and neurological disturbances, including paresis, stupor, and hyperesthesia. As in other septicemic diseases of pigs, the skin may show purple discoloration. The course is 1–2 days and without treatment, the mortality rate is very high. Usually, *serofibrinous meningitis, pericarditis, pleuritis, peritonitis, and synovitis of many joints* characterize the morbid picture. In individual cases, all these tissues, or any combination of them, may be inflamed. Occasionally the lesions occur in only one site and, in some pigs or some outbreaks, gross lesions are absent. *Predilection sites* for lesions of Glasser's disease are *meninges, joints, peritoneum, pleura, and pericardium in descending order*. Meningitis, which is more severe in the cranial than the spinal meninges, occurs in more than 80% of affected pigs. *Polyarthritis is most severe in the atlanto-occipital and large limb joints*. The synovial fluid is increased in volume and turbid due to increased numbers of neutrophils. The *synovitis* is characterized by the presence of gray-yellow fibrin, which covers the membrane or accumulates as a meniscus-like pad between articular surfaces. The *gastric fundic mucosa* is often intensely reddened due to venous infarction, a change that accompanies septicemia of several causes in pigs.

The *microscopic lesions* of *Haemophilus parasuis* infection in pigs are those of septicemia and fibrinous inflammation. Thrombosis of vessels in the skin, meninges, and renal glomeruli is often prominent. The organism can best be cultured from visceral pleura, providing the interval from death to postmortem examination is relatively short. It is seldom isolated from other sites.

Histophilus somni, previously known as ***Haemophilus agni***, ***Histophilus ovis***, or ***Haemophilus somnus***, produces an acute, fulminating, septicemic disease in **lambs** and a more chronic disease in older sheep. The disease appears to be associated with high levels of feeding but the reason for this association is unclear. Little is known of the biology of the organism, or the pathogenesis of the infection, but *H. somni* is a commensal of the genital tract of sheep and could be transmitted to newborn lambs during parturition.

Lambs with *H. somni* septicemia are usually *found dead*, the course of the disease being less than 12 h. Clinically, there is fever, depression, and extreme reluctance to move. Animals that survive for more than 24 h develop *fibrinopurulent arthritis, choroiditis, and basilar meningitis*. The disease tends to remain enzootic in a flock and losses may continue for several months. *The most constant postmortem findings are multiple hemorrhages throughout the carcass*. The hemorrhages vary in severity, but are usually most obvious in lambs dying acutely. The intermuscular connective tissue is wet and slightly stained with blood. The large blotchy hemorrhages of the serosa lack specificity, but *tiny streaks of hemorrhage that are quite diagnostic can usually be seen in the muscles*. They are best appreciated by viewing the intact muscle through the perimysium, and are usually most common near the tendinous attachments. In all cases except the most acute, small foci of necrosis, surrounded by a red halo, are present in the liver. The spleen is enlarged, the pulp soft and juicy. The *absence of pulmonary lesions* usually allows differentiation of this infection from *Mannheimia haemolytica* septicemia, which produces similar hepatic lesions. In *mature animals*, a more extended course is usual and lesions include myocarditis, embolic nephritis, and meningoencephalitis, similar to the lesions of *H. somni* infection in cattle.

Histologically, there is evidence of *overwhelming intravascular bacterial multiplication*. Blood vessels in many tissues are plugged with bacteria and some of the emboli give rise to *acute vasculitis and secondary infarctions*. All tissues share to some extent in this reaction, but there is preferential involvement of liver and muscle. In these organs, there is often severe inflammation in the parenchyma adjacent to the damaged vessels.

In spite of the fact that the tissues often teem with the organisms, bacteriological confirmation may not be obtained unless samples are taken very soon after death and cultured in media enriched with blood or tissue fragments, and preferably in an atmosphere of 10% carbon dioxide. Even so, previous antibiotic treatment significantly impairs isolation of this organism.

Acute serofibrinous arthritis involving one or two joints, usually including the atlanto-occipital joint, occurs regularly in **cattle** with meningoencephalitis caused by ***H. somni***. These animals die suddenly, usually have hemorrhagic necrosis in the brain, and yield *H. somni* on culture (see Vol. 1, Nervous system).

Borreliosis

Borrelia burgdorferi was first recognized in 1975 as a cause of a multisystemic disease (*Lyme disease, Lyme borreliosis*) in man. More recently, it has been associated with disease in domestic animals, including *dogs, horses, cattle, and cats*. In all species, *infection is far more common than disease*, but the host–bacterium interactions responsible are not well defined. *Arthritis is a common feature of disease in animals and human patients with borreliosis*. Other lesions include *myocarditis and nephritis in dogs, ocular disease and probably encephalitis in horses, and abortion in cattle.*

In North America, the three-host tick *Ixodes dammini* is the primary vector for *B. burgdorferi*. Tick eggs are deposited by engorged females in summer and hatch in about 1 month. Larvae engorge for a few days in the period May–September and about 2 months later molt to the nymphal stage. In the following spring–summer period they feed, drop off and molt to the adult stage. This 2-year cycle may be extended to 4 years since unfed larvae and nymphs may overwinter. Larvae and nymphs feed mainly on birds and small mammals in North America, *Peromyscus* spp. (white-footed mouse and deer mouse) are the main mammalian hosts. The adults attach mainly to large mammals, particularly *Odocoileus virginianus*, the white-tailed deer, but raccoons, dogs, horses, cattle, and people are among the potential victims. *Borrelia infection in the principal wildlife hosts is essentially asymptomatic.* Similar epidemiological patterns involving ticks of the *Ixodes ricinus* group and various animal hosts exist in other parts of the world. In North America, *B. burgdorferi* has been isolated from deer flies and horse flies, which are potentially effective mechanical vectors, and from mosquitoes, which are likely less important. Such vectors are significant only in areas where efficient tick vectors maintain infection among wildlife populations.

Both transovarial and trans-stadial transmission of *B. burgdorferi* occur, but only the latter is epizootiologically important. Intrastadial and interstadial transmission, which occur when several larvae and nymphs feed on an infected host, is of greatest significance in the spread of infection. *Transmission of infection to large mammals is usually by the bite of an adult tick and requires attachment for about 24 h.* The organism may be present in the urine of *Peromyscus* spp. and cattle, but the prevalence of infection by direct contact is not known.

The most common clinical signs in **dogs** with borreliosis are anorexia, lethargy, and lameness in association with fever and lymphadenopathy. Severe depression occurs in some cases and may be due to meningitis. The *arthritis is typically intermittent and involves one or more joints*, often including the carpus. Detailed pathologic descriptions are unavailable since antibiotic treatment appears to be successful and experimental reproduction of disease in dogs is not. In people, the arthritis may be recurrent, leading eventually to ulceration of cartilage. In experimentally infected Lewis rats, acute exudative arthritis, tendonitis and bursitis occur by 30 days postinfection, then regress, but exacerbations develop in some animals. Synovial, but not cartilaginous, ulceration occurs in rats, and there is villus hyperplasia with lymphoplasmacytic and macrophage infiltrates in the synovial membranes. Lymphoplasmacytic myocarditis also occurs in rats, and nonsuppurative myocarditis develops in a small proportion of affected dogs. Clinical evidence of renal disease is also seen in a few dogs and organisms can be demonstrated in the kidney, but the lesions are poorly defined.

In **horses**, signs of borreliosis include lethargy, low-grade fever, painful, swollen joints, and reluctance to move. Laminitis and panuveitis may also occur but are less common. The organism has been demonstrated in anterior chamber fluid and a probable case of encephalitis caused by *B. burgdorferi* is recorded in a horse. Few necropsies on affected horses are reported but it appears that arthritis is present and resembles that seen in dogs, with the addition of marked thickening and hyalinization of arterioles in synovial tissues.

Although there are few reports in **cattle,** it appears that the disease in this species is associated with *abortion*, and may develop into a chronic illness with relapses following treatment, eventually leading to emaciation. In other respects, the disease resembles that seen in dogs and horses. *Arthritis is common and there is limited evidence of myocarditis and nephritis.* In people, a characteristic skin lesion, *erythema chronicum migrans*, may develop at the site of the tick bite, and represents the first stage of Lyme disease. Similar areas of discoloration have been described on bovine mammary skin.

Borrelia burgdorferi has been isolated from blood, urine, colostrum, and synovial fluid of cows, and the blood of a newborn calf. Antibodies in the blood of an aborted fetus suggest that the organism may cross the placenta. Diagnosis of borreliosis is made to some extent by exclusion. *Borrelia burgdorferi* may be demonstrable by *dark-field or phase-contrast microscopy in urine or synovial fluid* and by *silver, immunoperoxidase or immunofluorescent stains in synovial membranes or other tissues*. Isolation of the organism may be possible by using special media. Often the diagnosis is based on typical signs in an animal with a high titer and potential or known exposure to the organism. There is serological cross-reactivity between *B. burgdorferi* and some other spirochetes, but apparently not with leptospires.

Rickettsial polyarthritis

Ehrlichiosis has occasionally been associated with polyarthritis in **dogs**. The syndrome is characterized by acute-onset fever with pain and swelling in one or more joints of the limbs. The synovial fluid has an increased protein concentration and a high cell count, of which 60–80% are neutrophils. *Morulae are occasionally observed within the cytoplasm of neutrophils, eosinophils, or monocytes in synovial fluid, and in circulation.* This differs from *Ehrlichia canis* infection, in which morulae typically are found in monocytes and lymphocytes. Although *Ehrlichia canis* titers are generally positive in affected dogs, the strain of the organism involved in *canine polyarthritis* has been tentatively named ***Ehrlichia ewingii***.

Chlamydial polyarthritis

The genera ***Chlamydia*** and ***Chlamydophila*** contain several species of obligate intracellular gram-negative bacteria characterized by the absence of cell-wall peptidoglycans. The former *Chlamydia psittaci* has been redefined as the *Chlamydophila* species: *C. abortus* (mammals), *C. psittaci* (birds), *C. felis* (cats), and *C. caviae* (guinea pigs). *Chlamydia pecorum* is renamed *Chlamydophila pecorum*. The former *Chlamydia trachomatis* has been subdivided to include the *Chlamydia* species: *C. trachomatis*, which infects humans, and *C. suis*, which infects swine.

- ***Chlamydophila abortus*** is an important cause of abortion in several species, including goats, cattle, and sheep, in which it is responsible for *"enzootic" abortion of ewes* in the United Kingdom.
- ***Chlamydophila psittaci*** is well recognized as an infectious agent of birds with zoonotic potential.
- ***Chlamydophila felis*** causes conjunctivitis and rhinitis in cats.
- Only ***Chlamydophila pecorum*** is currently recognized as a cause of arthritis in domestic animals.

Sporadic or epidemic C. pecorum polyarthritis occurs in calves and lambs, and occasionally in other animals. The natural habitat of chlamydiae is the intestinal tract, where the organism multiplies in the mucosal epithelium before entering the lamina propria. Nonvirulent strains rarely progress beyond the mesenteric nodes. Following oral exposure of calves to virulent strains, the chlamydiae spread to the liver and mesenteric nodes via blood vessels and lymphatics of the lower small intestine. Multiplication in these sites is followed by a primary, low-level chlamydemia with localization and multiplication in spleen, liver, lungs, and kidneys. The joints are infected during a secondary chlamydemia, and arthritogenic strains produce their most severe effects in synovial membranes, with clinical arthritis developing about 10 days after oral inoculation. Severe watery or bloody diarrhea often occurs a few days prior to the development of arthritis.

The disease in calves is severe, causing a high mortality rate both naturally and experimentally. Affected calves may be weak at birth, suggesting intrauterine infection. In these animals, fever, anorexia, reluctance to stand or move, and swelling of joints develop in 2–3 days and death occurs 2 days to 2 weeks after the onset of signs. *All or many joints are affected*, those of the limbs most severely. The subcutaneous and adjacent periarticular tissues are edematous with clear fluid, which also extends around tendon sheaths. Surrounding muscles are hyperemic and edematous with petechiae in the fascia. Joint cavities are distended with turbid yellow-gray fluid, and strands or wads of fibrin adhere to the synovium. Viscera may show changes attributable to systemic infection.

The ovine syndrome is less severe, being characterized by high morbidity but negligible mortality, even though the infection is systemic. Affected lambs show conjunctivitis, depression, anorexia, reluctance to move, joint stiffness that disappears with exercise, and loss of weight. Most lambs recover, but a few are permanently lame. *The articular lesions are similar to those in calves although modified by the milder reaction*, the longer course allowing fibrotic thickening of tendon sheaths and articular capsules and hyperplasia of synovial villi. In soft tissues, including the central nervous system, histologic traces of inflammation are present. The organism is sometimes demonstrable in the cytoplasm of synovial cells stained by the Giemsa, Gimenez, or modified Stamp methods.

Mycoplasmal arthritis

Mycoplasmas are ubiquitous organisms, which are difficult to isolate, propagate, and identify, and often difficult to associate with specific diseases. Polyserositis and polyarthritis produced by these organisms are problems of considerable magnitude in farm animals, and often complicate mycoplasma ("enzootic") pneumonia or other disease syndromes. The diseases are seldom fatal, but produce a lingering debility from which animals never completely recover. Because of the difficulty in isolating mycoplasmas from routine diagnostic specimens, the prevalence of diseases caused by these agents is probably underestimated.

Swine

Three *Mycoplasma* species are pathogenic for swine:

- *Mycoplasma hyopneumoniae (suipneumoniae)* causes enzootic pneumonia;
- *Mycoplasma hyorhinis* causes polyserositis and *polyarthritis*, usually in animals about 3–10 weeks of age;
- *Mycoplasma hyosynoviae* also causes *polyarthritis*, but not polyserositis, and usually in pigs over 10 weeks of age.

Other mycoplasmas are sometimes associated with various diseases of swine but they are not primary pathogens.

Mycoplasma hyorhinis *is a commensal or parasite of the nasal passages in most pigs*, but often colonizes pneumonic lesions, especially those of mycoplasmal pneumonia. Although it does not noticeably alter the lung lesion, infected lungs might be the primary site for entry of the agent into the blood. The pathogenicity of *M. hyorhinis* is enhanced by intercurrent disease and various forms of stress. After an incubation period of 3–4 days, the infection produces an erratic febrile reaction, anorexia, depression, and loss of body weight. Growth rate remains retarded, although after a month or so there may be signs of recovery. The infection is more likely to be fatal in suckling piglets or those with intercurrent pneumonia.

Mycoplasma hyorhinis has a predilection for collagen-containing structures, including serous and synovial membranes and cartilage, but evidence of meningitis is either absent or mild. When present, the meningitis is lymphocytic in nature. The systemic infection persists for at least 2 months after experimental inoculation. *The serosal lesions may vary and any combination of epicarditis, pleuritis, and/or peritonitis is possible.* The serosal reaction is serofibrinous, and the cellular component is mononuclear with focal accumulations of neutrophils. The epicardium is uniformly affected, whereas pleuritis may be confined to the ventral margin of the lung and the pleura between lobes, and may extend to the outer surface of the pericardial sac. The peritoneal exudate is patchy and may be concentrated in the anterior abdomen, especially between the liver and diaphragm, but often involves loops of intestine and the coiled colon. Progressive organization of exudates produces tough adhesions, but even after many weeks there is still histologic evidence of active inflammation, which is consistent with the persistence of the organism.

While the effects of polyserositis predominate early in the disease, signs of *polyarthritis* become evident once villus hypertrophy, synovial thickening, and organization of fibrinous exudate replace the initial synovial edema and hyperemia. In the chronic disease, thickening and brown discoloration of joint capsules, erosion and discoloration of articular cartilages, and pannus formation are observed. Discoloration of joint structures is probably a sequel to synovial hemorrhage.

Early *microscopic changes* consist of hyperemia, diffuse lymphocyte and macrophage infiltration, and mild villus hypertrophy, followed by ulceration of synovial membranes. Fibrinopurulent exudate is consistently present in virtually all joints, and is most abundant in the recesses where the synovial membrane is reflected from the articular cartilage. Later, perivascular lymphoplasmacytic accumulations and more pronounced villus hypertrophy become evident and fibrinous exudate is less prominent. Early in experimental infections, mycoplasmas invade the lacunae of superficial chondrocytes, and degeneration of chondrocytes combined with the enzymatic activity of adherent neutrophils produces erosions of articular cartilage.

In chronic *Mycoplasma hyorhinis* synovitis, there is marked villus hypertrophy and proliferation of synovial cells. Perivascular cuffs are less prominent, but *lymphoid follicles*, often surrounded by lymphatics, occur frequently in the villi. Dense fibrosis of some villi is evident. Erosions, developing first at the periphery of the articular cartilages, later occur centrally, and *erosion of cartilage and subarticular bone by pannus* is not unusual in advanced cases. Joint contractures are associated with the chronic arthritis and thickened joint capsules. Chronic lesions remain active for many months, and the organism can often be cultured from surface exudate in these joints.

Mycoplasma hyosynoviae is carried persistently in the pharynx and tonsils of many sows and may be transmitted to their offspring. Infection of pigs less than 6 weeks of age is uncommon and separation of piglets from their dams by 5 weeks of age usually prevents transmission. Clinical disease often develops following management stress and is more frequent, and more severe, in pigs with poor conformation and gait.

Following experimental infection with *Mycoplasma hyosynoviae*, there is an incubation period of 5–10 days. Lameness, lasting 3–10 days, occurs in many pigs and may involve one joint or several. *Many pigs recover completely but lameness due to chronic arthritis persists in 5–15% of infected swine.* The early pathologic changes resemble those caused by *Mycoplasma hyorhinis*. Chronic lesions are not fully described but are also likely to be qualitatively similar to those of *Mycoplasma hyorhinis*.

Failure to isolate organisms from the joints of many pigs with *chronic mycoplasma arthritis* may be due to difficulties in culturing the organism. Alternatively, the continued inflammatory reaction may be due to an immune response to persisting mycoplasma antigen, rather than a viable agent. Support for this view is derived from the observation that rabbits sensitized to *Mycoplasma arthritidis*, either by infection or hyperimmunization, develop chronic arthritis when challenged with nonviable *Mycoplasma arthritidis* antigen. Antibody in the synovial fluid of sensitized animals could retain antigen in immune complexes. These complexes may become deposited in synovial tissues and articular cartilage and stimulate a cell-mediated immune response with generation of cytokines capable of inducing tissue damage. The nature of the putative antigens is undetermined. Since mycoplasmas lack a cell wall and cannot synthesize peptidoglycans, the antigen must differ from the antigens responsible for inducing chronicity in some bacterial arthritides. Whether this hypothesis is correct, or relevant to the natural disease, is undetermined.

Goats

Mycoplasma spp. cause several important disease syndromes in goats, including contagious caprine pleuropneumonia (see Vol. 2, Respiratory system) and contagious agalactia (see Vol. 3, Male genital system). A **septicemia-arthritis** syndrome caused by either ***Mycoplasma mycoides* subsp. *mycoides*** or ***Mycoplasma capricolum* subsp. *capricolum*** occurs in goats. *Mycoplasma mycoides* subsp. *mycoides* is separable into two groups on the basis of colony type (large and small). *Mycoplasma mycoides* subsp. *mycoides* (small colony) type is the etiologic agent of contagious bovine pleuropneumonia and should not be confused with *Mycoplasma mycoides* subsp. *mycoides* (large colony) type, which is a common infection of goats in several countries.

Mycoplasma putrifaciens occasionally causes polyarthritis and mastitis in goats. *Mycoplasma agalactiae*, the cause of contagious agalactia, also may be associated with arthritis following extension of infection from periarticular connective tissues.

The **septicemia-arthritis syndrome in goats** is acutely febrile and associated with a drop in milk yield due to *mastitis*. In the course of about 2 days, affected animals develop *acute polyarthritis*, but in suckling kids, the disease is peracute and localization in joints is less obvious. During the *systemic phase of the infection*, there is a generalized acute lymphadenitis, splenitis, histiocytic meningitis, glomerulitis, renal tubular degeneration, and focal coagulative necrosis in the liver. Fibrinous peritonitis and pleuritis are sometimes present. Capillaries in many organs may contain thrombi, probably reflecting disseminated intravascular coagulation. Diffuse interstitial pneumonia characterized by infiltration of alveolar walls with neutrophils or monocytes, and leakage of protein-rich fluid into alveoli, develops in kids. In adults, the pneumonia tends to be less diffuse and more chronic. *The articular lesion is a severe fibrinopurulent inflammation, usually involving many synovial structures.*

The epidemiology of the septicemia-arthritis syndrome is incompletely understood. Some do probably acquire *Mycoplasma capricolum* subsp. *capricolum* via the teat canal and infection can spread to the opposite gland. Some kids are probably infected via milk but horizontal transmission of both *Mycoplasma capricolum* subsp. *capricolum* and *Mycoplasma mycoides* subsp. *mycoides* (large colony) type occurs among young kids housed together. An outbreak of septicemia and fibrinous polyarthritis caused by *Mycoplasma mycoides* subsp. *mycoides* (large colony type) occurred in New Zealand in 3–20 day old dairy goat kids fed pooled colostrum contaminated with organisms by a doe with mastitis. In total, 34 of 64 kids were affected and 3 died.

Sheep

Septicemia and arthritis caused by *Mycoplasma capricolum* subsp. *capricolum*, or a closely related organism, is reported in **lambs** exposed to goats' milk. The disease was similar to that described in kids.

Cattle

Mycoplasma mycoides subsp. *mycoides* (small colony) type, the agent of **contagious bovine pleuropneumonia**, causes *polyarthritis and endocarditis* in a proportion of **calves** in which it is used as a vaccine. Sporadic outbreaks of polyarthritis in cattle, not associated with *Mycoplasma mycoides* subsp. *mycoides* vaccination also occur in North America and Australia and are probably caused by *Mycoplasma bovis*. This organism also causes mastitis, with or without arthritis, and is often isolated from bovine fibrinous pneumonia where its significance is poorly understood. *Mycoplasma alkalescens, Mycoplasma californicum,* and *Mycoplasma canadense* have all been associated with arthritis and mastitis in cattle. Although *Mycoplasma mycoides* subsp. *mycoides* (large colony) type is not considered to be pathogenic for cattle, an outbreak of arthritis caused by this agent was recently reported in artificially reared dairy calves in New Zealand. This was the result of feeding contaminated goats' milk from a dairy goat farm where an outbreak of arthritis was also occurring in goat kids. No lateral spread of infection occurred amongst the calves.

Mycoplasma bovis probably enters the circulation *from the lungs* and localizes in synovial membranes. Oral infection of calves from the milk of a mastitic dam may also occur. Outbreaks of disease usually occur in *feedlots* and are often preceded by management stress. Usually 15% of animals show signs of lameness, followed within 1 or 2 days by severe swellings around joints. The *stifle, shoulder, hock, and elbow joints are most often affected*, but severe lesions usually develop in only one limb.

In *acute disease*, the joints are distended by opaque cream-colored fluid containing flakes of fibrin. Synovial membranes are red and swollen. Microscopic changes include light to diffuse infiltrations of lymphocytes, macrophages, and plasma cells in addition to hyperplasia of synovial cells and synovial villi. Focal perivascular necrosis and ulceration of the synovial membrane may be present and attract numerous neutrophils, which accumulate in joint spaces.

Most affected animals recover in 1–2 months but a few develop *chronic arthritis* and are culled. These animals have a *proliferative and erosive arthritis with well-vascularized pannus* extending from the thickened synovial membrane across the articular cartilage. Spread of inflammation to the subchondral bone with development of *osteomyelitis* occurs in some animals. The predominant cells in the chronic synovial lesions are lymphocytes and plasmacytes, with fewer neutrophils and macrophages. Isolation of mycoplasmas is relatively easy in the acute disease but is often more difficult in chronic stages.

Cats and dogs

Occasionally, mycoplasma arthritis occurs in cats and dogs. ***Mycoplasma gateae*** is reported as a cause of polyarthritis and tenosynovitis in cats, and ***Mycoplasma felis*** was recovered from the joint of a cat with suspected immune deficiency. ***Mycoplasma spumans*** was isolated from a Greyhound with polyarthritis and is considered a possible cause of the infectious arthritis seen in that breed in Australia.

Other infectious agents

Viral arthritis

Few viral agents have been incriminated either directly or indirectly with arthritis in domestic animals.

Goats

The best-characterized example of viral arthritis in animals is **caprine arthritis-encephalitis**. This syndrome is caused by persistent infection with a *nononcogenic retrovirus (lentivirus)*. The neurologic, mammary, respiratory and systemic features are described in Vol. 1,

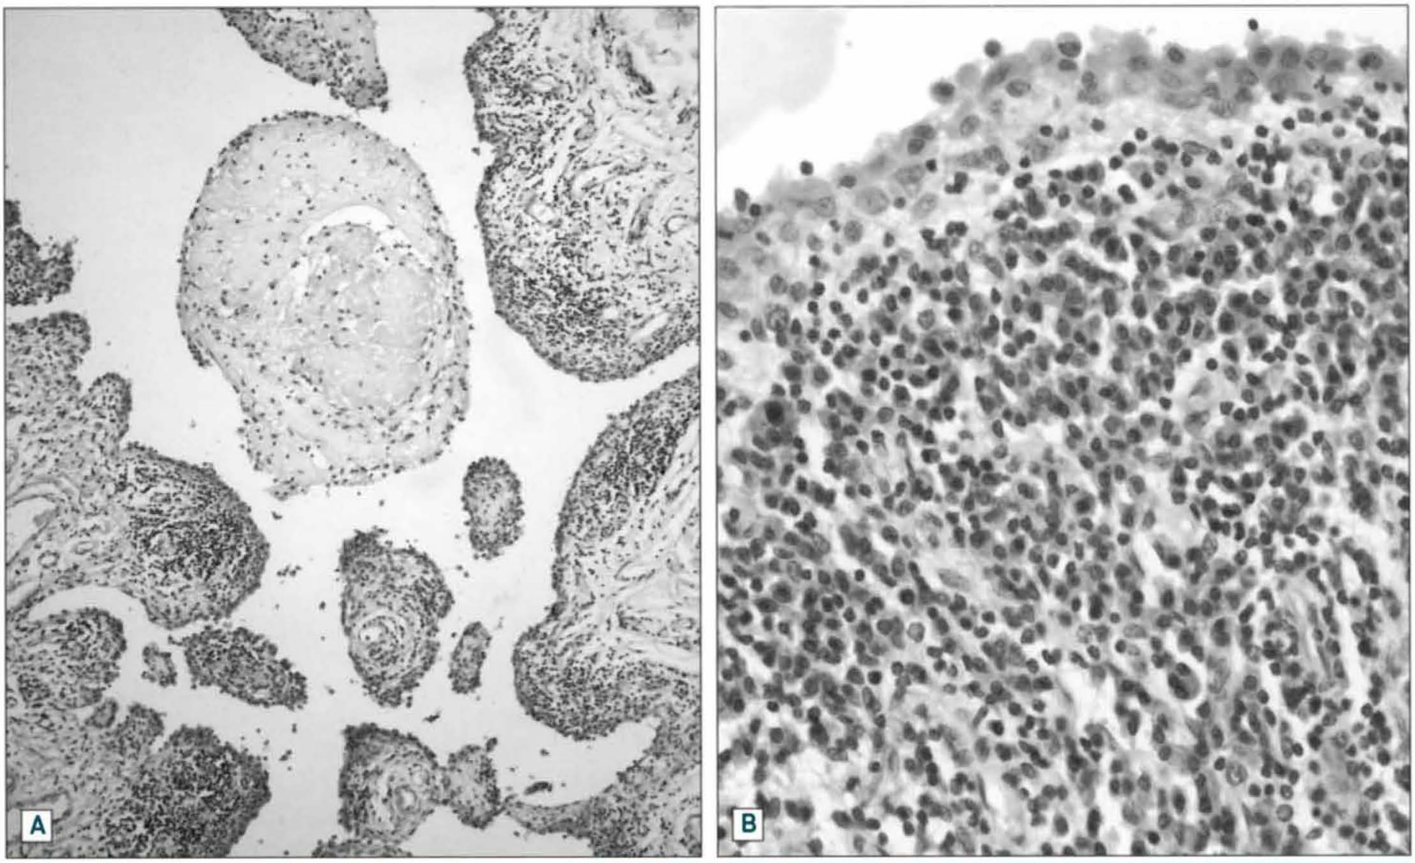

Figure 1.159 Caprine arthritis-encephalitis **A.** Hypertrophic, edematous synovial villi containing aggregates of mononuclear cells. **B.** Closer view showing intense plasmacytic infiltration of the synovium and hypertrophy of synoviocytes on the surface.

Nervous system. *In many herds, arthritis is the major or only clinical manifestation of infection*, with signs of lameness often associated with carpal hygromas, weight loss, and reduced milk production. The prevalence of infection in a herd may reach 100%, but expression of disease is variable and rarely exceeds 25–30%.

A high prevalence of unilateral or bilateral carpal hygromas is a characteristic clinical feature of caprine arthritis-encephalitis. The hygromas are chronic lesions that appear as flattened, cystic, subcutaneous distensions over the cranial carpus, and are filled with yellow or bloody fluid, often containing fibrinous or gelatinous masses. Usually, there is no communication with the carpal joint or tendon sheaths. The tendon sheaths and joint capsule are thickened by fibrous tissue, in which collagen degeneration and mineralization may occur. In many cases, the major joints, especially carpus and stifle, are distended with clear yellow fluid. Other gross changes, which are also seen most often in the carpus and stifle, include hypertrophy of synovial villi, fibrillation and erosion of cartilage, and destruction of joint structures by pannus. Lymphocytic/plasmacytic arthritis is demonstrable microscopically in many joints.

Caprine arthritis encephalitis virus is readily transmitted to kids in colostrum and milk, and horizontal transmission probably occurs. Although the colostrum may contain antibody this does not influence viral transmission. In blood, the virus is present in monocytes and is activated when they mature into macrophages. Following infection, there is vascular injury to synovial structures, with exudation of plasma proteins into synovial fluid. Synovial villi hypertrophy, become edematous and accumulate focal and diffuse infiltrations of plasma cells and lymphocytes (Fig. 1.159A, B) and scattered macrophages, which are sometimes multinucleated. Some villi may be fibrosed, and there is hyperplasia of synoviocytes on their surfaces. Hyalinized masses of fibrin also form villus-like structures in inflamed joints, and layers of fibrin may cover the synovial membrane in some areas.

Sheep

A related lentivirus of sheep, the ***Visna/maedi virus***, causes *chronic, nonsuppurative arthritis* in this species, and also produces arthritis in goat kids experimentally. Similarly, the *Caprine arthritis encephalitis virus* induces arthritis experimentally in lambs but natural cross infections are not known to occur.

In *lentivirus arthritis*, macrophages and lymphocytes are the predominant cells in synovial fluid. A small number of the macrophages are infected with the virus but there is a reduction in virus gene expression, possibly due to the presence of interferon in the synovial fluid. Plasma cells in the inflamed synovia produce immunoglobulin G_1, presumably in response to persistent infection, and the concentration in synovia is higher than that in serum. The relevance of this to lesion development is unclear since the predominant lymphocytes in the synovia are T cells and there is some suggestion that interaction between these cells and macrophages may be responsible for the chronic inflammatory response.

Cats

Lameness caused by acute arthritis is reported in cats in association with ***Feline calicivirus*** infection, or 5–7 days after live-virus vaccination. In one study, intra-articular inoculation or contact exposure of cats to a field strain of *Feline calicivirus* resulted in acute arthritis in addition to oral and nasal ulceration, conjunctivitis, and ocular discharge, which are more typical of the infection. Only mild lameness was induced by the vaccine strain. The gross and microscopic changes have not been well characterized, at least in natural infections, although viral antigen has been demonstrated in the supporting and lining cells of the synovial membrane by immunostaining.

Fungal arthritis

Arthritis involving one or more joints occurs in some dogs with systemic fungal infections. In some cases, the arthritis is probably *immune-mediated*, following the deposition of immune complexes in the synovial membrane, but *hematogenous localization* of fungal agents in joints, or *direct spread from osteomyelitic lesions* in adjacent bones also occurs. Fungi identified in arthritic joints of dogs have included *Blastomyces, Histoplasma, Coccidioides, Cryptococcus,* and *Sporothrix* species. Radiography may reveal a destructive process in a bone or bones adjacent to the joint and erosive changes in articular cartilage. The causative agent is sometimes evident on cytological examination of synovial fluid obtained by arthrocentesis. Histologically, the synovial inflammation is usually *pyogranulomatous*.

Protozoal arthritis

Proliferative synovitis may be associated with *visceral leishmaniasis* caused by the protozoal agent *Leishmania donovani*. Synovial villi in affected joints are hypertrophic and infiltrated with plasma cells and macrophages, some of which may contain the organism. The agent is occasionally demonstrated in macrophages collected from synovial fluid.

Miscellaneous inflammatory lesions of joint structures

Bursitis

Bursitis often occurs as part of the synovial localization of *hematogenous* infections. In addition, there are *isolated forms* of bursitis, especially in horses, that appear to be initiated by *trauma* and are characterized by accumulation of excess serous fluid and variable degrees of synovial hypertrophy. They represent loci of lowered resistance and are predisposed to the localization of organisms, which may alter the nature of the inflammatory reaction while contributing to its progression. *The bursae that cover bony prominences are especially liable to traumatic injury*. Capped elbow and capped hock are examples of *serous bursitis*. Carpal bursitis is also known as *hygroma* and is not uncommon in cattle and sheep. The distended bursae are sometimes filled with fibrin concretions (Fig. 1.160). In cattle, large hygromas should be suspected of being secondarily infected with *Brucella abortus*. Carpal hygromas are also common in adult goats infected with *Caprine arthritis encephalitis virus*.

"Fistulous withers" and "poll evil" are the most serious forms of bursitis in horses and mules, affecting the supraspinous and atlantal bursae respectively. The affected bursae are those between the nuchal ligament and the second, or less often, the third, fourth, or fifth, thoracic spine in the case of "fistulous withers," and between the nuchal ligament and the dorsal arch of the atlas in the case of "poll evil." In both syndromes, the inflammation is *suppurative and granulomatous*, and there

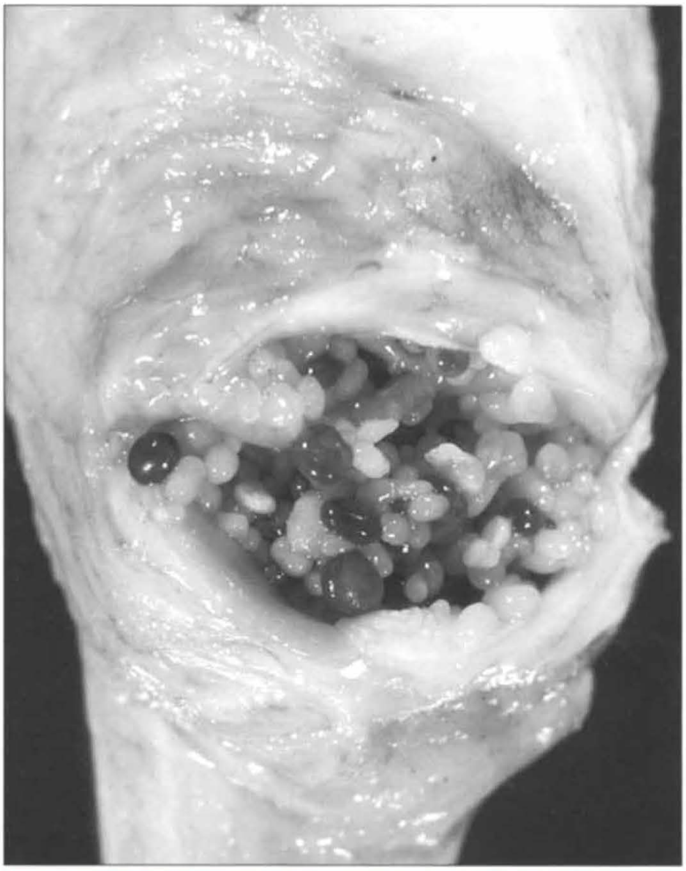

Figure 1.160 Chronic carpal bursitis in a sheep. Thickened fibrous wall surrounding numerous fibrin concretions.

is a tendency to fistulate to the skin surface. Less commonly, the inflammation extends into adjacent fibrous connective tissues as a cellulitis, or induces destructive osteitis of adjacent bones. Inflammation of the navicular bursa is discussed with navicular syndrome.

The primary lesions of "fistulous withers" and "poll evil" may be either *traumatic or inflammatory*. The trauma may be caused by a penetrating wound, with introduction of infection, or blunt injury, producing contusions in which organisms localize hematogenously. Inflammatory lesions are associated with a variety of organisms, including the nematode *Onchocerca cervicalis,* which localizes in the nuchal ligament and environs, provoking mineralized granulomas when it dies. However, in areas where the prevalence of *O. cervicalis* infection is high, the prevalence of bursitis is not, and *the etiologic role of the parasite is questionable*. In brucellosis-endemic areas, *Brucella abortus* is often isolated from closed lesions of bursitis, and vaccination is considered a useful method of treatment. *Actinomyces bovis*, a common component of the normal bovine oral flora, sometimes can be cultured from closed lesions in horses, and exposure to cattle is considered a predisposing factor. In North America, and other locations where the incidence of brucellosis and the exposure of horses to cattle are declining, isolation of *Brucella abortus* and *Actinomyces bovis* from equine bursitis has also waned. *Streptococcus zooepidemicus* is now the most common isolate from closed lesions but several other bacteria have also been implicated. The infections are *probably hematogenous*, but it is not clear whether a predisposing bursal lesion is required. *Actinomyces bovis,* in particular, is an unlikely primary pathogen, since in its own niche it is an uncommon opportunistic invader of traumatized oral mucosa. Furthermore, it does not establish itself in regional lymph nodes draining the lesions of osteomyelitis in which it flourishes.

Adventitious bursitis of the hock is common in finishing pigs, particularly those kept on slatted floors. A study conducted on 21 properties in south-west England revealed an overall prevalence of 51.0% with a range of 10.1 to 84.0%. The bursae are typically found immediately distal to the hock on the lateroplantar, plantar, and medial aspects of the joint. The lesions are thought to arise through traumatic injury to lymphatic vessels and capillaries, followed by the accumulation of fibrinous exudate within affected bursae.

Diskospondylitis

Diskospondylitis is inflammation of an intervertebral disk leading to osteomyelitis of contiguous vertebrae. It occurs occasionally in dogs and pigs, and less often in cats, horses, cattle, and sheep. Most cases are caused by bacteria, usually as a result of primary bacteremia, but also secondary to a chronic infection elsewhere in the body. Fungi, such as *Aspergillus terreus*, are occasionally involved in dogs.

In **dogs**, diskospondylitis occurs most often in *large males* and usually involves the *lumbosacral spine*, causing hyperesthesia, stilted gait, and/or pelvic limb lameness. *Staphylococcus aureus* is the most common cause, although several other bacteria have been incriminated and *Brucella canis* should be considered in countries or regions where it is known to occur. Often, there is concurrent disease, such as a urogenital infection. Diskospondylitis and osteomyelitis of lumbar vertebrae has been associated with migrating grass seeds in dogs. It is suggested that ingested seeds occasionally penetrate the intestinal wall at the caudal duodenal flexure and ascend in the mesoduodenum to the lumbar vertebrae, carrying bacteria with them.

In **pigs**, most lesions occur in the *upper thoracic and upper lumbar spine* following *hematogenous* localization of bacteria. *Erysipelothrix rhusiopathiae, Arcanobacterium pyogenes,* and *Staphylococcus aureus* are the most common agents involved but, in some geographic areas, *Brucella suis* may be an important cause of the disease. Diskospondylitis in **horses** most often involves the cervical vertebrae, inducing signs of neck pain. In some cases, there is a history of a penetrating wound to the neck. Medical or surgical therapy is often successful in dogs but seldom in horses.

Organisms causing diskospondylitis probably localize initially in the outer part of the annulus fibrosus, where they stimulate an inflammatory reaction. Alternatively, localization in the vertebral body with extension to the disk may occur. Early radiographic changes are reduction of the intervertebral disk space and loss of density in the vertebral endplates. Gross lesions appear as soft, gray areas of discoloration and disruption in the disk, often extending into adjacent vertebrae through disrupted end plates (Fig. 1.161). *Complete destruction of disks, with fibrous replacement and formation of vertebral osteophytes, occurs late in the disease.* Such lesions are easily confused with spondylosis due to primary degeneration of the annulus fibrosus. The inflammatory reaction may extend dorsally into the spinal canal causing meningomyelitis, or laterally, causing paravertebral abscessation. *Microscopic lesions* of diskospondylitis vary with the stage of the disease and the nature of the causative organism. Early bacterial infections are characterized by suppurative inflammation, hemorrhage, and necrosis of intradiskal structures and adjacent bones. In chronic lesions, vascular connective tissue, infiltrated with mononuclear or mixed inflammatory cells, predominates.

Calcium crystal-associated arthropathy (pseudogout)

A syndrome characterized by the deposition of *calcium pyrophosphate dihydrate* ($Ca_2P_2O_7{\cdot}2H_2O$) *crystals* in articular and para-articular tissues is well recognized in humans and is reported occasionally in *aged dogs*. The lesions may occur as single, tumor-like, periarticular masses (Fig. 1.162) developing over a period of several months or even years. The lateral and dorsal aspects of the metatarsophalangeal joint of the 5th digit were involved in a 13-year-old female Golden Retriever. A similar mass involving the carpal joint was diagnosed in a 15-year-old male English Pointer. Mild, progressive lameness was reported in

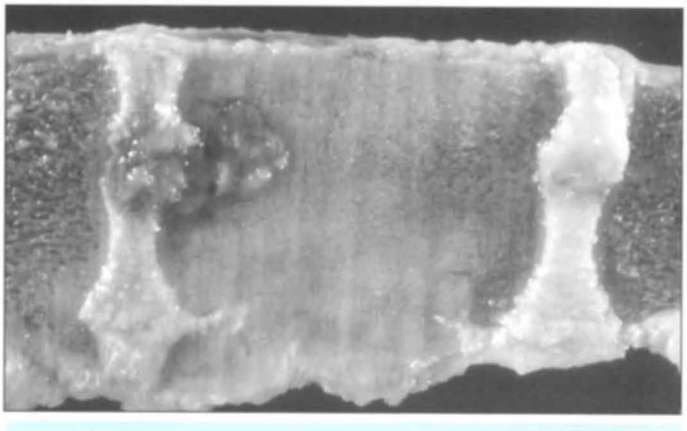

Figure 1.161 Diskospondylitis, dog. Inflammation of intervertebral disk and extension into adjacent vertebral body, causing local bone lysis. The remainder of the vertebral body is sclerotic.

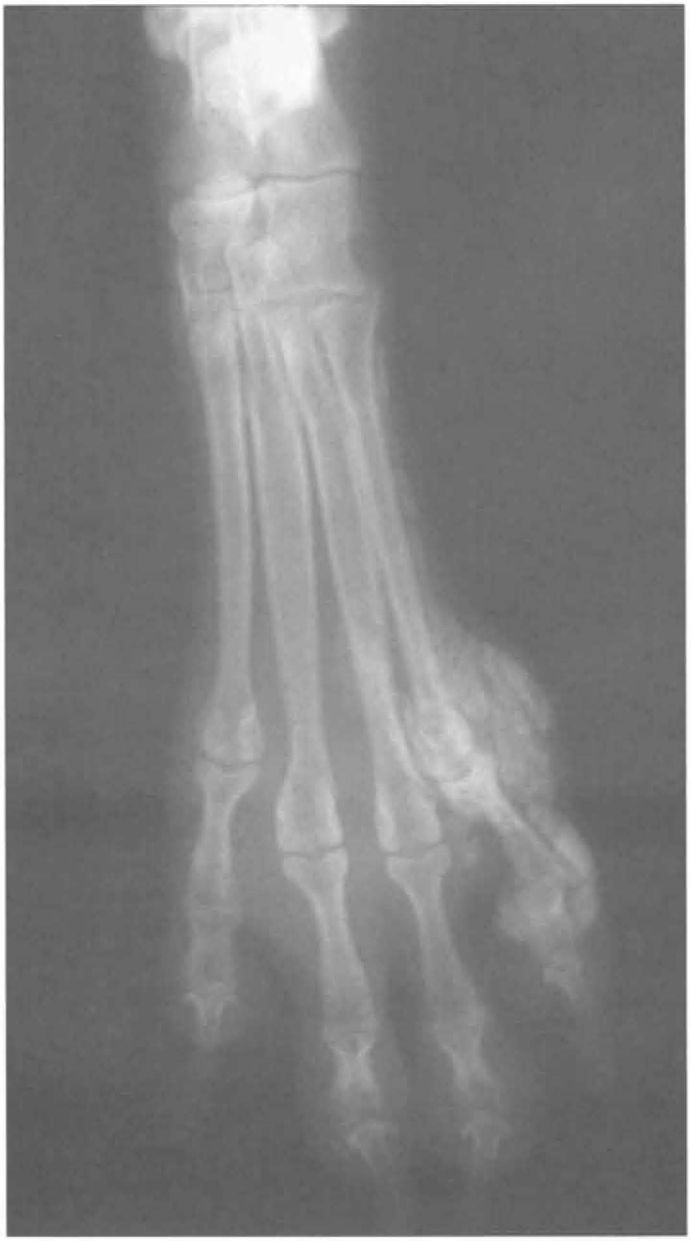

Figure 1.162 Calcium pyrophosphate dihydrate crystal deposition disease (**pseudogout**), dog. Radiodense mass adjacent to the metatarsophalangeal joint of the 5th digit and extending along the 1st phalanx.

the latter dog. In both cases, the lesions consisted of *multiple, hard, chalky white nodules separated by fibrous septa.* Although the masses were adherent to the joint capsule, they did not involve joint cavities or articular surfaces. Microscopically, the chalky nodules consisted of variable-sized deposits of pale brown crystalline material and were separated by bands or islands of fibrous or cartilaginous connective tissue. A *granulomatous inflammatory reaction*, which included many large, multinucleated giant cells, was closely associated with the crystalline deposits. The crystals were weakly birefringent, rhomboidal or rectangular, and stained positively with Alizarin red.

A more acute form of the disease characterized by nonweight-bearing lameness in both forelimbs and the left hindlimb was diagnosed in a 13-year-old Keeshond. Cytological examination of synovial fluid from both carpal joints revealed 60% mononuclear cells and 40% neutrophils. Weakly birefringent rectangular and rhomboid crystals, which stained positively with Alizarin red, were present extracellularly and within neutrophils, monocytes, and synovial lining cells. Clinically, *this acute form of pseudogout closely resembles septic arthritis.*

The pathogenesis of this syndrome, now referred to as calcium pyrophosphate dihydrate crystal deposition disease, is unknown, but acute episodes in human patients may follow surgery, trauma,or severe medical conditions, such as myocardial infarction.

True gout, which is associated with the deposition of urate crystals within joint structures occurs commonly in humans, but does not occur in mammalian species possessing the enzyme uricase. *There are no convincing reports of gout in either dogs or cats, and even Dalmatian dogs, with their high serum uric acid concentrations, do not appear to develop the disease.*

Noninfectious (immune-mediated) arthritis

The term **immune-mediated arthritis** is used to classify a group of *inflammatory but noninfectious diseases of joints.* The inflammation is in response either to persistence of antigenic material in the synovium of affected joints, possibly as a sequel to previous infection, or to deposition in the synovium of immune complexes derived from inflammatory lesions elsewhere in the body. The *lesions may resemble those of infectious arthritis*, which is not surprising, as the mediators produced during the inflammatory process are quantitatively and qualitatively similar. Furthermore, *synovial fluid from both forms of arthritis is characterized by the presence of increased numbers of neutrophils. Demonstration of toxic change in the neutrophils is often mentioned as a means of differentiating infectious from immune-mediated arthritis, but this is unreliable.* First, not all bacteria induce significant toxic change in synovial neutrophils. Second, unless the viscosity of the synovial fluid is reduced by the lytic action of lysosomal enzymes on hyaluronan, the neutrophils may not "flatten out" sufficiently in direct smears for signs of nuclear degeneration to be apparent.

Immune-mediated arthritis is typically a *polyarthritis* and occurs most often in *dogs and cats*. Erosive and nonerosive forms of the disease are recognized.

- In the *erosive form*, the immunologic process is centered in the joint and stimulates pannus formation, which may result in erosion of the margins of articular cartilage, instability or luxation of joints, or fusion of low-motion joints. The erosive pattern of immune-mediated arthritis is a feature of *rheumatoid-like arthritis of dogs, polyarthritis of Greyhounds, and feline chronic progressive polyarthritis.*
- In the *nonerosive form*, the primary disease is located elsewhere in the body and the products of the immune process are transported to the capillary bed of the synovium of affected joints. Since the primary disease may be transient, cyclic,or responsive to treatment, and is not centered in the joint, products of the immune response that initiate the synovitis can be cleared periodically or permanently from the joint. Consequently, there is no chronic stimulation of pannus or destruction of articular surfaces. Nonerosive immune-mediated arthritis is seen in *idiopathic polyarthritis of dogs, drug-induced arthritis, polyarthritis/myositis syndrome of dogs, lymphocytic/plasmacytic arthritis, and systemic lupus erythematosus*. It is also seen in some animals with chronic enteropathies and other chronic infections.

Erosive athritis

Rheumatoid arthritis

This potentially deforming and crippling disorder is well described in humans, where it is defined by a combination of clinical, pathological, and laboratory criteria. The American Rheumatism Association lists 11 features of the disease, at least seven of which must be present to establish the diagnosis. Furthermore, certain diseases, such as bacterial arthritis, bacterial endocarditis, and systemic lupus erythematosus, must be excluded in order to permit the diagnosis. *The cause of rheumatoid arthritis in humans is not known*, although many aspects of its pathogenesis are understood.

A disease resembling human rheumatoid arthritis is recognized uncommonly in **dogs** and rarely in **cats**. In dogs, it typically affects small and toy breeds, but there is no sex or age predilection. Affected animals initially have episodes of anorexia, depression, and fever, with generalized or shifting lameness associated with swelling around one or more joints.The clinical course is progressive and in the advanced stages of the disease, multiple joints, particularly carpal, tarsal, and phalangeal joints, are persistently swollen, painful, and may be unstable due to weakening of periarticular soft tissues and destruction of articular cartilage and subchondral bone.

Radiographic changes in the early stages of rheumatoid arthritis may be confined to soft tissue swellings, with no apparent alterations to the joint space.As the disease progresses, there is loss of bone density around the joint, collapse of the joint space, and focal radiolucent areas may develop in the subchondral bone (Fig. 1.163A). Other changes may include periarticular osteophytosis, subluxation, or luxation of the joint and fibrous or bony ankylosis, especially in the advanced stages of the disease.

The prominent gross features of early rheumatoid arthritis are thickening and brown discoloration of the joint capsule, with hypertrophy and hyperplasia of synovial villi (Fig. 1.163B, C). Fibrin may be attached to the synovial membrane. Histologically, the enlarged villi are infiltrated with large numbers of lymphocytes and plasma cells and are lined by hypertrophic synoviocytes. Extravasated erythrocytes are often seen within the synovium, as are hemosiderin-laden macrophages, which account for the brown discoloration seen grossly. Degeneration of articular cartilage commences at the margins of the joint where *granulation tissue from the inflamed synovium either spreads across the articular cartilage as a pannus* (Fig. 1.164A) or invades the epiphysis, destroying subchondral bone, and undermining the articular cartilage (Fig. 1.164B). Erosion of central regions of articular cartilage (Fig. 1.163B, C) occurs later in the disease process, probably as a consequence of joint instability and the action of enzymes and mediators released as part of the chronic synovitis. Periosteal new bone sometimes develops at the attachment of thickened joint capsules, but productive osseous changes are always minimal.

Various infectious agents have been implicated as etiologic factors in rheumatoid arthritis of humans and animals. Although none has been shown to be directly involved, indirect involvement through the generation of immune complexes or induction of autoimmunity by molecular mimicry, are possible mechanisms. *Whether the disease is triggered by an infectious agent, or is a manifestation of autoimmunity, there seems little doubt that deposition of immune complexes in articular structures is central to the pathogenesis of rheumatoid arthritis*. Local activation of the complement cascade by these immune complexes leads to generation of proinflammatory peptides such as C3a and C5a, which are chemotactic for neutrophils and induce their degranulation. Type A synoviocytes are efficient antigen-presenting cells and are capable of secreting cytokines that modulate the immune response. Furthermore, high concentrations of granulocyte-monocyte colony stimulating factors in rheumatoid joints can induce monocyte precursors to differentiate into dendritic cells, which are also highly effective at antigen presentation. *Rheumatoid factors*, autoantibodies of the IgM, IgG, or IgA subclasses directed against altered host IgG, are found in synovial fluid, and sometimes in the serum, of dogs with rheumatoid arthritis. *Anti-type II collagen autoantibodies* have also been demonstrated in the synovial fluid of dogs with rheumatoid arthritis.About 25% of dogs with rheumatoid arthritis have rheumatoid factor of the IgM type in their serum.The IgG rheumatoid factor may be more important in dogs but its prevalence in the serum of affected dogs is not known. Rheumatoid factors also are found in a small proportion of dogs and people that do not have joint disease.

Canine distemper virus antigens have been demonstrated in immune complexes precipitated from synovial fluids of dogs with rheumatoid arthritis, suggesting the possibility of a causal role for this virus either following natural infection or vaccination. This would not be surprising since several viral agents have been implicated in human rheumatoid arthritis and the disease in humans often follows viral infection or vaccination.

The joint lesions of *chronic erysipelas and mycoplasmal infections in swine* have features of rheumatoid arthritis and the difficulty in isolating infectious organisms from such joints suggests that an immune mechanism may be involved. In fact, these diseases have been suggested as models for human rheumatoid arthritis.

Polyarthritis of Greyhounds

An *erosive polyarthritis*, which does not appear to have an immune basis, is described in young Greyhounds in Australia, the UK, and the

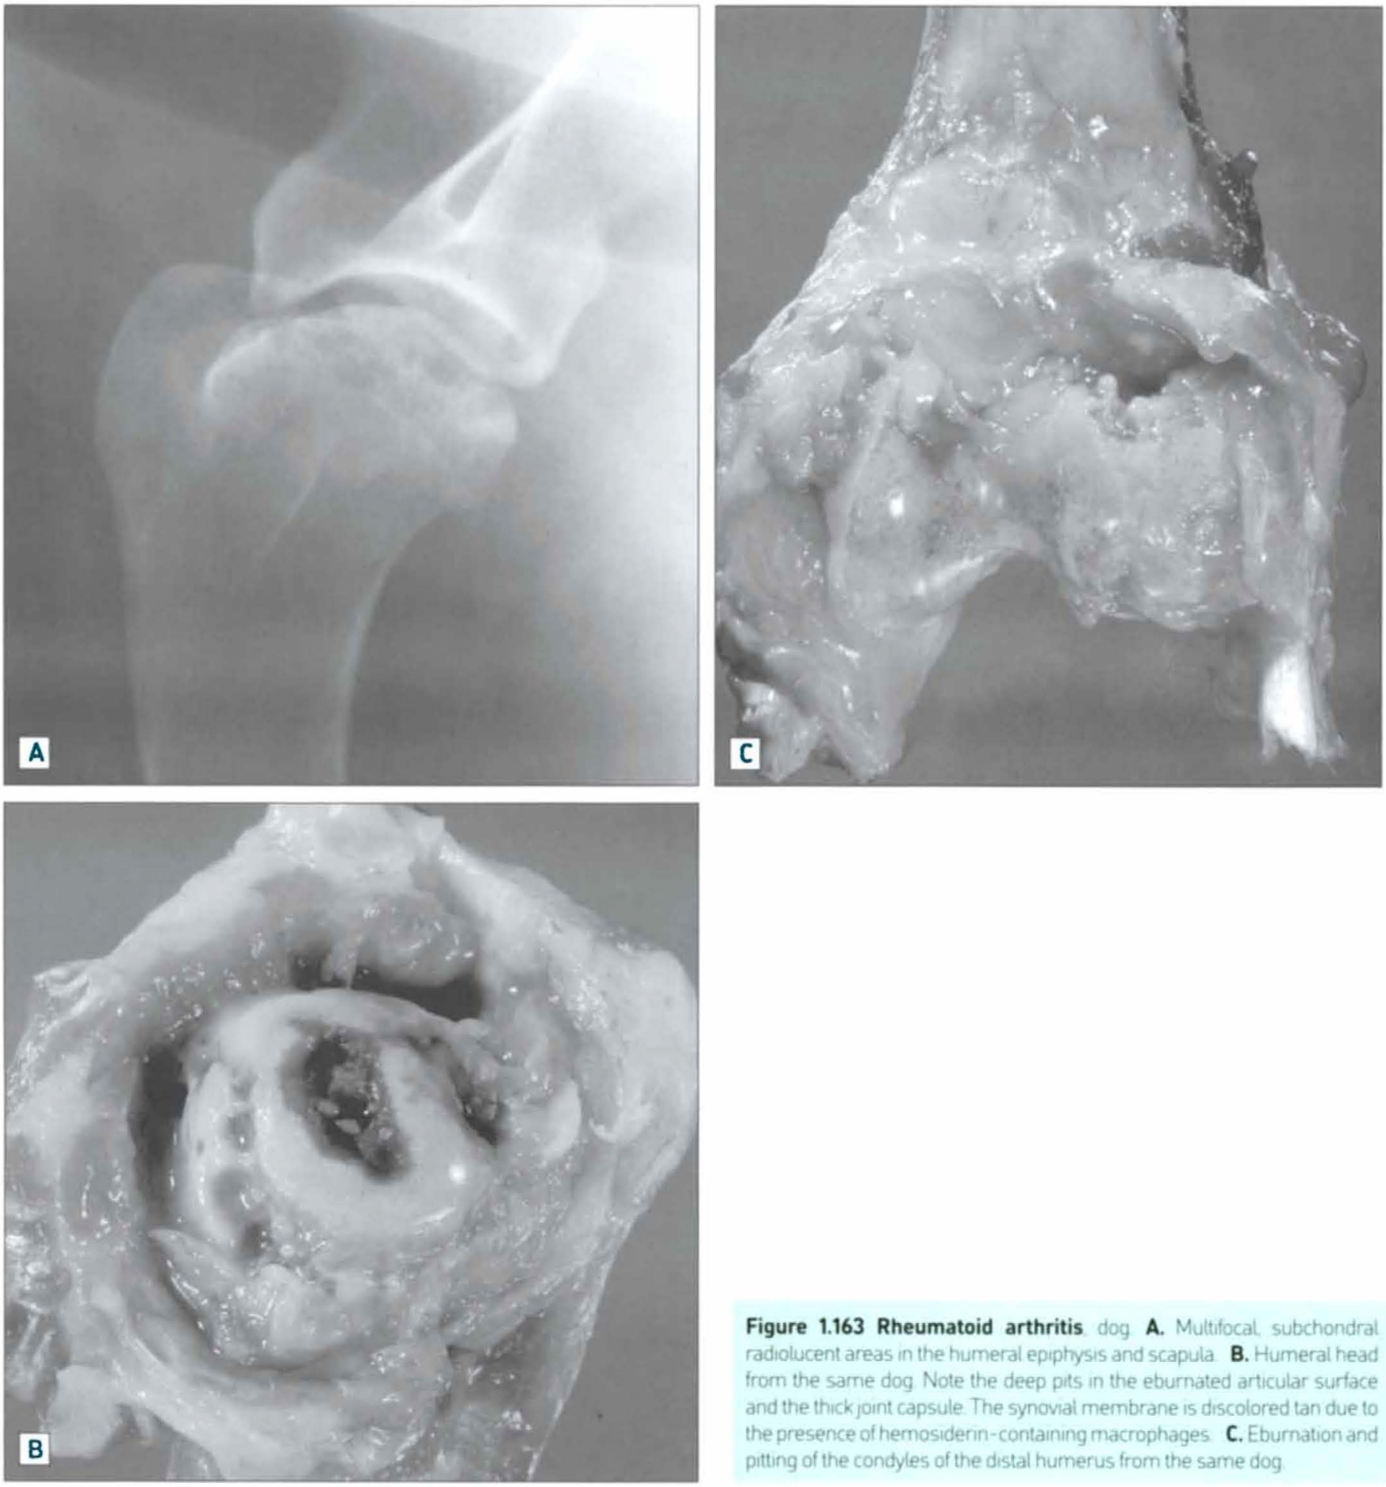

Figure 1.163 Rheumatoid arthritis, dog. **A.** Multifocal, subchondral radiolucent areas in the humeral epiphysis and scapula. **B.** Humeral head from the same dog. Note the deep pits in the eburnated articular surface and the thick joint capsule. The synovial membrane is discolored tan due to the presence of hemosiderin-containing macrophages. **C.** Eburnation and pitting of the condyles of the distal humerus from the same dog.

US. The disease affects dogs of both sexes and usually begins insidiously between 3 and 30 months of age. Mild to severe lameness and joint swellings, involving limb joints distal to, and including, elbows and stifles are observed clinically. Superficial lymph nodes are enlarged. Despite considerable effort, *no infectious agent has yet been identified and the syndrome does not appear to be related to athletic activity.*

Gross findings in affected joints include an excess of turbid synovial fluid, with fibrin clots in severe cases, yellow/brown discoloration, and thickening of synovial membranes, sometimes with adherent fibrin plaques, ecchymotic hemorrhages in the synovial membrane and erosions of articular cartilage. *Lesions are common in the first and second phalangeal joints, and in carpal, tarsal, elbow, and stifle joints.* Occasionally, shoulder, hip, and atlanto-occipital joints are involved.

Microscopic lesions include *necrosis of articular cartilage and proliferative synovitis.* The articular cartilage shows either full-thickness necrosis or necrosis of deep layers with relative sparing of superficial zones. Cartilage erosion sometimes extends to the subchondral bone. Typical changes in the synovium include villus hypertrophy, proliferation of synovial cells, and infiltration by lymphocytes, plasma cells, and neutrophils. In some areas, the lymphocytic infiltrates are

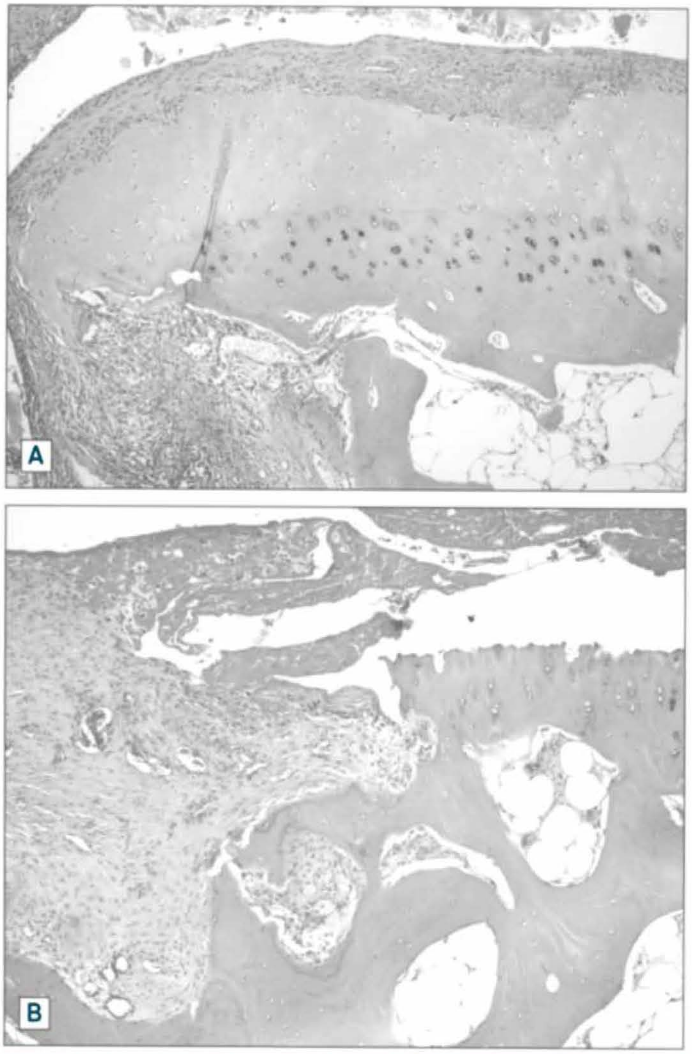

Figure 1.164 Rheumatoid arthritis, dog. **A.** Pannus spreading across articular cartilage from the joint margin. The cartilage beneath the pannus is degenerate. **B.** Granulation tissue invading the epiphysis and encroaching on the eroded articular surface. Note the osteoclasts resorbing bone in front of the advancing granulation tissue. Fibrin is adherent to the surface.

intense and may form follicles. There is no evidence of vasculitis. Pannus formation is often present, but never extensive, and changes in subchondral bone are usually minimal.

Feline chronic progressive polyarthritis

Two forms of this disease are recognized; an *erosive form*, which resembles rheumatoid arthritis of dogs and humans, and a more common form characterized by *periosteal proliferation*.

The **erosive form** occurs in older cats and can affect either sex. It has an *insidious onset, chronic progression,* and clinical signs are largely restricted to symmetrical deformities of the *carpus, tarsus, and digits* due to loss of joint margins, subluxation, collapse of joint space, and ankylosis. The synovial fluid contains low to moderate numbers of neutrophils and lymphocytes. Synovial membranes are heavily infiltrated with lymphocytes and plasma cells and enlarged synovial villi often contain prominent lymphoid follicles with germinal centers. Rheumatoid factor is absent. Infection with *Feline leukemia virus* is present in about 50% of affected cats.

The **periosteal proliferative form** occurs only in relatively *young, intact or neutered male cats,* usually between 18 months and 5 years of age. The disease is etiologically *linked to infection with Feline syncytia-forming virus and Feline leukemia virus.* Evidence of *Feline syncytia-forming virus* infection is present in all affected cats and 60% also have evidence of *Feline leukemia virus* infection, but the disease cannot be reproduced by experimental infection with either of the two agents, or with cell-free synovial tissue from affected cats. Because many cats are infected with both viruses without ever becoming ill, it is thought that the periosteal proliferative form of feline chronic progressive polyarthritis is an *unusual manifestation of Feline syncytia-forming virus infection in cats that are somehow predisposed.* The role of *Feline leukemia virus* is unclear, but it may potentiate the activity of the other viral agent. A similar syndrome has been reported in a 4-year-old cat that was seropositive for both *Feline syncytia-forming virus* and *Feline immunodeficiency virus.*

The disease is characterized by sudden onset of high fever, severe pain in joints and tendon sheaths, and lymphadenopathy associated with affected joints. Synovitis is initially characterized by the presence of *fibrinopurulent synovitis but later, plasma cells and lymphocytes predominate.* Rheumatoid factor is absent. Synovial lining cells are hyperplastic throughout the course of the disease, but villus hypertrophy and pannus formation are uncommon until late in the disease. Swollen lymph nodes biopsied early in the disease have exuberant lymphoid hyperplasia, including marked extracapsular extension, and could be mistaken for lymphosarcoma.

The skeletal lesions are bilateral and *most frequently involve the tarsometatarsal and carpometacarpal joints,* but the elbow and stifle joints, and the articular facets of the thoracic and lumbar spine, may also be affected. The periosteal new bone consists of trabeculae of woven bone and the intertrabecular spaces often are infiltrated with lymphocytes and plasma cells. Pannus formation usually occurs late in the disease and leads to periarticular erosions of joint margins, collapse of joint spaces, and fibrous ankylosis, but subluxation is not a feature. This pattern of disease is similar to Reiter's arthritis of humans.

Nonerosive arthritis

There are several diverse causes of noninfectious, nonerosive arthritis in dogs and cats, but the mechanism in each syndrome appears to be immune mediated and the presenting signs are similar. Clinically, the joint disease tends to be intermittent, and periods of remission may occur. One or several joints of the distal limbs may be involved, particularly the smaller joints of the manus and pes. There are essentially no radiographic changes except for joint distension and soft tissue swelling, although signs may have been present for months. Occasionally, slight narrowing of the joint space is evident, and distension of the joint cavity is demonstrable by contrast arthrography. Gross lesions in affected joints are minimal. Histologically, there is edematous thickening and inflammation of the synovial membrane. Neutrophils are concentrated at the intimal layer of the synovium and may be quite numerous, depending upon the stage of the disease. Sparse accumulations of plasma cells and lymphocytes are present in the deeper layers of the synovium and fibrous joint capsule. Villus hyperplasia and pannus are not seen.

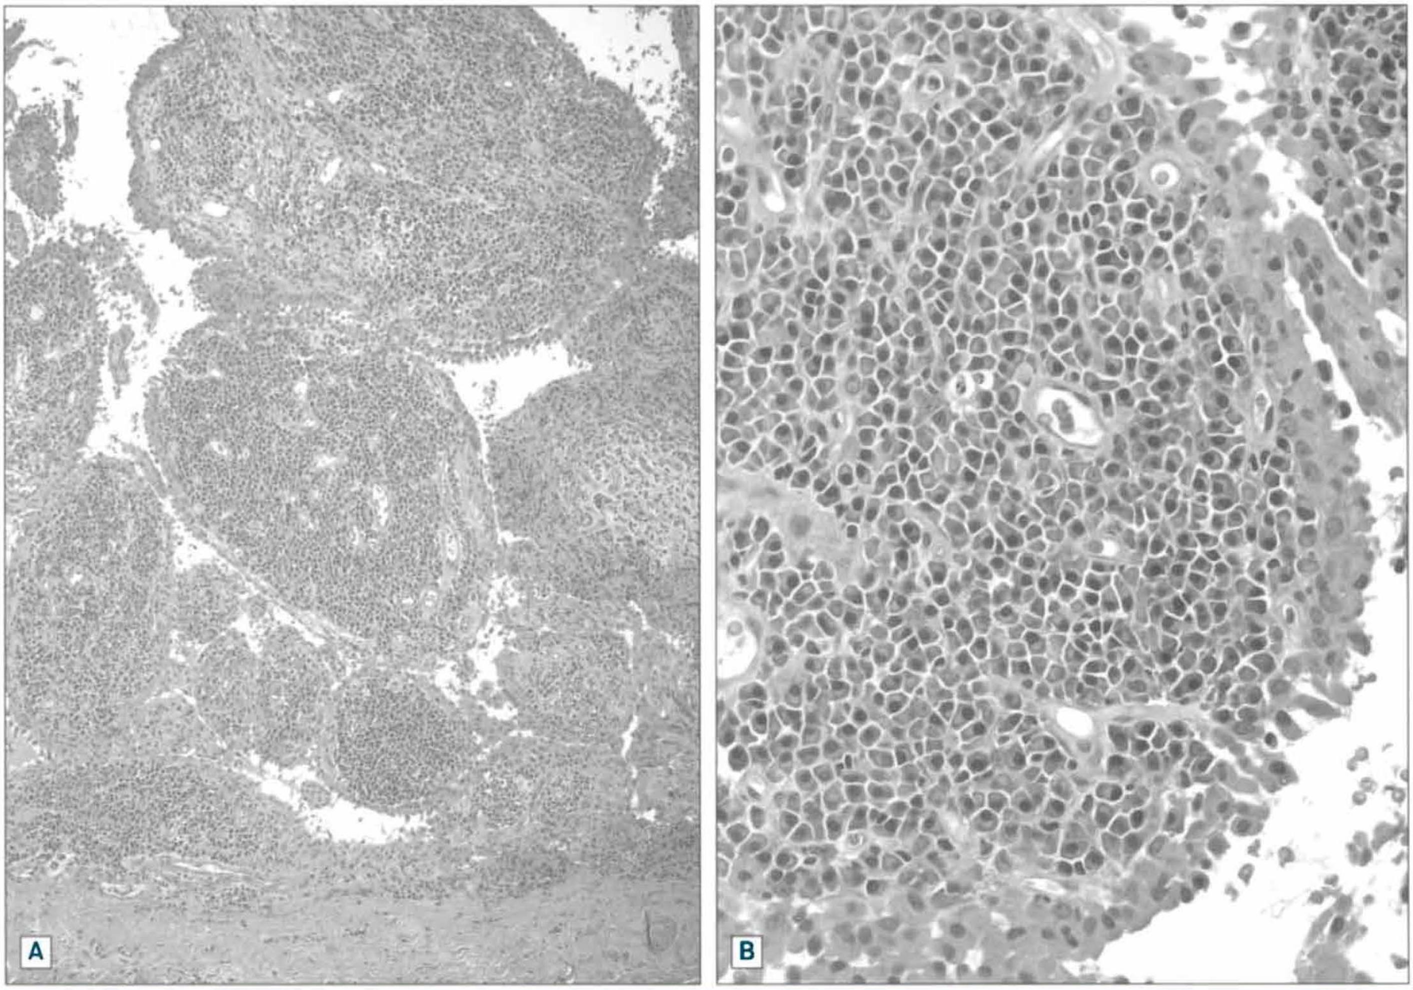

Figure 1.165 Lymphocytic/plasmacytic synovitis, dog. **A.** Hypertrophic villi heavily infiltrated with mononuclear cells in the stifle joint of a dog, 2 years after surgery for correction of patellar luxation. **B.** High-power view of a villus from the same dog. The villus is infiltrated with an almost pure population of plasma cells. Note the hypertrophy and hyperplasia of synovial cells.

Synovial fluid cytology is useful in the diagnosis of noninfectious, nonerosive arthritis, but is not specific and often does not allow differentiation from infectious arthritis or from erosive forms of noninfectious arthritis. The characteristic feature is a mild to moderate increase in cellularity, most cells of which are nondegenerate neutrophils.

Idiopathic polyarthritis is considered the most common form of nonerosive, immune-mediated arthritis in dogs, but is diagnosed only when other types of inflammatory joint disease have been excluded. Arthritis is the only manifestation, but pyrexia, inappetance, and lethargy generally accompany the lameness. The polyarthritis associated with **systemic lupus erythematosus** of dogs and cats is similar to that of idiopathic polyarthritis, but may be accompanied by evidence of disease in other organs systems, such as the skin, kidney, bone marrow, or neuromuscular system. *In many cases, only the presence of antinuclear antibody in serum distinguishes the two syndromes.* Neutrophils containing phagocytosed, partially degraded nuclear material, referred to as lupus erythematosus cells (LE cells), are rarely detected in the synovial fluid of animals with systemic lupus erythematosus. The phagocytosed nuclear material in LE cells is dense, diffusely pink or purple, and displaces the nucleus to the periphery of the cell. Leukophagocytic macrophages and neutrophils containing more granular nuclear remnants are common in the synovial fluid of acutely inflamed joints and should not be misinterpreted as LE cells.

Nonerosive polyarthritis has been recognized in animals and humans in association with a **variety of chronic diseases**, such as bacterial endocarditis, urinary tract infections, diskospondylitis, periodontitis, chronic otitis media or interna, pyometra, dirofilariasis, and fungal infections. **Inflammatory bowel disease** has also been associated with polyarthritis in canine and human patients. Although the possibility that infection may be involved in some of these nonerosive forms of polyarthritis is virtually impossible to exclude, the weight of evidence suggests that the synovitis is secondary to deposition of circulating immune complexes in the synovial capillary bed. In those cases associated with inflammatory processes at other sites, the inflammation presumably does not persist long enough, or is not severe enough, to initiate pannus formation or induce cartilage erosion. In the most common primary or idiopathic form, the origin and nature of the antigen responsible for initiating the disease is unknown.

Drug-induced polyarthritis, thought to be immune-mediated, develops in a small proportion of dogs, particularly Dobermans, treated with *sulfonamides*. Combination drugs containing sulfadiazine are usually responsible but sulfamethoxazole is also incriminated. The drug may act directly as *an antigen or as a hapten* in combination with host proteins. Signs of polyarthritis and fever, sometimes with lymphadenopathy, anemia, leukopenia, and thrombocytopenia, develop after 8–20 days of treatment. Clinical signs regress within 2–5 days of drug withdrawal and, in one report, recurred within 2 hours to 5 days in six of six dogs that were re-exposed.

A syndrome characterized by nonerosive **polyarthritis** and **polymyositis** has been reported in six young adult dogs, five of which were Spaniels. Clinical signs included stiffness, pain and swelling of multiple joints, muscle pain, muscle atrophy, and pyrexia. Affected dogs have no circulating antinuclear antibodies or rheumatoid factors but show chronic active inflammatory changes in muscle and synovial membrane biopsies.

Plasmacytic/lymphocytic synovitis is an insidious, nonerosive arthritis involving primarily the *stifle joint of small and medium-sized breeds of dog*. The syndrome may be accompanied by joint laxity and partial or complete rupture of the cranial cruciate ligament but it is seldom possible to determine which lesion came first. It is possible that the synovitis in these animals reflects an exaggerated immune response to mediators or antigens released following ligament damage, surgical correction, or as a result of an ensuing degenerative joint disease. Radiographic evidence of degenerative joint disease may be present in some cases. The synovial membrane is thickened, edematous, and red/yellow on gross examination. Microscopic examination reveals a *marked diffuse and/or nodular plasmacytic/lymphocytic infiltration of the synovium and hypertrophy of synovial cells* (Fig. 1.165A, B). Villus hypertrophy may also be a feature. Unlike other forms of immune-mediated arthritis, the increase in cellularity of the synovial fluid is due predominantly to small mononuclear cells rather than neutrophils, the latter comprising only 10–40% of the cell population.

TUMORS AND TUMOR-LIKE LESIONS OF JOINTS

A range of neoplastic and non-neoplastic lesions occurs in domestic animals in the vicinity of joints, but most are rare and poorly characterized. The most recent World Health Bulletin on the histological classification of bone and joint tumors lists only synovial sarcoma and villonodular synovitis as tumors and tumor-like lesions of joints and related tissues. Although veterinary pathologists recognize many lesions other than these two, only the most common are included here. For further information, the reader is referred to the bibliography at the end of this section.

Tumors in the region of joints may be either *benign or malignant* and *arise from synovioblastic cells* in the synovial membrane *or from a range of supporting structures*, including fibroblastic, vascular, and nervous tissue. Because of the similarity between synovial tumors and other mesenchymal tumors, the potential for misdiagnosis is high, especially when these lesions occur so infrequently and diagnostic criteria are largely extrapolated from the human medical literature.

As with tumors of bones, the availability of a detailed clinical history and knowledge of the radiographic and gross findings prior to microscopic examination of the lesion are likely to enhance the accuracy of the diagnosis. In particular, radiography will usually indicate whether the lesion is centered on a joint or tendon sheath, the presence of mineralization, and any bone involvement. Cytological evaluation of fine-needle aspirates or scrapings prepared from tissue biopsies may provide useful information on the nature of the tumor cells, but in most cases, histologic examination is required.

Benign tumors and tumor-like lesions of joints

Although several benign proliferative lesions of the synovium have been described in man and animals, most are rare and, for many of them, there is debate over whether they are neoplastic or inflammatory.

Pigmented villonodular synovitis is recognized occasionally in the *major weight-bearing limb joints, particularly the stifle and hip, of* *adult dogs*. Grossly, the synovial membrane in affected joints is thickened with plump, tan or dark brown villi and articular surfaces show features of mild degenerative joint disease. Histologically, the thickened synovial membrane consists of *closely packed villi of various sizes and shapes, and slit-like spaces lined by synovial cells*. The spaces may represent tangential sections through gaps between adjacent villi. Hyperplastic synovial cells are present throughout much of the thickened synovium but do not invade the joint capsule and although binucleate forms are often present, they show no cytologic features of malignancy. Multinucleated giant cells are sometimes present, together with hemosiderin-containing macrophages. *The lesion may be difficult to differentiate from chronic infectious synovitis, or a chronic synovial response to either hemarthrosis or degenerative joint disease.*

Villonodular synovitis of the *equine metacarpophalangeal or metatarsophalangeal joints* is a chronic inflammatory condition characterized by the formation of a nodular mass involving the synovium near the dorsoproximal attachment of the joint capsule. As mentioned earlier in this chapter, this lesion is considered *secondary to persistent trauma* and has features of a resolving hematoma.

Localized nodular tenosynovitis is another benign lesion of questionable origin and with a variety of synonyms in the human literature, including benign synovioma; a term that is no longer advocated for use in either humans or animals. The lesion has been reported only occasionally in *dogs*, although nodular lesions of tendons previously diagnosed as benign synovioma probably constitute additional examples of localized nodular tenosynovitis. The most common sites for these firm, solitary lesions are the *tendons and tendon sheaths of the extensors and flexors of the feet, particularly in the region of the metacarpus and metatarsus*. The microscopic appearance varies between and within lesions, but usually includes cellular areas containing proliferating synoviocytes, hemosiderin-containing macrophages, multinucleated giant cells and mononuclear inflammatory cells. Cleft-like spaces lined by synoviocytes are often present in some areas. There are *similarities between this lesion and benign giant cell tumor of tendons and tendon sheaths*, and it is possible that these are variants of the same disease process.

Benign giant cell tumors of tendons and tendon sheaths appear to arise from synovioblastic cells surrounding tendons and tendon sheaths and are relatively common in animals. Microscopically, the lesion is characterized by the presence of *numerous multinucleated giant cells, which are thought to develop from proliferating synovioblasts*. Some lesions are predominantly solid while others contain many cleft-like spaces. The tumor cells show no convincing features of malignancy but, although they do not metastasize, recurrence following surgical removal is likely.

Benign vascular lesions referred to as either **synovial hemangiomas** or **vascular hamartomas** have been reported in the *carpal and digital sheaths of the forelegs in young horses*. The lesions may be apparent from an early age and enlarge slowly, or may become acutely apparent following rupture and formation of hematomas. Microscopically, the lesions consist of *multiple nodules of well-differentiated capillaries separated by septa of fibrous tissue*. Apparent invasion of adjacent structures, including tendons, occurs in some cases, but the endothelial cells lining capillaries show no features of anaplasia, and metastasis is not reported. Reports of hemangiosarcomas involving the tendon sheaths of young horses are most likely further examples of benign vascular tumors that would be more appropriately classified as vascular hamartomas.

Synovial chondromatosis (osteochondromatosis) is a tumor-like lesion characterized by the presence of *multiple nodules of hyaline cartilage, some of which may undergo ossification, in the synovial membrane*. Although synovial chondromas are widely considered to arise by metaplasia of synovial cells within the synovial membrane, an alternative hypothesis suggests that the cartilage nodules may in fact be derived from fragments of cartilage from the articular surface. Such fragments released into the joint space may continue to enlarge within the joint as they derive their nutrients from the synovial fluid. Some may become incorporated into the synovial membrane, where they could also survive and grow within the richly vascular synovial membrane and, in some cases, become ossified following vascular invasion. This mechanism is most likely in cases where there is an associated degenerative joint disease, but the syndrome sometimes occurs in the synovial membrane of apparently normal joints or bursae. In such cases, chondroid metaplasia of synovial mesenchymal cells is a more attractive pathogenesis.

Various other benign, tumor-like lesions occurring in the vicinity of joints, including **tumoral calcinosis** and **fibrodysplasia ossificans progressiva** are discussed earlier in this chapter under the heading Ectopic mineralization and ossification.

Malignant tumors of joints

Because of the infrequent occurrence of these tumors in animals, their classification has largely been based on extrapolation from the medical literature. This has not been straightforward, as the classification of certain malignant periarticular tumors of humans is confusing. For example, there is evidence that tumors classified as synovial sarcoma in human patients are not of synovial origin at all. Furthermore, there is debate over the use of such terms as malignant fibrous histiocytoma and malignant giant cell tumors of soft parts, both in animals and humans. The use of such categories in this section is more in recognition that they are well established in the veterinary literature than an endorsement of their validity. *A more precise and widely accepted classification system for malignancies of joints will necessitate the use of immunochemical or molecular techniques to better determine the histogenesis of the tumor cells.*

Synovial sarcoma in humans is characterized by a biphasic pattern, comprising both *mesenchymal and epithelial elements*. In some tumors, a "pseudoglandular" appearance is created by epithelial elements, which often form irregular cleft-like spaces surrounded by neoplastic mesenchymal cells. In other cases, the mesenchymal elements predominate and the tumor may be difficult to differentiate from other sarcomas, particularly fibrosarcoma. The neoplastic epithelial cells in these tumors possess tight junctions and are arranged on a basal lamina. In addition, they stain positively with the epithelial markers cytokeratin and epithelial membrane antigen. *Synovial cells are of mesenchymal, rather than epithelial, origin* and are not arranged on a basal lamina. The fact that these tumors in human patients frequently occur at sites distant from joints creates further doubt over their synovial origin and suggests that extrapolation to animals is inappropriate.

Synovial sarcoma is rare in animals, but has been reported in dogs and occasionally in cats and cattle. In **dogs**, synovial sarcoma is reported mainly *in large but not giant breeds* and although it is most common around middle age, the *age range is broad* (1–15 years). The tumor is found most often near one of the *major weight-bearing joints*, the *stifle* being the most common and followed in decreasing order by the elbow, shoulder, tarsus, carpus, and hip. Occasionally, joints of the axial skeleton are involved. Synovial sarcoma may also originate from the region of *tendons or tendon sheaths*, usually the flexor or extensor tendons of the limbs proximal to the carpus and tarsus. Grossly, *the tumor has indistinct borders* and may infiltrate along fascial planes leading away from the affected joint. Some synovial sarcomas contain cystic spaces filled with mucinous material. The synovial membrane may be largely replaced by tumor tissue and invasion of epiphyseal bone may occur at the insertion of the joint capsule.

Histologic descriptions of synovial sarcoma in animals frequently imply the presence of two distinct cell populations by reference to a synovioblastic or "epithelioid" cell type and a fibroblastic cell type. This no doubt reflects extrapolation from synovial sarcoma in humans, although *there is some doubt that these biphasic tumors actually occur in animals.* The tumor cells in synovial sarcomas of animals may vary in shape from polygonal to spindle-shaped, the relative proportion of each type varying between tumors, and even within the same tumor. *In cases with a predominance of spindle cells, the tumor may be virtually indistinguishable from fibrosarcoma, but other tumors may consist predominantly of sheets of synovioblastic cells more closely resembling normal synoviocytes.* Cavities or slit-like spaces containing *proteinaceous fluid or mucoid material* and lined by a poorly defined layer of malignant synovioblasts may form within sheets of tumor cells (Figs 1.166A, B, 1.167A). The malignant synovioblastic cells of synovial sarcoma often have eccentric circular to oval nuclei, which vary in size and may contain one or more prominent nucleoli. The mitotic rate is highly variable, as is the frequency of binucleate and multinucleate giant cells. Individual cells may be surrounded by an eosinophilic matrix resembling osteoid (Fig. 1.167B), sometimes leading to an incorrect diagnosis of osteosarcoma. In some canine synovial sarcomas, especially those involving tendons or tendon sheaths, *nodules of myxomatous tumor tissue* are scattered among areas that are more solid. The myxoid matrix may surround individual stellate tumor cells, clusters of tumor cells, or fill multiple spaces within the tumor. Synovial sarcomas with abundant myxoid change are difficult to differentiate from myxosarcoma or malignant peripheral nerve sheath tumors. The perivascular orientation of synovioblastic or fibroblastic tumor cells in some tumors might also cause confusion with hemangiopericytoma, especially in lesions where there is infiltration of the skin adjacent to the joint or tendon sheath.

In cytologic preparations, synovial sarcoma may yield a population of plump, malignant mesenchymal cells with eccentric nuclei and basophilic cytoplasm, together with variable numbers of spindle cells and multinucleated giant cells, but histopathology is required to reliably differentiate the tumor from osteosarcoma and various other sarcomas.

Canine synovial sarcomas *commonly recur following surgical excision* and, in one study, *20 of 37 cases (54%) metastasized.* Metastases were found most often in the lungs and regional lymph nodes. The clinical course may vary from less than a month to greater than a year.

Only isolated cases of synovial sarcoma are reported in species other than dogs, and the diagnosis is not always conclusive.

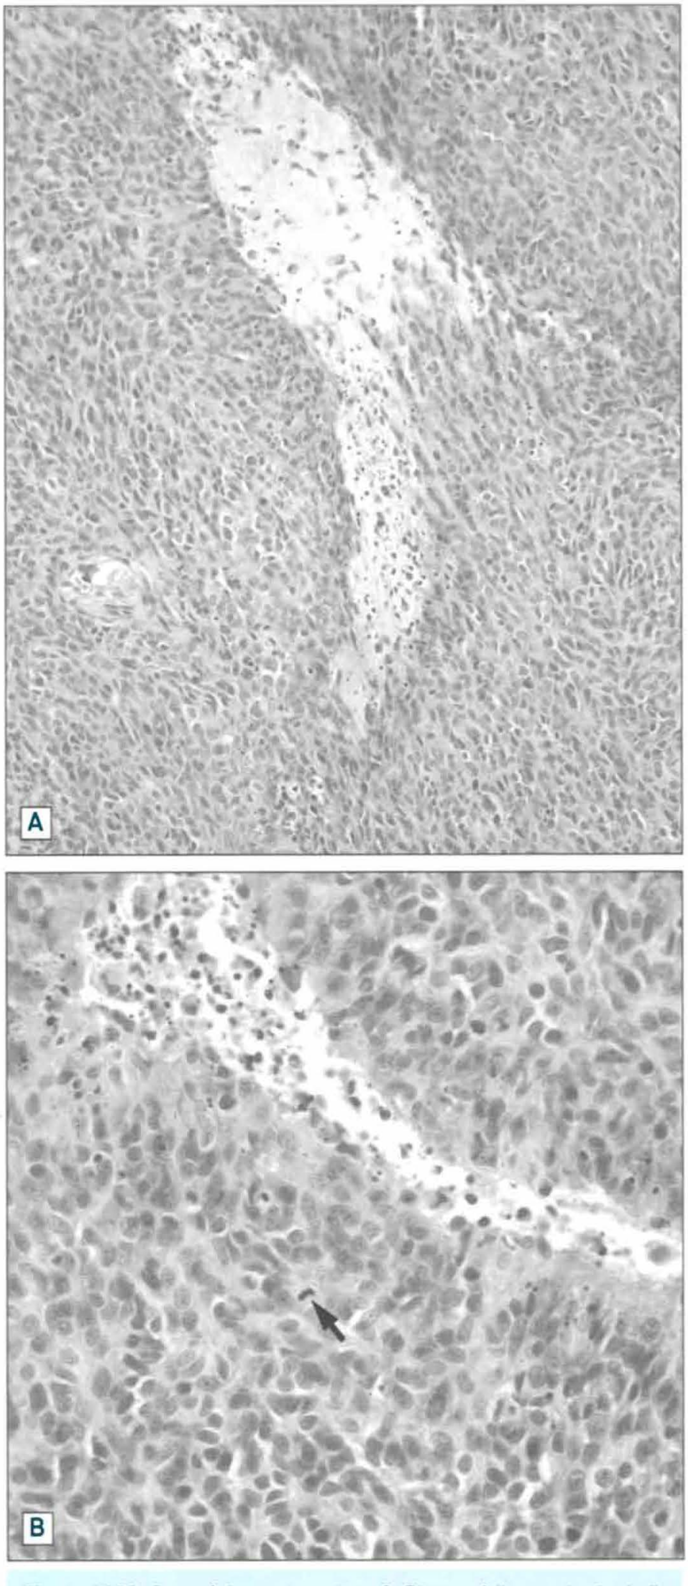

Figure 1.166 Synovial sarcoma, dog. **A.** Sheets of disorganized spindle cells surrounding and lining a poorly defined cavity. **B.** Higher-power view of the same tumor showing a narrow cleft surrounded by tumor cells. Occasional mitotic figures are present (arrow).

Histiocytic sarcoma is recognized as a *rapidly growing, locally aggressive tumor* often occurring in *close proximity to a joint in dogs*, particularly flat-coated Retrievers, Golden Retrievers, Labrador Retrievers, Bull Mastiffs and Rottweilers. The tumor has been recognized in dogs of both sexes from 4 to 13 years of age. Similar tumors also arise from the skin or subcutaneous tissue and infiltrate underlying tissues. It is likely that many histiocytic sarcomas originating in the joint capsule are incorrectly diagnosed as synovial sarcoma.

A recent retrospective study of 35 canine synovial tumors, using immunochemical staining for antibodies to cytokeratin and CD18, found that 51% of them were histiocytic sarcomas.

Dendritic (Langerhans) cells, which are known to occur in the synovial membrane, are considered the cell of origin of histiocytic sarcomas in the region of joints, although precise classification of the tumor requires the development of specific immunochemical stains.

Clinically, the tumor produces soft tissue swellings around or in the vicinity of major limb joints and may be accompanied by lytic lesions in the epiphyses or metaphyses of adjacent bones. On gross examination, the synovial membrane and joint capsule may show marked nodular or diffuse thickening with gray/pink, fleshy tumor tissue (Fig. 1.168A), which may extend into adjacent soft tissues. Histologically, *the synovial membrane and joint capsule are infiltrated with malignant histiocytic cells*, sometimes forming nodules protruding into the joint space (Fig. 1.168B) or causing marked thickening of synovial villi. The nuclei of tumor cells vary considerably in size and shape, and often contain large, irregularly shaped nucleoli (Fig. 1.168C). The cells have a moderate to large quantity of eosinophilic cytoplasm, which sometimes contains many small vacuoles. Multinucleated giant cells with variable-sized nuclei are common and the mitotic rate is usually high. Neutrophils, eosinophils, lymphocytes, and plasma cells may be present in variable numbers throughout the tumor. Similar tumor cells may be present between bone trabeculae in adjacent bones, presumably due to direct invasion from the attachment of the joint capsule or the adjacent muscle. *Cytological preparations* generally reveal a monomorphic population of large round cells with circular to oval or indented nuclei and abundant cytoplasm, which may contain many discrete vacuoles (Fig. 1.169A, B). Multinucleated giant cells containing nuclei of various sizes are common, as are abnormal mitotic figures.

Canine histiocytic sarcoma is not only locally aggressive, but *frequently metastasizes* to regional lymph nodes and occasionally to the lungs and other visceral organs. In the retrospective study referred to above, 91% of histiocytic sarcomas metastasized, and the average survival time was 5.3 months. The prognosis is therefore poor, and early diagnosis followed by amputation of the affected limb offers the best chance of survival.

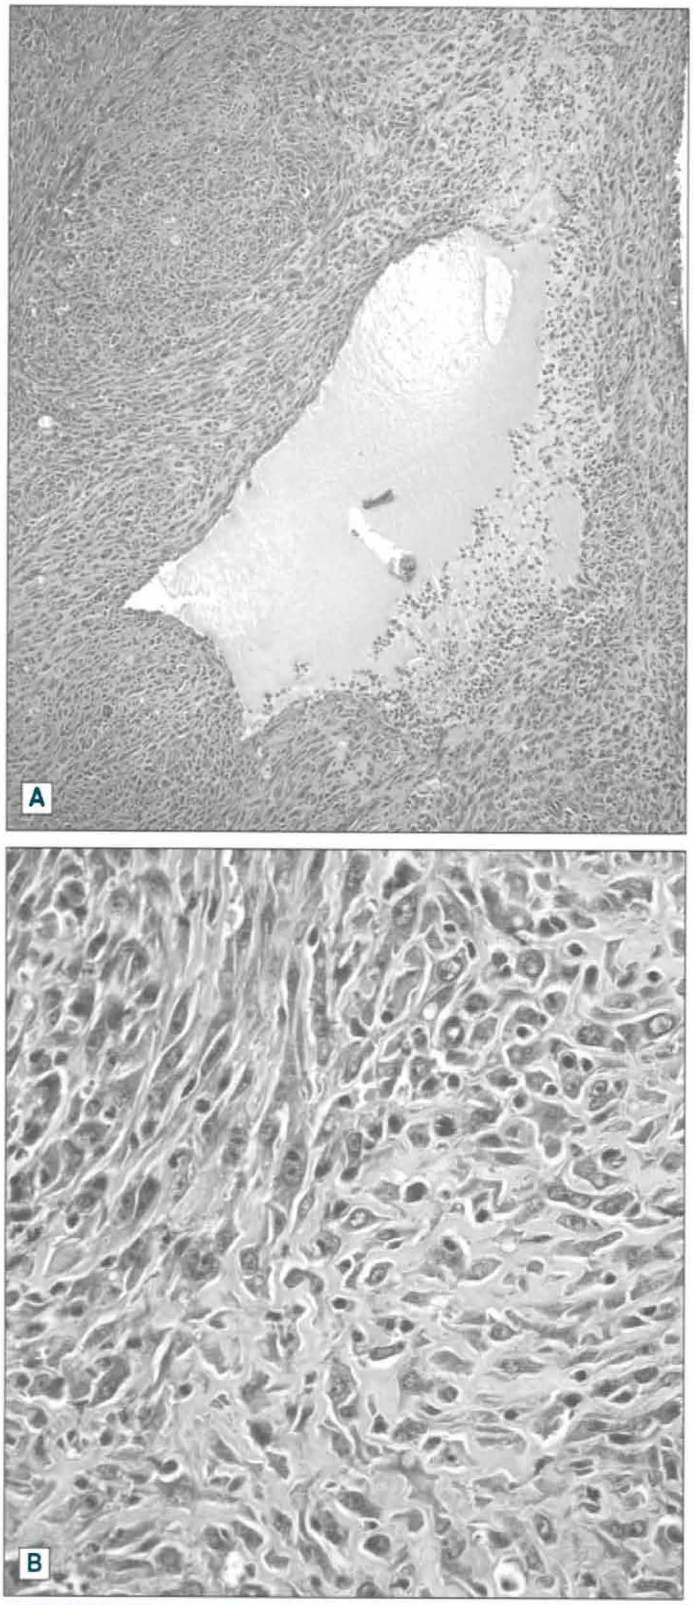

Figure 1.167 Synovial sarcoma, dog. **A.** Large cavity surrounded by malignant synovioblastic cells and containing proteinaceous fluid. **B.** Same tumor at higher power showing fusiform to polygonal tumor cells, many of which are surrounded by eosinophilic matrix similar to osteoid.

ACKNOWLEDGMENTS

Dr. Thomas J. Hulland (University of Guelph), author of this chapter in the 2nd, 3rd, and 4th editions, is fully acknowledged for his great contribution to the original text and illustrations. Dr. M. Donald McGavin (University of Tennessee) generously gave his time and energy to review this chapter and assist with photomicroscopy. We also appreciate the manuscript review and comments of Dr. Brad Hanna (University of Guelph).

Muscles

DEVELOPMENT AND STRUCTURE

Development

Development of striated muscle in the embryo is from *mesodermal somites,* which give rise to *myotomes.* Within each myotome, which corresponds roughly to a vertebral body segment, with its spinal nerve, the individual muscles develop by a process of aggregation and migration of presumptive myoblastic cells. It is very likely that the undifferentiated mesodermal cells will be committed to a muscle destiny some time before significant structural change is visible, and the earliest detectable modification to presumptive myoblasts is a cross-sectional rounding of the spindle-shaped cells. By this time as well, there may be subtle distinctions between those cells that will become myofibers and those that will become satellite cells.

The first clear sign of differentiation is the *migration of presumptive myoblasts,* destined to become myofibers, into the regions where future muscles will appear; this occurs before any nerve influence is exerted. The direct connection of the nerve to the myotome determines the subsequent route of innervation, but because migration has occurred, the muscle may receive nerve sprouts (as it has received myoblast group components) from more than one myotome.

The second phase of muscle development is incompletely separated from the first and subsequent phases. It begins with the *early development of sarcoplasmic components,* such as myofibrils, which identify the cells as muscle. The commitment to myogenesis is mutually exclusive with cell replication, and, with possible rare exceptions, committed myoblasts are post-mitotic. Myoblasts begin to fuse into elongated multinucleated cells about the time myogenesis begins.

Subsequent development of the myotube allows it to become a well-developed muscle fiber and consists of stepwise construction of *actin and myosin filaments,* the formation of the *Z band* into which the thin actin filaments insert, and the evolution of the *tubular systems.* The last of these steps, the invagination of the T tubular system from caveolae or other small, regular recesses on the outer sarcoplasmic membrane, provides an elaborate system of tubules that run parallel to the Z bands and make contact with all developing myofibrillar units.

The fourth phase of development is one in which the evolving fiber grows, increases the number of myofibrils and nuclei, and moves the latter to the subsarcolemmal position. During the final phase of development, the development of a basal lamina and an additional sheath of collagen, fibroblasts and capillaries invest each developing myotube as orientation of the fiber into its final position of tension takes place. Development of fibers up to this point, just after the end of the first trimester, is independent of any neural connection, but subsequent fiber enlargement and the considerable increase in the number of fibers that occurs during the immediate prenatal and postnatal periods, is dependent on a functional neural connection. The terminal differentiation of skeletal muscle is therefore largely determined by the characteristics of the neural connections although locally acting myogenic factors also contribute.

The genetic and molecular events in muscle development, and also in muscle regeneration, are rapidly becoming known. As might be expected, the organization and control of gene and protein expression during muscle cell specification and differentiation is complex. *Myogenic regulatory factors* (MRF) are centrally involved in transcription regulation in muscle and include MyoD, myogenin, Myf5, and MRF4. These muscle-specific proteins and a variety of growth factors influence gene and protein expression during the development of skeletal muscle.

The muscle fiber increase in late gestation in domestic animals is probably comparable in all species, but it has been particularly well studied in the pig and is more orderly in that species than in others. Within what will become a primary bundle of muscle fibers, *1–6 primary or template myofibers become the focal point of the proliferation* that, by early postnatal life, has produced one or more sublobular clusters of fibers within each primary bundle. It is not clear whether new fibers are produced next to the template fiber by a process of template fiber budding, or by incomplete or complete longitudinal division. Alternatively they may be derived from local myoblastic or satellite cells that begin development within the basal lamina of the primary fiber and then separate and develop their own completely investing basal lamina. What is clear is that they are produced in waves, with subsequent fibers pushing those formed earlier to the periphery of the sublobule. Template fibers are always histochemically type 1, but the newly formed fibers are type 2 until near the time of birth when a proportion of them (few or several depending on the muscle and the species) which lie closest to the template fiber will begin to modify to become type 1 fibers (Fig. 2.1A, B). The latter process may continue for 6 months or more after birth, and it may be that the process reverses again in early postnatal life in some muscles of the body.

During the period when templating is occurring, new fibers rapidly become innervated and, it seems, do not later change neural connections. In view of the described changes of fiber type, thought to be associated with exercise, it is difficult to reconcile other evidence that suggests that a single motor nerve axon can serve only one histochemical type of muscle fiber. The paradox may be resolved if it is accepted that some fibers have, or develop, different kinds of energy metabolism that they use selectively depending on work demands. Alternatively, a change in the activity of the nerve may induce biochemical changes in the muscle fiber clusters, and hence a change in fiber type identity. This explanation is consistent with the fact that the functional capacity of a muscle fiber is limited by its nerve connection and its cytoplasmic components and of these probably only the latter can be modified.

Gross anatomy

Muscle structure is arranged around *muscle fibers.* Muscle fibers are variable in size depending on age, exercise, nutritional status, position and function of the muscle in question, and on species, although the fibers of a mouse are only a little smaller than those of a horse. Muscle fibers in the extrinsic muscles of the eye are consistently small (10–30 μm in diameter) and round; those of the major limb muscles vary from an average least diameter of 40–65 μm and, although rounded in the fresh state, often appear polygonal when

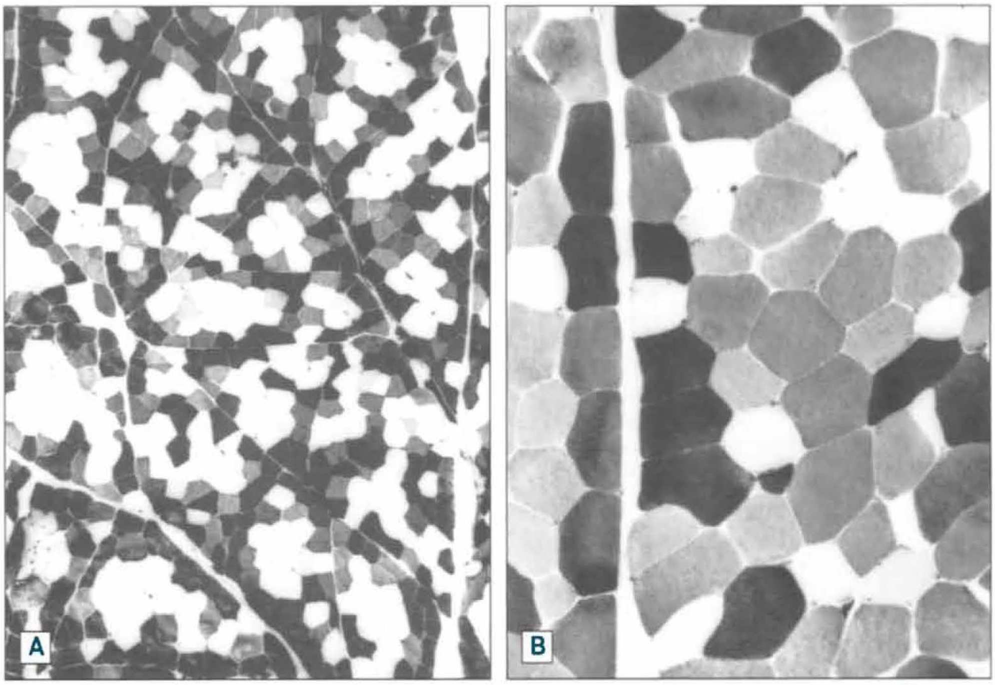

Figure 2.1 A. ATPase (alkaline) histochemical preparation of normal calf muscle to show light type 1 sublobular "**template clusters**." **B. Dark type 2 fibers** clustered along edges of primary bundles. (Courtesy of TJ Hulland.)

fixed. The size of fibers increases with age until puberty, at which time males have slightly larger fibers than females. In old age, with certainty, but perhaps beginning in early maturity, the fiber diameter slowly decreases. In those domestic animals that have been studied, the size distribution of muscle fibers conforms more or less to a biological distribution curve, although in most postural muscles the curve is skewed by a small population of large fibers extending upwards from the expected upper size limit. In most instances, these large fibers are from the type 1 fiber population, but in some muscles in some species they may be from the type 2 group. A distinctly bimodal curve readily develops in a muscle when disease, pregnancy, or nutritional status prompts withdrawal of muscle protein for general maintenance. This also increases the likelihood that large fibers will be round rather than polygonal in routine preparations.

Microscopic structure

The **structure of the muscle cell** or muscle fiber is quite well defined (Fig. 2.2). The outer component is a thin amorphous, but apparently quite tough, *basal lamina* consisting of three layers which, on most muscle cell surfaces, seems to be thrown into gentle folds. Atrophy of the fiber leads to much more obvious accordion-like folds of the basal lamina. *Within this basal lamina are two separate cell populations with very similar nuclei: the multinucleate myofiber, and the small, more numerous satellite cells,* which play an important role in fiber repair and regeneration (Fig. 2.3A, B). The nuclei of both cell types are oriented to the long axis of the muscle fiber and are distributed regularly in a spiral manner. In normal muscle, less than 3% of the nuclei of the multinucleate myofiber cell are displaced internally, but

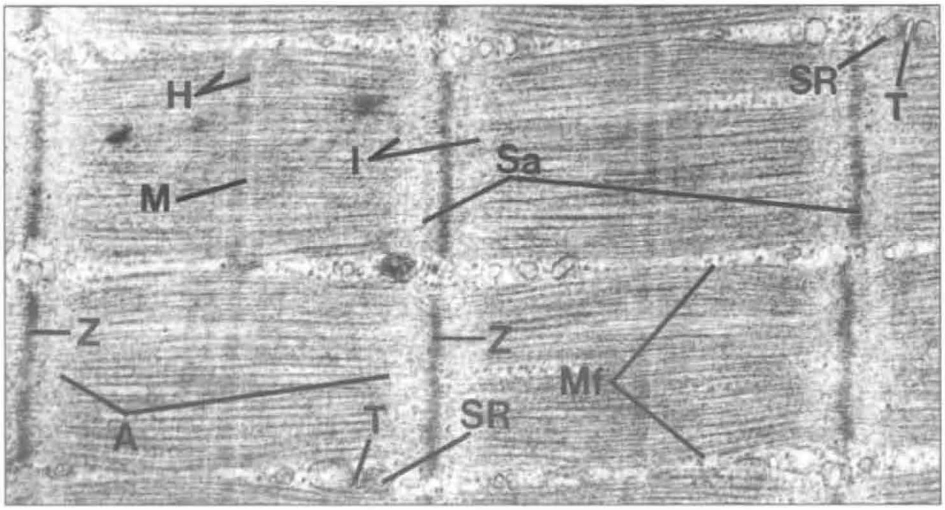

Figure 2.2 Normal horse muscle. Anisotropic band (A), H band (H), isotropic band (I), M line (M), myofibril (Mf), one sarcomere (Sa), sarcoplasmic reticulum (SR), T-tubule (T), Z band (Z). (Courtesy of TJ Hulland.)

the number tends to be higher adjacent to points where muscle and tendon interdigitate, or where muscle and bone meet through a short ligament or tendon. Nuclei are slender, oval, have evenly distributed chromatin and single, small nucleoli. The **satellite cells**, initially described by Mauro in 1961, consist of a simple cell membrane around a nucleus, a minimum of cytoplasm with mitochondria and a scant tubular system, all of which lie in a shallow indentation on the myofiber surface within the basal lamina. Satellite cells constitute 1–30% of the visible nuclei associated with a muscle fiber; the higher figure describes the neonatal state, the lower, old age. In mature muscle, 3–5% of the nuclei are satellite cells; a modest concentration of them occurs adjacent to motor end plates.

Satellite nuclei have been thought to be the only ones in muscle capable of mitotic division in postnatal life, and each time these cells divide in a growing muscle they contribute one myocytic nucleus and a minute amount of cytoplasm to the growing pool of nuclei in the enlarging multinucleate, myofiber cell. The other daughter cell remains as part of the satellite cell pool outside the myocyte and retains mitotic capability. It is clear that this mechanism will make the satellite cells a progressively smaller proportion of the total nuclear population within the basal lamina since their number remains constant from birth while the nonreplicating postmitotic myofiber nuclei increase in number cumulatively.

New concepts are emerging on the exclusive role of satellite cells in postnatal growth, repair and maintenance of skeletal muscle. Recent studies in mice have demonstrated that *hematopoietic stem cells from bone marrow may participate in regeneration of skeletal muscle.* However, the contribution of bone marrow-derived myogenic progenitor cells in the overall process of muscle cell regeneration, a process previously thought to exclusively involve satellite cells producing myogenic precursor cells, is still unclear. The potential may now exist for therapy by delivery of bone marrow-derived stem cells, via injection into the circulation, to damaged muscle cells to augment regeneration in diseases such as muscular dystrophy where the satellite cell population has become depleted and/or ineffective.

Ultrastructure

The most distinctive characteristic of skeletal muscle cells is the presence of **striated myofibrils**, approximately 0.5–1.0 μm in diameter, consisting, in cross-section, of thousands of regularly sized and regularly oriented **myofilaments** (Fig. 2.2). In longitudinal section, *contractile units or sarcomeres* about 20 μm long extend from one Z band to the next, and consist of bands and lines created by the stacking of thick and thin filaments with protein aggregates at certain places. The *thin filaments* (6 nm wide; actin, tropomyosin, and troponin) are fixed into the electron-dense *Z band* of noncontractile protein and incompletely overlap the *thick filaments* (16 nm wide; myosin). The zone of no overlap adjacent to the Z band is referred to as the *I band*. The central zone between the ends of the thin filaments in which only thick filaments are visible is the *H band*, and this is divided by a *thin dense line of M substance* on each filament, and collectively these create the *M line*. The *A band* is the wide central zone which extends from one end of the thick filaments to the other and alternates with the I band. *In sarcomere contraction, Z bands move closer together reducing I and H band widths.* In cross section at a central point where thick and thin filaments are present, one myosin filament is surrounded at regular intervals by six thin filaments, or 12 when the sarcomere is in strong contraction.

Myofibrils are surrounded by *sarcoplasm*, which makes up 30–40% of the fiber volume, and in it are elements of the T-tubular system, the sarcoplasmic reticulum, mitochondria, lysosomes, glycogen granules, and often, fat droplets. The endoplasmic tubular systems in the muscle fibers of all mammals regularly come together to surround myofibrils and meet in triads with the T tubule between two tubular segments of sarcoplasmic reticulum at frequent regular intervals. In many animals these triads can be found at each end of each sarcomere, an arrangement which ensures very extensive direct surface membrane contact between the cell surface, the sarcomeres and the endoplasmic reticulum. Sarcoplasm between the myofibrils and the outer cell membrane is often rich in mitochondria and glycogen granules.

Quite apart from their ability to shorten in active contraction, *myofibrils are capable of easy and rapid length adjustment accomplished by shedding or adding one or more sarcomeres.* Under ideal experimental circumstances, up to 25% of the sarcomeres may be lost in a 24-hour period, a statistic which emphasizes that, even in the healthy animal, there is potential for a considerable flux of muscle protein to allow for rapid dismantling and reconstruction of myofibrils. Muscle has a high requirement for arginine, glucogenic amino acids, and energy, reflected in part by the high turnover of glycogen in normal muscle. The breadth of myofibrils increases or decreases equally rapidly by building or discarding myofilaments. When new myofibrils are required, an existing large myofibril splits longitudinally, but when atrophy reduces the need for some myofibrils they are simply dismantled sarcomere by sarcomere or reduced in size by destruction of the most peripheral myofilaments.

Outside the muscle fibers and their satellite cells are *three magnitudes of connective tissue framework.* Intimately applied to the basement membrane of each muscle fiber is the net-like **endomysium,** which carries the capillary network with its longitudinal orientation. Around each primary bundle of 40–150 fibers is the thicker **perimysium** in which run larger vessels, nerve trunks, and sensory neuromuscular spindles. Around the outside of the muscle, or a major head of a muscle, lies the **epimysium,** which carries tendon organ sensory endings and sometimes prominent tendinous bands.

Histochemical fiber types

Types of muscle fibers may be distinguished by many histochemical and immunohistochemical techniques available for studying the enzyme components; each new technique demonstrates an ever-expanding heterogeneity of muscle fibers. Many of these techniques subdivide the muscle fiber population in the same ways, and in many instances the subdivisions seem to bear little relationship to the biological response created by disease. The two techniques that seem best to identify different biological activities are the *alkaline- and acid-resistant adenosine triphosphatase procedures* and the *nicotinic acid dehydrogenase tetrazolium reductase (NADH-TR) test* for oxidative enzyme activity. These allow the division of the muscle population into two major groups and several subgroups (Fig. 2.1A, B):

- **type 1 fibers** rich in oxidative enzymes and showing slow-twitch, red color characteristics (myoglobin); generally assumed to be fibers with a predominantly oxidative energy source appropriate for sustained activity;
- **type 2 fibers** rich in glycogen showing a fast-twitch response and paler color; generally assumed to be fibers with a predominantly glycolytic energy source appropriate for short-term, strong activity.

Both types of fiber contain a broad spectrum of enzymes, which makes them capable of a wide range of biochemical activity and, in certain circumstances, an interconversion of working types.

Some species, particularly the pig and the horse, have fibers apparently rich in both oxidative and glycolytic ingredients, and *many domestic animals have fibers that lack the clear-cut divisions that seem evident in the muscles of man and laboratory animals.* The type 2 fibers can be histochemically subdivided by ATPase response into subtypes but, for purposes of predicting biological activity and identifying diseases, the two main types seem to have the greatest relevance. A special subgroup of the glycolytic, type 2 group found in the masticatory muscles of the dog represent an exception to this because they display antigenic differences from other muscles and this makes them vulnerable to a unique disease process. Examination of a muscle in which about equal numbers of type 1 and type 2 fibers are present might suggest a random checkerboard distribution of the types; however, *type 2 fibers are disproportionately found on the periphery of primary bundles, and type 1 fibers are disproportionately at the center of nests of fibers within the primary bundle* (Fig. 2.1A, B). These observations are consistent with knowledge of the late fetal fiber evolution.

Muscles used repetitively but slowly and persistently should have high levels of type 1 fibers while those used for short bursts of activity should have high levels of type 2 fibers. This is often the case; for example the diaphragm of cattle often has 80–95% of type 1 fibers while most other skeletal muscles have 10–60% type 1 fibers. On the other end of the scale, the longissimus and semitendinosus muscles, the two muscles which are most enlarged in racing Greyhounds and Thoroughbred horses, have ~80–95% type 2 fiber content. Obligatory postural muscles, such as the supraspinatus, tend to have a 40–50% type 1 component, but so do muscles which are used relatively sparingly. Individual variation in fiber proportions is quite wide, and this is magnified by breed, muscle region, and species differences. The anatomic position and the function of a muscle in an animal can provide only a general indication of its fiber composition. In the horse, the proportion of type 1 fibers increases in deeper levels of large muscle masses, and the very deep postural muscles of the limbs, such as the medial head of the triceps and the vastus intermedius, are almost entirely type 1 fibers.

Specialized structures

Sensory muscle spindles *are found in all skeletal muscles in and anchored to the perimysial connective tissue and associated with a small nerve radicle, which contains 6–20 large sensory fibers.* They are more numerous in some muscles than others and are generally difficult to find in the larger muscles of mature animals. Spindles are about 0.5–3.0 mm long and 200–500 μm wide (Fig. 2.4). The intrafusal (central) space

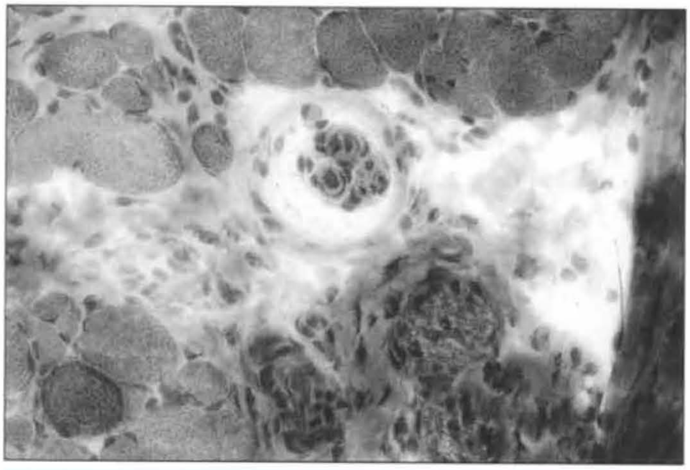

Figure 2.4 Sensory muscle spindle in cross-sectioned normal muscle. Frozen section, modified Gomori's trichrome.

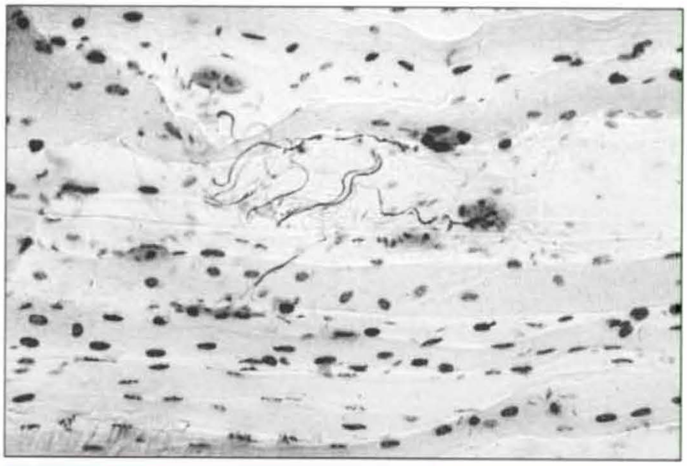

Figure 2.5 Motor end-plate in longitudinal section of canine muscle. Silver stain. (Courtesy of BJ Cooper.)

enclosed within the fibrous, multilayered outer sheath is continuous with lymphatic space and contains 2–20 specialized *small intrafusal muscle fibers*. The intrafusal fibers are histochemically different from the extrafusal fibers but share the same motor nerve. However, intrafusal fibers are innervated by a different, smaller group of motor neurons than those innervating extrafusal fibers. The intrafusal fibers have a high content of nuclei often contained in a central "nuclear bag" region, or linearly distributed up the middle of the small round fibers. Abundant sensory axons entering the spindle have "flower-spray," "grape-cluster," or spiral endings on the intrafusal fibers, and these structures collectively give rise to impulses, which record muscle stretch and contribute to proprioception. *Complex spindles* consisting of 2–10 spindles, incompletely overlapping end on end, are sometimes found in skeletal muscles and may be an expression of anomalous development. Intrafusal fibers generally do not participate in the pathologic processes, which involve extrafusal fibers, with the possible exception of nutritional myopathy. Intrafusal fibers are also resistant to atrophy.

Motor end-plates *are the sites of synaptic transmission of acetylcholine from nerve ends to muscle receptors at which sites a surface-membrane-conducted, polarizing impulse is initiated.* The interface takes the form of a complex, pretzel-shaped neural termination, which is pressed into a shallow but convoluted, cholinesterase-laden, synaptic gutter of matching shape on the myofiber surface. The end plate is contained within the endomysium, and extensions of the endomysial connective tissue ensheath the bare terminal axon for a short distance until its myelin sheath is reached (Fig. 2.5). A little more than one end-plate for each muscle fiber exists in skeletal muscle, and although supernumerary endings (subterminal sprouts) can develop, such structures are rarely found in normal muscle. One motor neuron gives rise to an extremely variable number of terminal axons with one end-plate each, the number being inversely proportional to the fineness of motor movement required of the muscle, and directly proportional to the relative diameter of the muscle fibers. Thus, in the extrinsic ocular muscle the axon:end-plate ratio may be as low as 1:10 on small round muscle fibers, whereas in the gastrocnemius or gluteus muscles the ratio may be 1:2000 on muscle fibers near the upper size limits. Terminal axons are given off at nodes of Ranvier in clusters of 5–30 per node to make muscle end-plate contact locally via a short, fine terminal axon. Although a low neural impulse level to skeletal muscle is translated into contraction of only a proportion of the muscle fibers, this is clearly not a form of muscle regulation that can lead to finely controlled movement and consequently fine movement must be controlled by a low neural ratio.

DISTURBANCES OF GROWTH AND POSTMORTEM ALTERATIONS

As with many tissues, muscle has a fairly limited repertoire of changes. Many of the same histopathologic features are seen in different muscle disorders. Determination of possible causes for muscle changes often requires careful evaluation of the signalment, clinical history, and clinicopathologic findings as well as gross and histopathologic findings. *Muscle atrophy, hypertrophy*, and *postmortem changes* are commonly encountered in pathologic specimens and are the focus of this section. Degenerative and regenerative reactions are discussed in the next section.

Atrophy

Muscle atrophy *can refer to reduction in overall muscle mass.* Reduction in mass most often reflects *decreased myofiber diameter* that can involve all fibers uniformly or that can selectively involve muscle fiber types. Histochemical evaluation of fiber types is often necessary to clearly distinguish the type of atrophy present. In many circumstances, type 2 glycolytic fibers are more sensitive to atrophy than are type 1 oxidative fibers. Morphometric analysis of overall fiber diameter may be necessary to confirm a decrease in muscle mass due to mild overall reduction of myofiber diameter.

All fibers undergoing a reduction in size *lose myofilaments and myofibrils* by a process of more or less simultaneous disaggregation of actin and myosin filaments and disintegration of the protein of Z bands. Briefly, in the sequence, a slight sarcoplasmic space appears between the shrinking myofibrillar mass and the plasma membrane, but the membrane (and the basal lamina) soon begins to wrinkle and condense to accommodate the new slimmer lines. After a brief lag, mitochondria, glycogen granules, and lysosomes are reduced in number and size. After a slightly longer lag phase, the tubular systems are reduced in volume. Removal of cytoskeletal proteins, organelles, and glycogen is by autophagy. Atrophy does not involve sarcolemmal damage and therefore is not associated with increased serum activity of CK or AST. Provided that the time interval is relatively short, the influences inducing atrophy are removed, and the muscle environment is returned to normal, *the sequence can be reversed* and fibers can be restored to normal size.

Denervation atrophy

Myofibers that have lost connection with peripheral nerves due to neuropathy or neuronopathy undergo rapid and severe atrophy due to denervation. This form of atrophy has also been referred to in the somewhat contradictory terms "neurogenic atrophy." Denervation atrophy is characterized histologically by *severe fiber atrophy involving type 1 and type 2 fibers*. Mild denervation will result in scattered single or small contiguous groups (*small group atrophy*) of severely atrophied fibers compressed into angular shapes (*angular atrophy*) by adjacent innervated fibers (Fig. 2.6). More extensive denervation will result in large groups of small rounded fibers (*large group atrophy*), as there are no innervated fibers in the area to cause angular change in the denervated fibers (Fig. 2.7). Even in the absence of histochemical preparations, muscle containing extensive small and large group atrophy is most likely to be denervated, and a careful examination of intramuscular nerves (Fig. 2.8), peripheral nerve trunks, ventral nerve roots, and motor neurons is indicated. In addition to those features of atrophy described above, the rapid and severe atrophy due to denervation often results in clustering of myonuclei (nuclear clumping).

Denervation atrophy is relatively common in animals. It is part of many congenital dysplasias involving skeletal muscle that cause contracture or arthrogryposis. Denervation atrophy is always accompanied by muscle weakness or paralysis, but the clinical signs may be mild if the nerve is small or the damage is mild. Some of the best-known examples of denervation atrophy in animals are *laryngeal hemiplegia in horses* caused by axonal degeneration of the left recurrent laryngeal nerve, injury to the supraspinatus nerve by trauma or the pressure of a poorly fitting collar in a work horse ("*sweeney*"), symmetrical (such as due to equine motor neuron disease), or

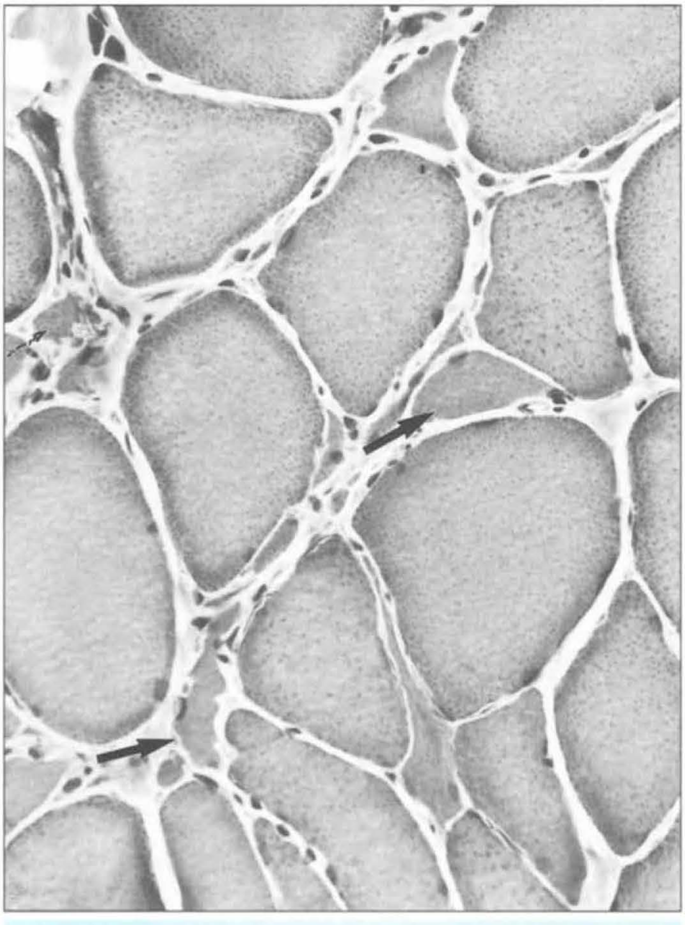

Figure 2.6 Severe angular atrophy (arrows) of small continguous groups of fibers (small group atrophy) due to denervation in a dog. (Courtesy of TJ Hulland.)

asymmetrical (the hallmark of equine protozoal myeloencephalitis) *gluteal atrophy in the horse*, and *radial or brachial paralysis in dogs and horses* due to trauma. Lesions involving the ventral gray matter of the spinal cord or the ventral roots emerging from the spinal canal, and inherited or acquired peripheral neuropathies, are also common causes of denervation atrophy.

Denervation atrophy is rapid and severe. It is accompanied by abnormal spontaneous activity (fibrillations, positive sharp waves, and sometimes myotonic bursts) detectable with concentric needle electromyography. *Within 2–3 weeks, two-thirds of the muscle mass can be lost.* This reduction in mass may be readily observed or may require careful palpation of muscle mass for detection. Given the variable muscling of different breeds of dogs and horses, a diagnosis of symmetric muscle atrophy can be difficult.

As stated above, *the hallmark of denervation atrophy is involvement of both type 1 and type 2 fibers.* Type 2 fibers can, however, be preferentially atrophied, especially early on in the denervation process. The denervation of equine motor neuron disease is somewhat unique, in that there is preferential atrophy of type 1 fibers, presumably due to oxidative injury to type 1 motor neurons due to vitamin E deficiency (Fig. 2.9). The fiber type of the muscle is determined by the electrical activity of the nerve fiber supplying that motor unit. If a denervated motor unit is reinnervated by terminal nerve sprouts from an adjacent intact nerve, the fiber type will be converted to that of the newly innervating nerve, and the reinnervated myofibers will rapidly regain normal diameter. Thus, alteration of the normal mosaic distribution of fiber types to one of clusters of type 1 and type 2 fibers (*fiber type grouping*), which can only be demonstrated on histochemical preparations, is characteristic of denervation followed by reinnervation (Fig. 2.10). If there is subsequent degeneration of the reinnervating nerve this will result in denervation atrophy of a group of fibers all of the same fiber type (*type-specific group atrophy*). This finding is indicative of on ongoing denervating process. Although such disorders occur, it is curious that type-specific group atrophy is rarely seen in animals.

Severe and chronic denervation will be accompanied by a variable degree of endomysial fibrosis. Admixed innervated fibers often undergo

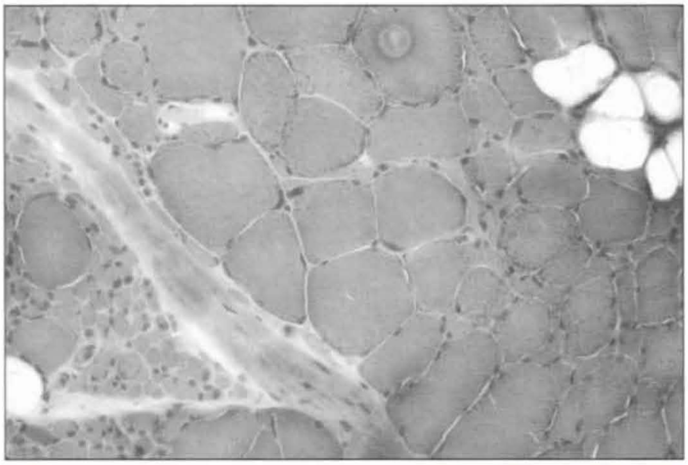

Figure 2.7 Small and large group atrophy in the vastus intermedius muscle of a horse with denervation due to equine motor neuron disease. Figure 2.10 Fiber type grouping of type 1 (dark staining) and type 2 (light staining) fibers due to denervation and reinnervation in the laryngeal muscle of a horse. Frozen section, ATPase, acid preincubation.

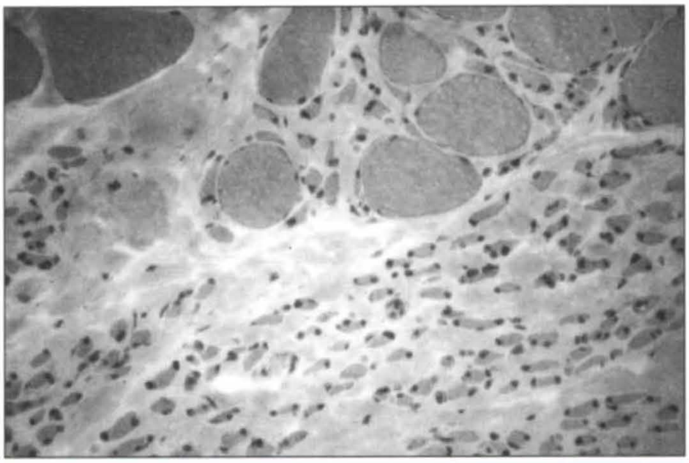

Figure 2.11 Severe large group atrophy with marked endomysial fibrosis due to chronic denervation in the medial head of the triceps of a horse with chronic equine motor neuron disease. There is severe compensatory hypertrophy of other fibers. Frozen section, modified Gomori's trichrome.

compensatory hypertrophy (see below; Figs 2.7, 2.11). Although both type 1 and type 2 fibers will undergo hypertrophy, type 1 muscle fibers appear to be somewhat resistant to denervation atrophy in many circumstances, and may be the predominant hypertrophied fiber type seen. Even without histochemical preparations to determine fiber types, *a pattern of large-diameter fibers admixed with severely atrophied fibers is very characteristic of severe and chronic denervation.* In very severe cases, there can be eventual loss of denervated myofibers, with replacement of muscle by fibrous connective tissue and often also by fat. Determining the cause of the severe atrophy in such "end-stage muscles" can be very difficult, as both severe chronic neuropathic processes and severe chronic myopathic processes are possible.

Disuse atrophy

Disuse atrophy *occurs due to decreased contractile activity of innervated muscle.* Decreased muscular activity due to painful lameness, bone fracture or disease, or limb immobilization are most common. Disuse atrophy in humans and experimental animals *classically involves predominantly type 2 fibers*, although this pattern is not seen in all muscles in people with disuse atrophy. Although a type 2 predominant atrophy is seen in some cases of disuse atrophy in domestic animals, in many cases there is overall atrophy of all fiber types with no clear preferential pattern. As no workload is imposed on muscle fibers undergoing disuse atrophy, there will be no compensatory hypertrophy of fibers.

Atrophy of cachexia

Atrophy of cachexia and malnutrition *occurs when an animal is unable to supply enough dietary nutrients to maintain muscle; muscle proteins become the source of nutrients for the rest of the body.* One to five per cent of the contractile muscle substance is dismantled each day, and in normal animals an equal or greater amount is reconstructed. In view of the large bulk of the body muscle, this represents a very large amount of protein that can be borrowed on a daily basis. Net loss of muscle protein probably starts hours after negative nitrogen balance has been reached. The muscle atrophy of cachexia associated with chronic illness and neoplasia is hastened by circulating cytokines such as *tumor necrosis factor* ("*cachectin*"), which act systemically to increase catabolism, including catabolism of myofibers. The atrophy of cachexia is gradual, and the process may take years if the net withdrawal of muscle protein is subject to fluctuations, or is irregular or slight.

In the dog, *atrophy of temporal muscles* is often prominent and can occur fairly rapidly in animals ill for any reason. The *back and thigh muscles* are also susceptible to severe atrophy due to cachexia. Histochemically, *type 2 fibers are depleted preferentially in cachexia* (Fig. 2.12A, B). Similar to the case in denervation atrophy and some cases of disuse atrophy, type 1 muscle fibers are resistant to atrophy due to cachexia. In most cases, the degree of atrophy achieved through cachexia is not as severe as that seen in denervation atrophy, and the history will provide clinical features and a time frame for the atrophy that should enable differentiation of cachexia from disuse and denervation atrophy.

Atrophy of endocrine disease

Neuromuscular weakness and muscle atrophy can accompany hypothyroidism and hypoadrenocorticism in the dog. In both disorders, *selective atrophy of type 2 fibers* is seen (Fig. 2.13). No compensatory type 1 hypertrophy occurs. The finding of contiguous groups of mildly angular atrophied fibers can suggest denervation atrophy, and histochemical preparations to reveal the selective type 2 involvement may be necessary. In general, the atrophy of type 2 fibers in endocrine myopathy is not as severe as the atrophy of denervation. *Selective type 2 fiber atrophy due to endocrine disease must be differentiated from that of cachexia or disuse.*

Myopathic atrophy

Atrophy of fibers commonly occurs in myopathic conditions, and contributes to the nonspecific myopathic change of increased fiber size variation. Selective type 1 fiber atrophy is seen in many congenital myopathies in humans, and also occurs in cats with nemaline myopathy (Fig. 2.14). In such cases, *the use of histochemical procedures is essential to distinguish the selective type 1 atrophy that is suggestive of primary myopathy*. Other myopathies result in mild rounded atrophy of both fiber types, usually occurring randomly throughout the sections. Chronic myopathic change often involves hypertrophy (see below) as well as atrophy. Hypertrophied fibers are prone to fiber splitting, and some of the rounded small-diameter fibers interpreted as atrophic in chronic myopathic conditions may represent fiber splitting.

Hypertrophy

As with atrophy, **hypertrophy** *can refer to the muscle as a whole or to increased diameter of myofibers.* Overall muscular hypertrophy occurs in cattle as an inherited defect in myostatin, resulting in an increased number of otherwise relatively normal-diameter fibers ("*double muscling*"). Overall muscular hypertrophy occurs due to physiologic increase in myofiber diameter due to *exercise conditioning*. The muscles of animals with myotonic myopathy often appear enlarged, which may be due to prolonged muscle contraction as well as to myofiber

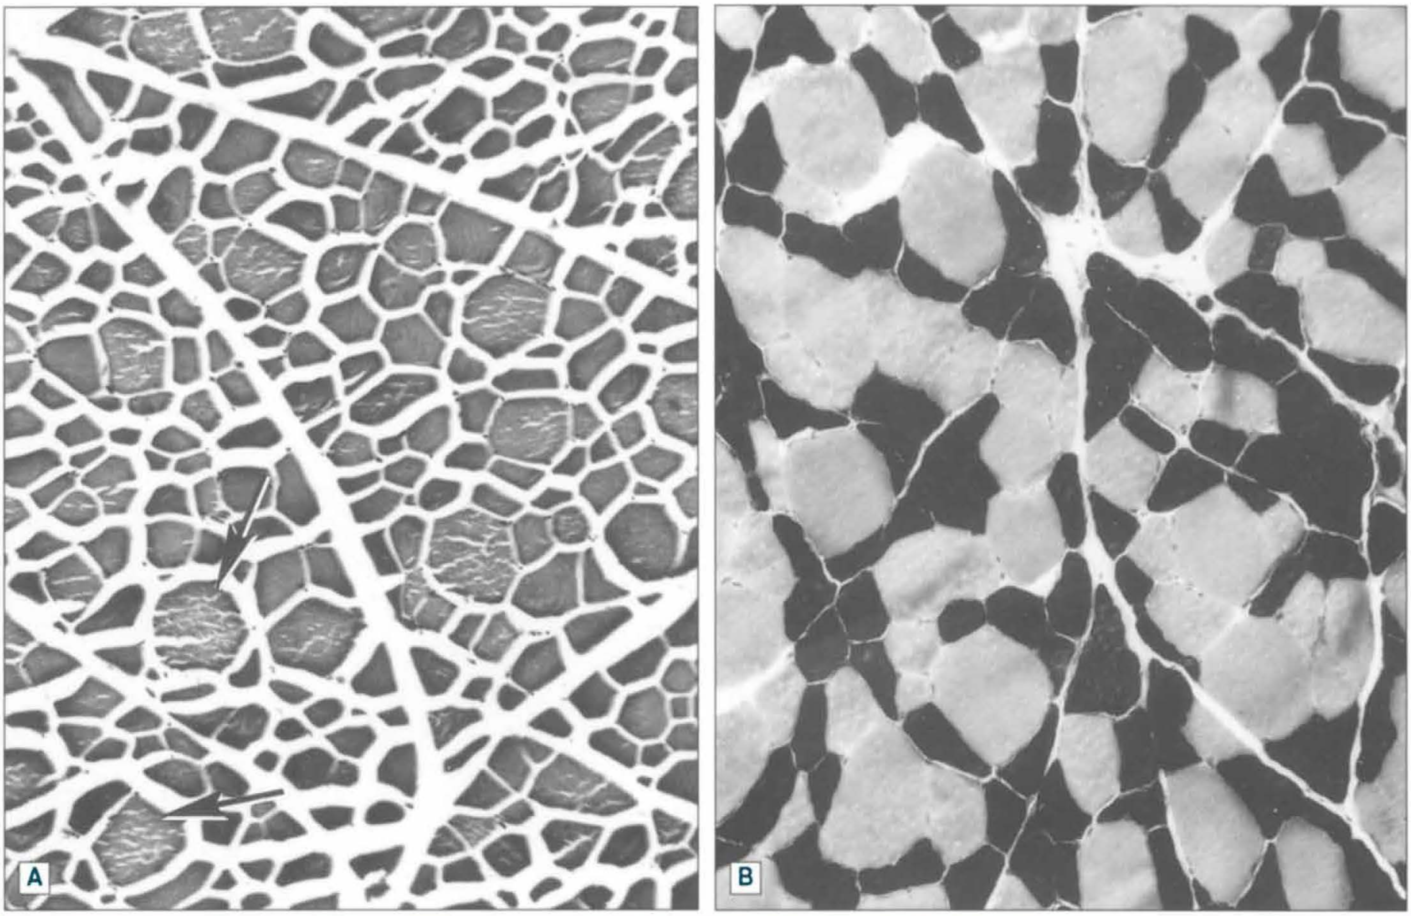

Figure 2.12 **Atrophy of cachexia**. **A.** Atrophy-resistant type 1 fibers are prominent (arrows) in formalin-fixed muscle from a calf; H&E stain. **B.** Preferential atrophy of type 2 (dark-staining) fibers in an emaciated sheep; frozen section, ATPase, alkaline preincubation. Figure 2.14 Selective atrophy of type 1 (light staining) fibers in a cat with congenital **nemaline myopathy**. Frozen section, ATPase, alkaline preincubation.

hypertrophy. Muscular hypertrophy is a characteristic feature of Duchenne-type X-linked muscular dystrophy in the cat, and occurs to a lesser degree in dystrophic dogs. Individual myofiber hypertrophy is often seen histologically in myopathic and neuropathic conditions in which there is overall reduction in muscle mass due to concurrent myofiber atrophy or loss. Lastly, muscle may appear enlarged due to pseudohypertrophy, as in chronically damaged muscles replaced by masses of fibrous tissue and/or fat, or due to fascial thickening in cats with fibrodysplasia ossificans progressiva.

Physiologic hypertrophy

Myofiber hypertrophy is considered physiologic when it occurs due to increased workload. This is a desirable process in athletes, and is accomplished through exercise conditioning. This process of physiologic hypertrophy of fibers is *accomplished by adding sarcomeres, by adding myofilaments to the periphery of myofibrils, and by adding new myofibrils to the existing ones by a process of longitudinal splitting.* There are sharp upper limits for this type of hypertrophy, and for animals it lies somewhere between 80 and 100 μm in diameter.

Compensatory hypertrophy

Compensatory myofiber hypertrophy occurs in muscle in which some myofibers are weak or dysfunctional due to myopathic or neuropathic disorders. In a sense, *this is a type of workload-increased hypertrophy* imposed on fibers less severely affected or unaffected by the myopathic or neuropathic condition. In such cases, fibers of 150–200 μm diameter can develop. Hypertrophied fibers in myopathic and neuropathic conditions are often abnormal, and may contain one or more internal nuclei, may undergo longitudinal splitting, or can develop bizarre cytoarchitectural disarray such as the formation of ring fibers and whorled fibers (Fig. 2.15). Longitudinal splitting allows one or more capillaries to be located near the center of the muscle fiber (Figs 2.16A, B, 2.17). When division is more or less complete, two or often more fibers become arranged in an "orange section" array (Fig. 2.16B) and appear as a cluster of the same fiber type that should not be mistaken for fiber type grouping.

Postmortem changes

It is an unfortunate fact that veterinary pathologists are often involved in the postmortem examination of animals that have not recently expired. *Postmortem changes in muscle are common but variable,* making interpretation of the gross appearance of muscle difficult. In a well-fed animal that dies suddenly, the muscles can become very pale. Pallor may be caused by the accumulation of lactic acid in ischemic muscle. In other animals, particularly those whose glycogen stores have been depleted by chronic disease or malnutrition, the muscles become unusually dark after death. A wide range of differences in color and consistency of muscle normally exists among various species. Pallor of muscles also is present in animals that are anemic from copper or iron deficiency or blood loss, and is often normal in neonatal animals. Dark-red staining of muscle can be indicative of antemortem rhabdomyolysis, or can occur during putrefaction. Given the difficulty in interpretation of gross changes, it behooves the pathologist to take multiple muscle samples for histologic evaluation.

Rigor mortis *is contracture of the skeletal muscle that develops after death.* Rigor mortis is characterized by stiffening of the muscles and immobilization of the joints. It proceeds in orderly fashion from the muscles of the jaw to those of the trunk and then to those of the extremities, and it passes off in the same order. The time of onset, in average circumstances, is 2–4 h after death; maximum rigor is achieved in 24–48 h, after which it disappears. The intensity of rigor varies considerably as does the time of onset. *The factors influencing the time of onset and degree of rigor are the glycogen reserves, the pH of the muscles at the time of death, and the environmental temperature.* Rigor is slight or absent in cachectic or chronically debilitated animals. Rigor occurs with extraordinary rapidity in animals that die during or shortly after intense muscular activity, when muscle pH and glycogen stores are low. Onset of rigor can be delayed in well-rested, well-fed animals. It is hastened in onset and disappearance in a warm environment, and retarded in a cold environment. The chemical events in rigor are a modification of those occurring in normal contraction. Immediately after death, glycogen is converted to lactic acid by anaerobic glycolysis and creatine phosphate is broken down to produce creatine. These are both mechanisms for the resynthesis of adenosine triphosphate from adenosine diphosphate. Rigor will occur when the rate of adenosine triphosphate degradation exceeds its rate of synthesis. Muscle does not require energy to contract, but contraction is dependent on the presence of free calcium ions. Sequestration of calcium requires energy and is necessary for muscle relaxation. *Rigor develops because muscles deprived of energy are unable to maintain calcium in sequestered stores.* The eventual disappearance of rigor, and its failure to develop in cachectic animals, may be due to complete exhaustion of the chemical systems that produce energy and/or myofibrillar protein loss or breakdown.

Skeletal muscle is also prone to various *artifactual changes* that interfere with accurate histologic evaluation. Muscle collected from freshly dead animals, especially horses, is often still capable of vigorous

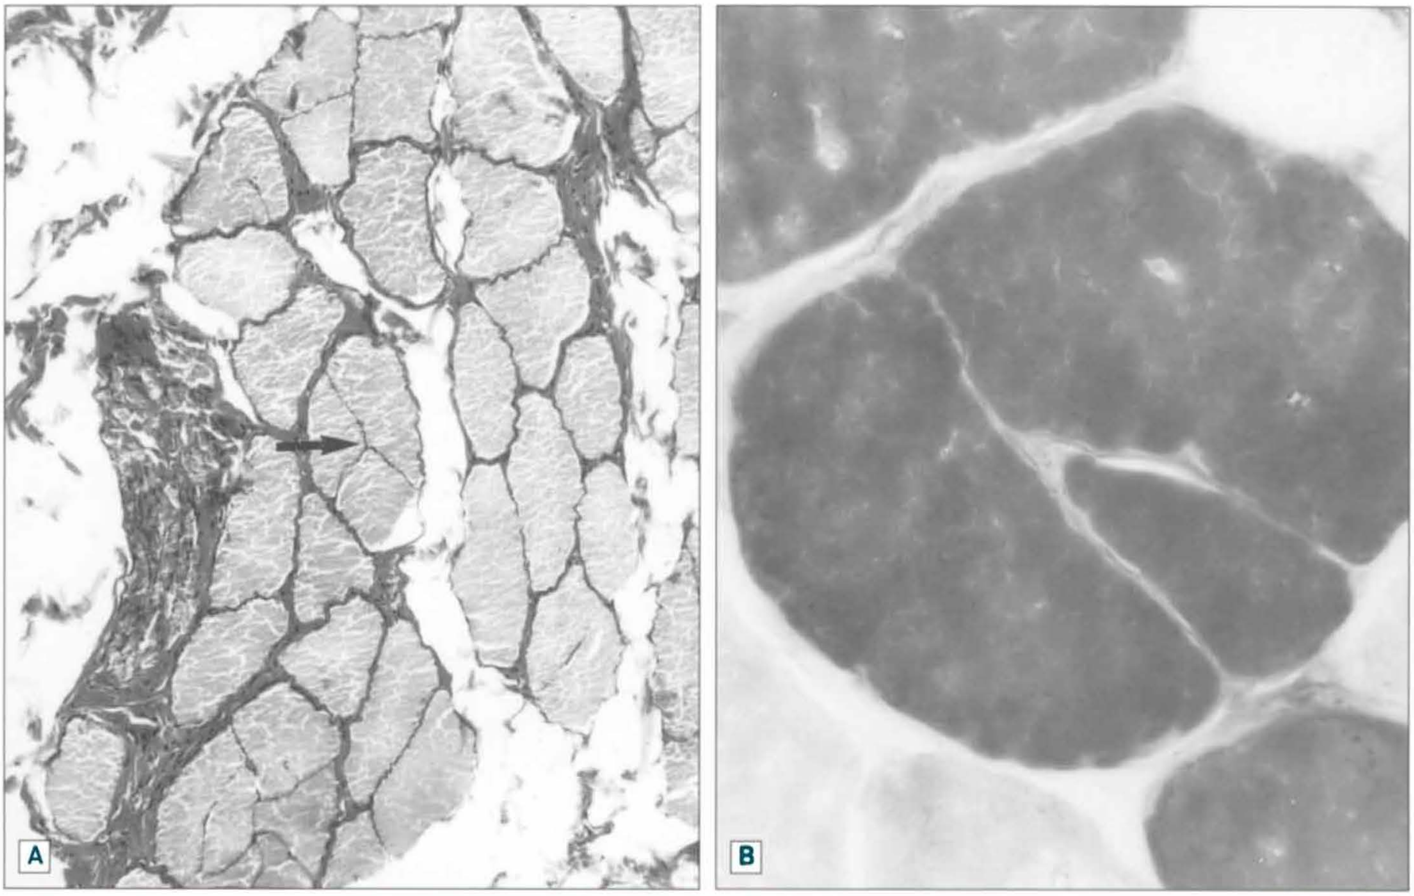

Figure 2.16 Fiber splitting. A. Fiber hypertrophy with fiber subdivisions (arrow). **B.** Hypertrophied fiber with early subdivision ("orange section" array). (Courtesy of TJ Hulland.)

contraction when myofiber ends are cut, allowing calcium-rich extracellular fluid to enter the myofiber and trigger the contractile apparatus. Exposure to formalin can also trigger contraction in fresh muscle samples. Various procedures have been advocated for elimination of the resultant contraction band artifact in muscle. It has been suggested that delayed sampling, following "curing" of the carcass, will result in better histologic preparations. Although the myofilamentous elements of myofibers are somewhat resistant to autolysis, and overall architecture of muscle will be better preserved postmortem than that of nervous tissue or gastrointestinal mucosa, this type of processing must still be considered less than ideal. Rapid postmortem loss of glycogen will often result in inability to diagnose a glycogen storage myopathy, and postmortem alterations in mitochondria and other organelles will interfere with ultrastructural evaluation. Histochemical procedures are also affected by postmortem autolysis, with resultant loss of fiber typing ability.

An extremely valuable procedure for collection of fresh muscle samples at necropsy, but also by biopsy, is *collection of muscle strips in a specially designed muscle clamp*. Samples are clamped in situ, following careful undermining of a strip of longitudinally arranged muscle fibers. The clamp ensures that the calcium influx occurring when fibers are cut transversely does not result in fiber contraction. It is recognized, however, that not all veterinary pathologists will have access to these muscle clamps. Utilization of a similar sampling technique, i.e., the isolation of a longitudinal strip of muscle approximately 2–3 cm long and 1 cm diameter and undermining the strip prior to cutting transversely across myofibers, will minimize artifact during sampling if followed by *pinning the strip to a rigid surface such as a piece of wooden tongue depressor*. This procedure will mimic the action of a muscle clamp and will provide good pathologic specimens for routine pathologic evaluation. Fixation in formalin cooled to refrigerator temperature can aid in preservation of glycogen.

When evaluating skeletal muscle samples, *it is essential to prepare both transverse and longitudinal sections*, and the sampling method described above will help to ensure that such sections are obtained. *Transverse sections* are needed in order to evaluate fiber diameter and presence of internal nuclei, as well as for detection of various cytoarchitectural changes. *Longitudinal sections* are often useful to confirm acute myonecrosis and regeneration as well as to determine the length of segment involved. Intramuscular nerves are often easier to find and to examine in longitudinal muscle sections. The use of *special staining techniques*, such as Masson trichrome stain, reticulin stain, phosphotungstic acid hematoxylin, and periodic acid-Schiff (PAS) stain for glycogen can be particularly useful when evaluating muscle samples fixed in formalin. Interpretation of early degenerative change and its distinction from artifactual or autolytic change sometimes requires all available information about time and circumstances of death as well as clinical signs and biochemical changes shown prior to death.

DEGENERATION AND REPAIR OF MUSCLE

Degeneration may involve parts or all of the cellular structures and often occurs segmentally along the length of the myofibers. The myofibrils alone, or myofibrils and sarcoplasm may undergo degenerative change leaving the sarcolemmal basal lamina, myonuclei, and satellite cells viable and intact. The next level of segmental degeneration leaves only the satellite cell nuclei and the basal lamina in place, and the third level destroys the satellite cells. The fourth level of segmental destruction destroys endomysial connective tissue cells and capillaries as well. *Regenerative responses* differ at each of these levels. Because the myofibers are so long, it is quite possible for a segment or several segments of a fiber to be destroyed without all of the cells being adversely affected although subsequent reparative events sometimes fail to reconstruct the original fiber completely. On the other hand, it is distinctly possible for a fiber to suffer repeated segmental destruction throughout its life span, and to be restored each time to completeness.

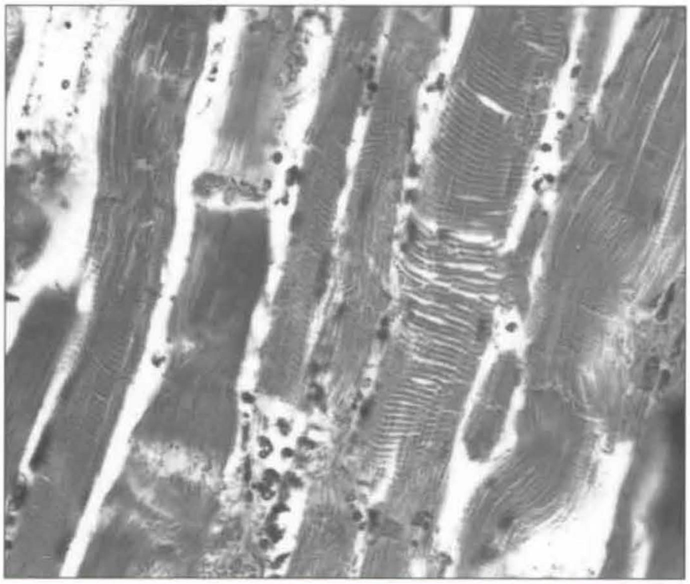

Figure 2.18 Hypercontracted fibers in a downer cow. (Courtesy of TJ Hulland.)

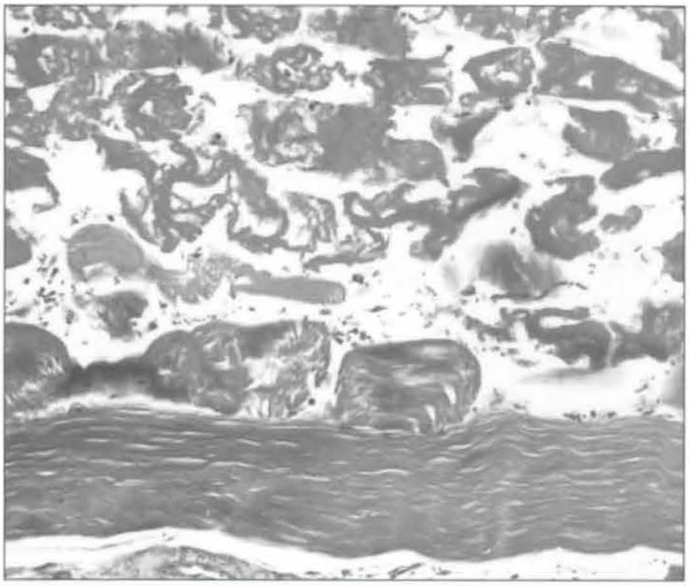

Figure 2.19 Hyaline degeneration in nutritional myopathy in a cow. (Courtesy of TJ Hulland.)

Thus, complete muscle cell death is an exceptional event even in extensive lesions, but destructive events usually have some lasting effect on the shape or number of fibers (see Regeneration and repair of muscle).

Histopathologic evidence of segmental degeneration of muscle fibers along with the events of regeneration and repair are the common expression of many muscle diseases in animals. Kakulas developed a classification for the degenerative lesions of muscle based on spatial distribution and temporal patterns that is often useful to identify broad etiologic categories of muscle disease. *Four categories of muscle injury reactions were established as follows: (1) focal monophasic, (2) multifocal monophasic, (3) focal polyphasic, and (4) multifocal polyphasic* (Kakulas, 1981).

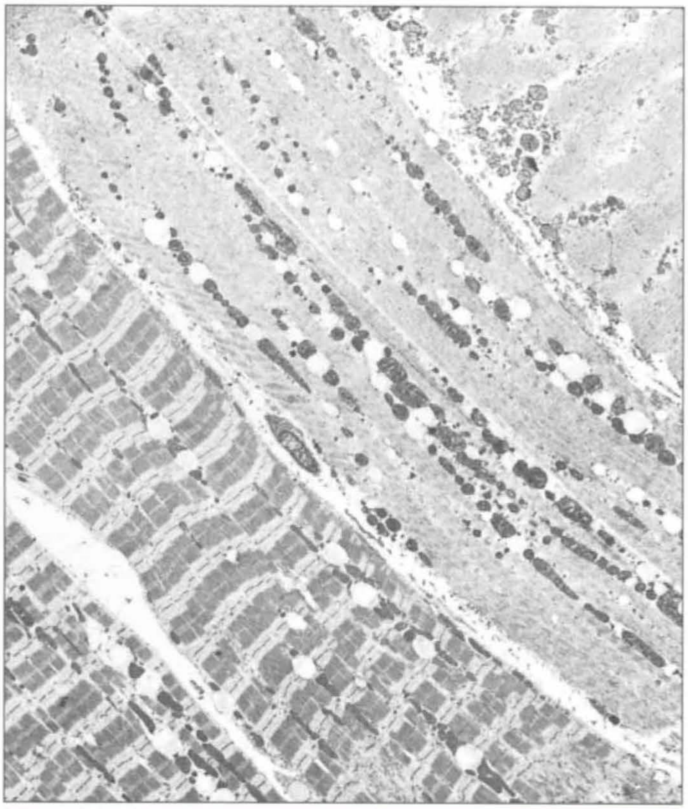

Figure 2.20 Coagulative necrosis (top) and areas of myofibrillar lysis (bottom) in a foal. (Courtesy of TJ Hulland.)

- *Focal monophasic reactions* result from an isolated single mechanical injury, such as external trauma or needle insertion.
- In *multifocal monophasic reactions*, a single insult – such as exposure to various myotoxic drugs, chemicals, or metabolic disorders – may initiate widespread muscle lesions, but all the alterations are in the same phase of injury.
- *Focal polyphasic reactions* result from repeated mechanical injury in the same site.
- *Multifocal polyphasic reactions* are frequent in muscular diseases of animals, and result from continued insults applied over a prolonged time, such as from nutritional deficiencies and genetic disorders (as in muscular dystrophies). The lesions are widespread in the musculature and various pathological reactions – including degeneration, leukocytic invasion during resolution, and regeneration – will occur concurrently.

Muscle fiber degeneration is frequently associated with alterations of cellular membranes, and membrane failure takes the form of segmental myofiber degeneration. Initiation of events that lead to contraction is by nerve-triggered activation of skeletal muscle ion channels resulting in a muscle action potential. Muscle contraction is initiated by passive release of calcium ions from the sarcoplasmic reticulum, but energy is required to recapture calcium ions to allow muscle fiber relaxation. Exhaustion of phosphate-bonded energy reserves often leaves the muscle fiber in a state of calcium-abundant contraction or hypercontraction which soon reduces the complex myofilaments to a coagulum of contractile proteins (Figs 2.18–2.21). *There appears to be a final common destructive pathway of* **mitochondrial calcium overload,** *which begins with many different causes of*

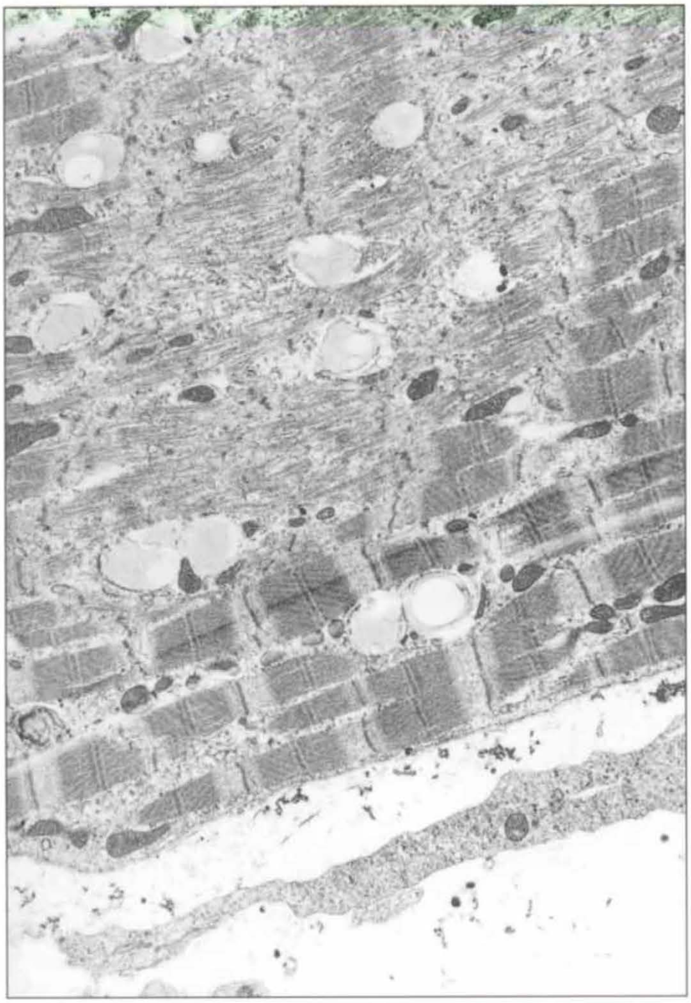

Figure 2.21 Myofibrillar lysis and lipid droplet accumulation in a foal. (Courtesy of TJ Hulland.)

membrane or energy failure and ends with hypercontraction and coagulation of the contractile proteins. Most animal myopathies seem to fit well into this sequence of events, particularly the nutritional myopathies. Grossly visible mineralization occurs several hours after the onset of protein coagulation during which striations are lost (*hyaline degeneration*). Calcium is released belatedly in degenerated myofibrils from calcium-saturated mitochondria as they disintegrate. Although the almost chalky mineralization seen grossly in many cases of nutritional myopathy is usually referred to as dystrophic, it is not at all certain that such accumulations can occur as a result of a purely passive collection of mineral from the blood on dead tissue protein. At the very least, it seems to require that mitochondria become overloaded with calcium early in the degenerative process.

Some cases of nutritional myopathy and toxic myopathy may have very similar microscopic degenerative changes not characterized by mineralization to any appreciable extent, even though the lesions are as extensive as those in typical "white muscle disease." Degenerate muscle may be very difficult to detect on gross examination when it is unmineralized, and consequently is likely to escape detection. The event that determines whether mineralization occurs in addition to the variable of the amount of blood calcium available may well be the period after hypercontraction, during which cellular membranes allow calcium into the cell and mitochondria continue to collect calcium from the cytosol. Eventually such activity will be ended by membrane disintegration and a release of calcium to the cytosol again, but calcium gathering could continue for a period of several hours.

The hypercontracted eosinophilic coagulum in segmental hyaline degeneration is readily removed by macrophages both in its earlier, premineralized state and in the later mineralized stage of granular degeneration. *The early pale, hyaline stage develops into typical* **Zenker's degeneration**, *which is a highly eosinophilic, homogeneous mass.* It sometimes retains faintly visible, tightly contracted striations, although these are eventually lost.

Regeneration and repair of muscle

The ability of muscle to repair itself is remarkable considering its high specialization and the great length and great vulnerability of individual fibers. The ability to rapidly repair the damaged segment of a fiber, without apparent complication to the rest of the fiber, is without parallel in other cells of the body. A muscle cell consists of a single large multinucleate myofiber adjacent to which is a large population of uninuclear satellite cells, outside the plasma membrane but within the tough basal lamina. *The major participants in the regenerative sequence are macrophages from the blood, the satellite cells, because only they, within the muscle, have retained the capability for mitotic division, and the basal lamina, which acts as a very efficient scaffold.* The integrity of the basal lamina determines from the very beginning how effective regeneration will be and whether the outcome will be regeneration of myofibers, fibrous replacement, or a mixture of the two. An intact basal lamina effectively keeps myonuclei, satellite nuclei, and myoblastic cells inside. It is equally efficient in keeping fibroblastic cells out, but allows phagocytic cells easy entry and exit.

If damage to the fiber is *segmental* and such that only the myofibrils and the sarcoplasm along with its subcellular components have been injured, the first visible event of regeneration is an early rounding-up of satellite cells as they prepare to undergo mitotic division. The proliferated satellite cells become apparent in hours as they leave their former sublaminal site. After about 12 hours, macrophages appear and they may or may not be accompanied by a short-lived wave of neutrophils and eosinophils. These inflammatory cells are rich sources of growth factors and cytokines such as insulin-like growth factor (IGF)-1, platelet-derived growth factor (PDGF), and interleukin (IL)-6 that promote satellite cell and myoblast proliferation and differentiation. These cell types freely enter the mineralized damaged fiber. Macrophages dissolve and remove the debris (Fig. 2.22); neutrophils disappear unless infection complicates the process. Removal of sarcoplasmic debris leaves some space enclosed within the collapsing sarcolemma; and proliferating satellite cells are seen in the sarcolemmal tube. These cells are now termed myoblasts.

Myoblasts increase in number until a critical myoblastic mass is reached. Only then do myoblasts begin to fuse, and this triggers the next sequence of events. Five or six days after degeneration occurred, fusion of myoblasts has produced *unpolarized myotube giant cells* that begin to send out cytoplasmic processes as their nuclei divide (Fig. 2.23). Guided by the basal lamina, some processes make contact with remaining viable segments of the original fiber. They make effective union by dissolving cell membranes and uniting the cytosols into a single myofiber. The free pole of the myotube giant cell then

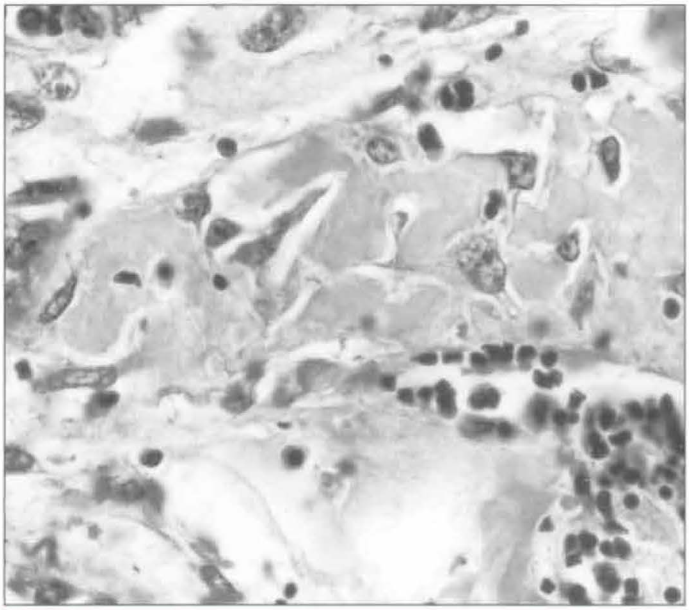

Figure 2.22 Necrotic myofiber with surviving satellite cells and invading macrophages. (Courtesy of TJ Hulland.)

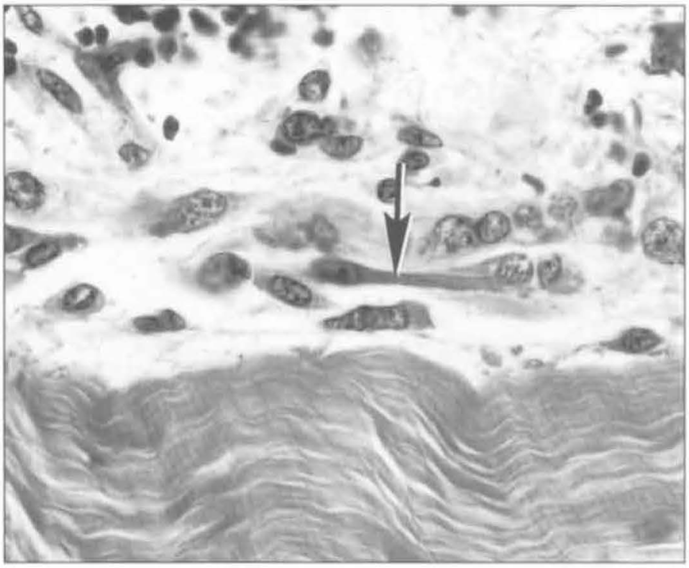

Figure 2.23 Regeneration, with elongating myoblasts (arrow). (Courtesy of TJ Hulland.)

becomes a *polarized regenerative probe,* which grows within the cleared space of the collapsed sarcolemmal sheath. Other myotube cells in the regenerating myofiber may not make contact with other myotubes for some time, and remain as unpolarized giant cells until an adjacent myotube's process contacts them. *A growing myotube characterized by its basophilic cytoplasm and central row of nuclei can grow for relatively long distances as long as the basal lamina is intact and no fibrous tissue intrudes and obstructs* (Fig. 2.24). If the basal lamina sheath is ruptured, the myotube protrudes from the ruptured sarcolemmal tube as a syncytial giant cell and can grow into the proliferating fibrous tissue for only 2–5 mm.

When a myotube has made contact with the next viable segment of the original fiber, at about 10–14 days, the next stage consists mostly of *production of new sarcomeres in the enlarging fiber.* The new fiber has to find growing space between existing fibers but seems able to do this efficiently. As myofibrils, sarcoplasm, and other organelles are added, the fiber becomes less basophilic, and from 7–21 days the nuclei migrate from their central or internal position to lie just under the new cell membrane – the normal position in a mature myofiber. Only in the most ideal of circumstances are all the parts restored to the predegeneration state by the efficient regeneration process described above. At the very least, two basal laminae, one inside the other, persist; later they may fuse. Any proliferating satellite cell/myoblasts, which do not enter the original cell, or any myotube processes which escape from it, may produce muscle giant cells that reflect abortive attempts at myofiber regeneration.

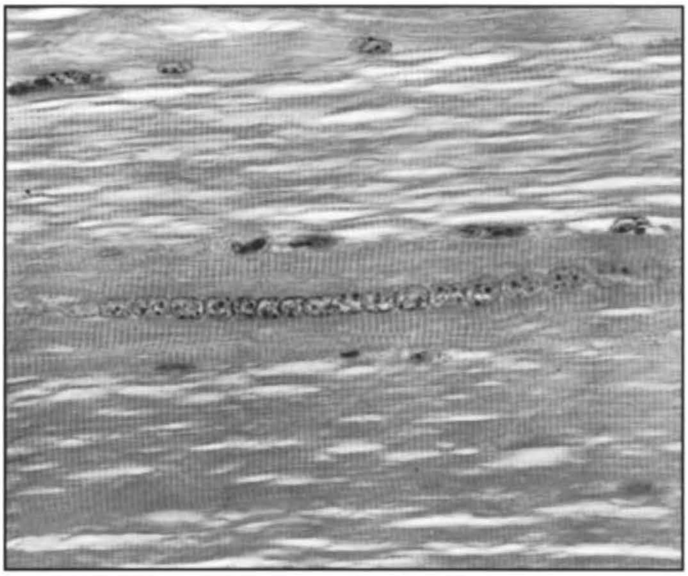

Figure 2.24 Regeneration, with a fiber with a row of central nuclei. (Courtesy of TJ Hulland.)

Considering the possibility of breaks in the sarcolemmal tubes, the potential for myoblast formation, which may be inside or outside the original myofiber and the potential for distortion of development by fibrous tissue invasion, it is easy to understand that the final result may not be perfect. *The longer and more numerous the gaps in sarcolemmal tubes are, the more potential there is for aberrations in repair.* The most important factors in preventing such aberrations seem to be the viability of nuclei and the wholeness of the basal lamina. Although sometimes extensively destructive, *nutritional, exertional and most toxic myopathies are likely to repair very well with minimal fibrosis. Primary dystrophies repair well but degenerate again* and eventually residual lesions of fibrosis will become prominent. *Ischemic damage repairs badly or not at all* because satellite nuclei and endomysial cells may have been killed. Fibrous replacement will be the end result. Ischemia with early reflow permits some regenerative repair, particularly around the outside of primary bundles where blood flow returns first but central fibrous replacement will occur. *Fibrosis may be the dominant feature in healed lesions of myositis and physical injury.*

The reduced regenerative capability that develops with maturity may be related to low numbers of potential myoblasts as the proportion of satellite cells to the total nuclear population in the fiber drops with age.

Other myofiber alterations

Vacuolar degeneration, an infrequent alteration in muscle fibers (Fig. 2.25) is associated with *electrolyte abnormalities,* such as hyperkalemia in horses with hyperkalemic periodic paralysis, and in the diaphragm of rodents given intraperitoneal injections of doxorubicin. **Fatty degeneration** with small fat vacuoles is a very common finding in *emaciated or anorectic animals* because muscle is able to use triglycerides directly as a source of energy. Rows of minute droplets are held in considerable quantity by type 1 (oxidative) fibers, but type 2 fibers often contain neutral fat also (see Fig. 2.21). The presence of these fat droplets may be more evident in those myofibrils remaining in advanced cachectic atrophy, but it apparently implies no pathologic change in muscle as even well-nourished animals carry some droplets in their muscles. Quite separate from these aggregations of minute fat droplets, larger fat droplets may be seen in muscle fibers in the dog and horse. Their cause is not known.

So-called **discoid degeneration** represents the phenomenon of *hypercontraction*. It develops when hypoxia plays a major part in the production of muscle lesions. The muscle striations, but not all of their fine features, are preserved and the fiber begins to separate at the Z bands (see Fig. 2.18).

Xanthomatosis (lipofuscinosis) is the term used to describe the *accumulation of abnormal amounts of yellow-brown to bronze pigment in some skeletal muscles and myocardium, and often also in adrenal cortex and distal convoluted tubules of the kidney*. Black hair coats may become brown, and white skin may become yellow, but the presence of the pigment appears not to be detrimental to the health of the animal. The build-up of "wear-and-tear pigments" in old animals, particularly high-producing dairy cows is indistinguishable morphologically from xanthomatosis but it is sometimes associated with myocardial failure. There appears to be a disproportionately high incidence of xanthomatosis in Ayrshire cows and among old cows of all breeds slaughtered for human consumption; in one study the incidence was about 0.1–0.5% overall compared to 10–25% for Ayrshires.

Skeletal muscles most frequently or most extensively involved are the *masseter muscles* and the *diaphragm*. Muscle fibers are of normal diameter or smaller, but may be dark brown or even black-brown. Pigment granules, some of which stain positively with lipid and PAS stains, tend to be located within lysosomes found perinuclearly under the sarcolemma or centrally in the fiber. Particles are irregular in size and shape and on electron microscopic examination show a wide variation in shape and organization. All are electron-dense and some are membrane-bound and it is presumed that they represent degraded lipid substances that have accumulated in phagolysosomes.

Other types of degeneration

A variety of inclusion-like structures or focally abundant or altered structural components occur in the myopathies of animals and are termed **cytoarchitectural changes** (Figs 2.26, 2.27). Similar alterations in the muscles of humans sometimes are associated with specific diseases but such relationships have not been established in most animal diseases. **Nemaline rods** have been found in a myopathy of cats and in occasional cases in dogs, with or without hypothyroidism. The rods represent accumulations of Z band material as confirmed by electron microscopy (see Congenital and inherited defects). **Targetoid fibers** (central zones of myofibrillar disruption)

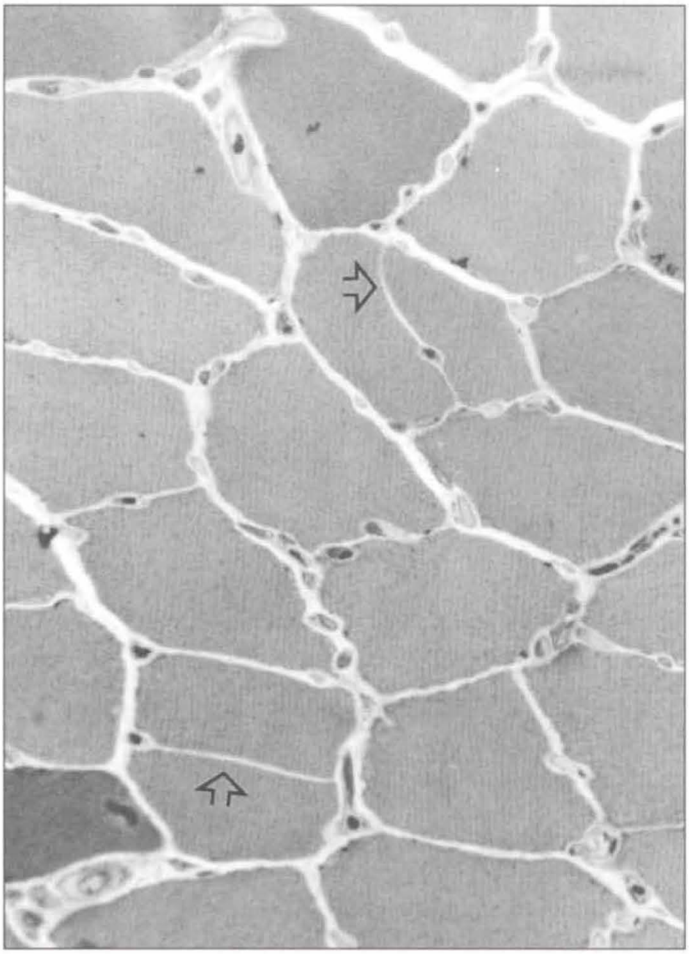

Figure 2.27 Myopathic alteration of **fiber splitting** (arrows) in a horse. (Courtesy of TJ Hulland.)

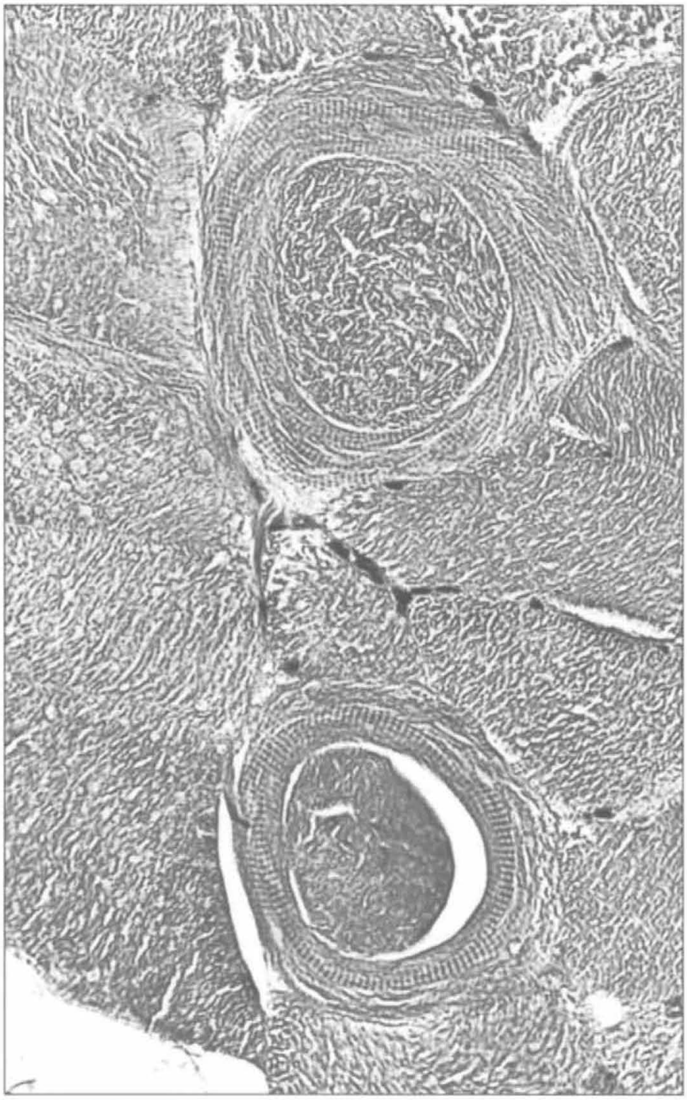

Figure 2.28 Two fibers with **ringbinden** in a horse. (Courtesy of TJ Hulland.)

and **ragged red fibers** (mitochondrial-laden) have been seen in myotonic muscle disease in dogs, and **peripheral and central sarcoplasmic masses** have been observed in the muscles of sheep and cattle in dystrophy. Abnormal **glycogen accumulations** may develop in the muscles of dogs, sheep, cattle, cats, and horses (see also Congenital and inherited defects). In all species, these are generally nonmembrane-bound collections. The deposits are PAS positive and digested by diastase and are usually just under the sarcolemma.

Ringbinden (ring fibers) is one of the unusual findings that may be left behind when denervation or tenotomy is combined with atrophy and regeneration. *It is a formation of disoriented peripheral myofibrils, which wrap themselves around a muscle fiber in a tight spiral fashion* (Fig. 2.28). Satellite cell nuclei can migrate and they sometimes orient their long axes transversely rather than longitudinally. Circular myofibrils accompanied by a mass of disrupted subsarcolemmal contractile elements presumably represent a true, but nonspecific, degeneration of myofibers. Ring fibers most often occur naturally in animals showing evidence of denervation atrophy, with or without evidence of ischemic muscle damage. Horses cast and anesthetized for several hours may also develop these lesions.

The role of **apoptosis** in skeletal muscle disease is still unclear. Although apoptosis represents an important activity in myoblasts during normal differentiation and development, its *role in postmitotic mature myofibers is uncertain*, but activated satellite cells may undergo apoptosis. Multinucleated skeletal muscle myotubes in cell culture exposed to staurosporine, a protein kinase inhibitor known to induce apoptosis in a variety of cell types, underwent the morphologic and biochemical features of apoptosis. In several models of muscle disease (X-linked muscular dystrophy in mouse, bupivacaine injury of immature rat muscle), apoptosis precedes the development of necrosis. Further studies are needed to establish the role and the importance of apoptosis in muscle diseases of animals and human beings.

CONGENITAL AND INHERITED DEFECTS

There are numerous conditions affecting skeletal muscle development, integrity, and function in animals. Congenital myopathic and neuropathic conditions are apparent at birth or soon thereafter, usually within the first year of life, and may or may not be inherited. *Pedigree analysis and breeding studies often help to distinguish those congenital disorders that are also inherited.* Inherited disorders affecting skeletal muscle in animals in which the gene defect is known are listed in Table 2.1. Gene mutations leading to skeletal muscle dysfunction are most often *point mutations*, e.g., hyperkalemic periodic paralysis (HYPP) in horses, phosphofructokinase (PFK) deficiency in dogs, and myophosphorylase deficiency in cattle. Some disorders, e.g., canine X-linked muscular dystrophy, can occur due to either point mutations or deletions, and the genetically characterized cases of feline X-linked muscular dystrophy have been due to a gene deletion.

Following tradition, congenital and inherited defects of skeletal muscle are discussed separately from the congenital and inherited myopathies, although it is recognized that the distinction between these two groups is not always clear. Numerous disorders are difficult to classify using traditional classification schemes, and diseases or syndromes can change their status as a result of investigation and new information.

Abnormal development of neuroectoderm that involves the lower motor neuron portion of the nervous system will also affect skeletal muscle. Although the primary defect is in the nervous system, the profound effect these disorders can have on skeletal muscle development and function warrant a brief discussion here.

Primary CNS conditions

Neuroectodermal defects affecting the innervation of individual myotomes and the muscles that form from them can result in abnormal muscle development. Given the complex interaction of myogenic and neurogenic cells during development, it is often difficult to define the exact nature of the defect. Neuroectodermal defects can result in abnormal muscle development or structure due to lack of innervation, to loss of innervation, or to abnormal motor neuron activity.

For proper in utero development, muscles require normal innervation. Without it they atrophy or fail to develop normally (hypotrophy) and are more or less replaced by fibrous tissue and fat. Associated with each embryonic spinal cord segment is a myotome, a collection of cells with myoblastic potential, which migrate as the fetus develops and that ultimately form muscle. Committed myoblastic cells from one myotome may contribute to several muscles. Later, nerves from the same spinal segment follow the route of the myoblastic cells and innervate the same muscles. Most developing muscles are formed from myoblastic cells and nerves from two to six cord segments, but a few small muscles of the distal limbs receive contributions from only one. This explains why some muscles innervated from only one segment are vulnerable to denervation or lack of innervation resulting from a cord lesion involving a single segment, while a cord lesion of similar extent contributing innervation to muscles receiving cells and nerves from multiple segments can be associated with apparently normal muscle and nerve development. In the latter case, collateral innervation from nerves arising in normal cord segments can develop.

Developing skeletal muscle motor units are innervated by more than one nerve and, in some species such as the dog, this polyinnervation is still present at birth. With maturation of the neuromuscular unit the innervation pattern is simplified to one of one nerve fiber per motor unit. This pattern of polyinnervation can further complicate the pathologic findings in muscle from animals with neuroectodermal defects.

Arthrogryposis and dysraphism

Arthrogryposis *literally means crooked joint.* The terms *congenital articular rigidity* and *arthrogryposis multiplex congenita* are also used to describe this syndrome. Arthrogryposis can involve one or more limbs, depending on the underlying neuroectodermal defect. Severely affected animals may also have scoliosis, kyphosis, and torticollis, and the limbs or parts of limbs may be rotated, abducted, or curled backwards or forwards in grotesque positions (Fig. 2.29). Newborn animals afflicted with arthrogryposis are sometimes stillborn and may show autolysis indicative of in utero death 2–4 days earlier. Hydramnios is disproportionately associated with these, as is dystocia. Many, perhaps most, are of normal skeletal size although some are

Table 2.1 Animal myopathies in which the gene defect is known

Disorder	Gene affected	Type of disease	Species/breed affected
X-linked muscular dystrophy	Dystrophin	Muscular dystrophy	Various dog breeds. DSH cats
Double muscling	Myostatin	Muscular hyperplasia	Various beef breeds
Porcine stress syndrome	Ryanodine receptor	Malignant hyperthermia	Various pig breeds
Phosphofructokinase (PFK) deficiency	PFK, muscle isozyme	Carbohydrate metabolic defect	English Springer Spaniels, American Cocker Spaniels
Hyperkalemic periodic paralysis (HYPP)	Skeletal muscle sodium channel	Channelopathy leading to myotonia and paralysis	Impressive line of Quarter Horses
Glycogen storage disease	Myophosphorylase	Carbohydrate metabolic defect	Charolais cattle
Canine myotonia	Skeletal muscle chloride channel - ClC-1	Channelopathy leading to myotonia	Miniature Schnauzer

considerably smaller than normal or smaller than littermates. In the rare cases in which the limb involvement is unilateral, the animal is likely to be born alive.

The causes of arthrogryposis are often not clear, although the underlying cause is generally agreed to be decreased limb movement in utero. Both myogenic and neurogenic disorders can result in decreased limb movement and arthrogryposis, but *denervation is by far the most common cause*. Arthrogrypotic fixation of the joints of lambs, calves, piglets, and foals, and less frequently of kittens and puppies, occurs with some regularity, and sometimes in epidemics. In cases of epidemic incidence, viral infections or toxins affecting the nervous system (see below) are most likely.

Unequivocal links exist between arthrogryposis and *the recognizable lesions caused by arrest or delay of neural tube closure* (**dysraphism**). These include, in the extreme, spina bifida and cord agenesis, but also anomalies of the dorsal septum, anomalies of the central canal such as hydromyelia and syringomyelia, anomalies of the dorsal, central or ventral gray matter (Fig. 2.30), and anomalies of the ventral median fissure (see Vol. 1, Nervous system). Dysraphism does not always lead to arthrogryposis; segmental lesions are sometimes found in clinically normal animals.

Obvious spinal cord and/or peripheral nerve abnormalities are present in a proportion, perhaps a majority, of arthrogrypotic domestic animals. In the rest, although an absence of primary myogenic or osteogenic lesions seems to point to a neurologic cause, the identity of the failed neural component is not obvious on routine investigation. Several careful studies of unilateral arthrogryposis in animals and children have indicated that the neural changes can be subtle and varied. The number of motor neurons in an apparently normal cord may be segmentally reduced, particularly in the caudal portion of the thoracic and lumbar eminences; or the number of motor neurons may be increased, or the neurons may be disoriented. Beyond this, conjecturally, there could be failure of neural direction, or connection, or of end-plate development.

Affected animals may have obvious reduction in mass of affected muscle due to atrophy or hypotrophy. Muscle mass can, however, appear superficially normal if there is replacement of the lost muscle mass by local masses of neonatal fat (Fig. 2.31). Dissection of major nerve trunks and muscle often is very difficult. Nerve trunks often appear to be normal on gross examination. Where comparisons are possible, peripheral nerve trunks in affected limbs may be demonstrably smaller and lacking some fascicles, although individual axons are normal.

Histologically, marked fiber size variation due to irregularity of muscle development may be evident. Groups of normal muscle can occur admixed with, or adjacent to, groups of small round muscle fibers (Fig. 2.32). Rarely, a typical denervation pattern of clusters of large

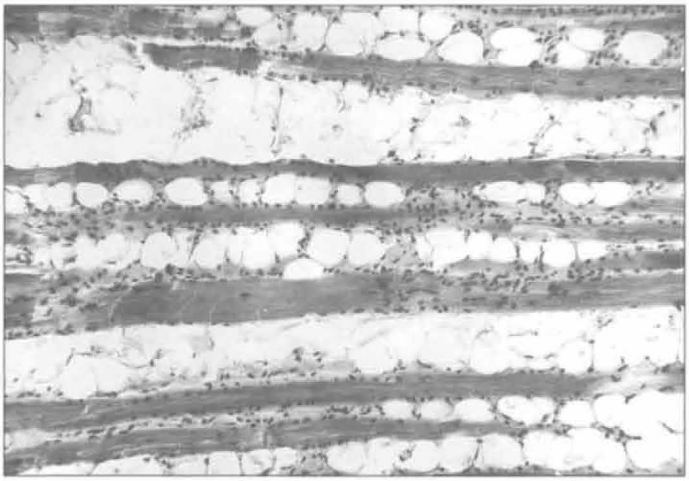

Figure 2.31 Muscle hypotrophy and fat replacement in a calf with arthrogryposis due to myelodysplasia. (Courtesy of TJ Hulland.)

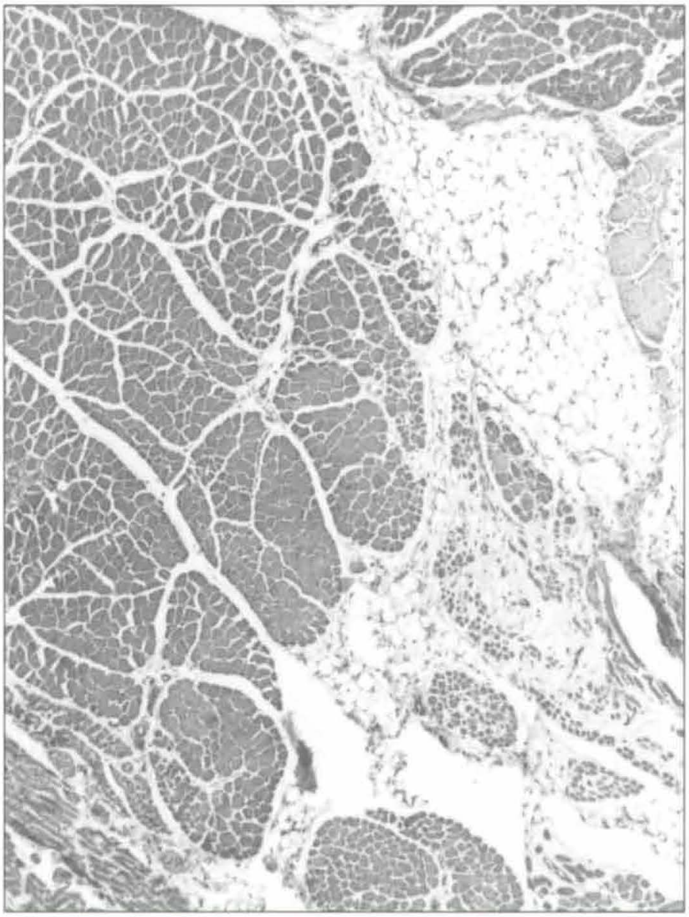

Figure 2.32 Admixed fascicles composed of myofibers of varied diameter, often with admixed fat infiltration, indicative of **asynchronous myofiber development** in an animal with arthrogryposis. (Courtesy of TJ Hulland.)

and clusters of small fibers can be seen. Abnormalities resulting in denervation and reinnervation will result in fiber type grouping. Other alterations in the fiber type pattern, such as type 1 fiber predominance (Fig. 2.33), are more difficult to explain but may reflect abnormal innervation or neural activity. Variable portions of muscle may be composed of adipose tissue.

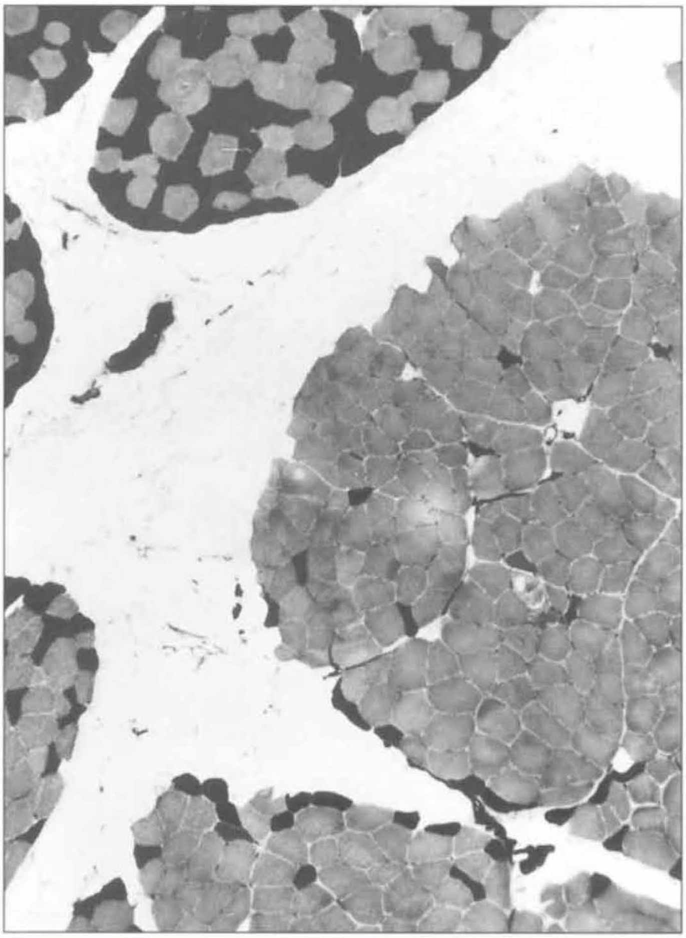

Figure 2.33 Fascicles exhibiting **type 1** (pale staining) **fiber predominance** in a lamb with arthrogryposis. Frozen section, ATPase, alkaline preincubation. (Courtesy of TJ Hulland.)

As noted above, it is often impossible to relate lesions to a specific cause. The critical event must occur early in pregnancy. *Genetic causes* are postulated in calves, sheep, and pigs, but the establishment of such a relationship does not require a different pathogenetic mechanism since the gene effect would apparently be directed at the neural component. Syndromes in the Charolais, Friesian, Swedish, and Red Danish breeds of cattle, sometimes associated with cleft palate, are consistent with that of a simple recessive or modified recessive characteristic. *Environmental toxins or viruses* may result in a similar disease pattern. The viruses of Akabane disease, Cache Valley fever, bluetongue, and border disease cause outbreaks of arthrogryposis in cattle and/or sheep. *Lupinus laxiflorus* (wild lupine), and other plant toxins, also cause deformities in fetuses when they are ingested by the dam during early pregnancy (see Vol. 1, Bones and joints).

Congenital flexures

Pastern contracture and immobility by itself can sometimes be part of arthrogryposis. If the flexure is combined with some degree of distal limb rotation, the pathogenesis is likely to be associated with neural and muscle changes as a minor expression of arthrogryposis. Many lambs, foals, and calves are born with an apparent inability to straighten the fetlock and sometimes other distal joints, yet deformities are minimal and muscle loss is not apparent. The problem in these cases seems to relate to the holding of the affected joint or joints in flexion without relief during a period of time in late gestation. The affected muscles appear to have reacted as they would following tenotomy by losing sarcomeres from the ends of myofibrils. This makes the joint initially incapable of extension, but under more or less constant tension the lost sarcomeres are quickly returned in hours or days. Such an explanation seems applicable because many affected foals and lambs recover completely within a few days to weeks. The original joint-fixing event can only be guessed at, but it would be easy to understand how it might happen in species in which the fetal size and limb length are high in relation to dam size.

Muscular defects

Defects in the form and disposition of muscles associated with neuraxial deformities are quite common but there are four syndromes of importance affecting muscle that are not associated with lesions in nervous tissue.

"Splayleg" (myofibrillar hypoplasia) in piglets

Splayleg, *also called spraddle-leg, is a disease of neonatal piglets.* It occurs in all countries with a well-developed pig-rearing industry. The incidence of the disease fluctuates inexplicably but frequently appears as a farm or regional outbreak. The disease incidence within litters is variable and a sow may produce consecutive litters with the disease. Genetic predisposition and infectious or nutritional causes are postulated but not proven.

Piglets with splayleg assume a posture with the hindlegs or all four legs laterally extended (Fig. 2.34). They are apparently unable to adduct them or retrieve them from a forward or backward position. Mobility is reduced and affected pigs are susceptible to accidents or may starve due to an inability to compete to suckle. *The locomotor defect is transient and within a week, or at most two, survivors appear normal.*

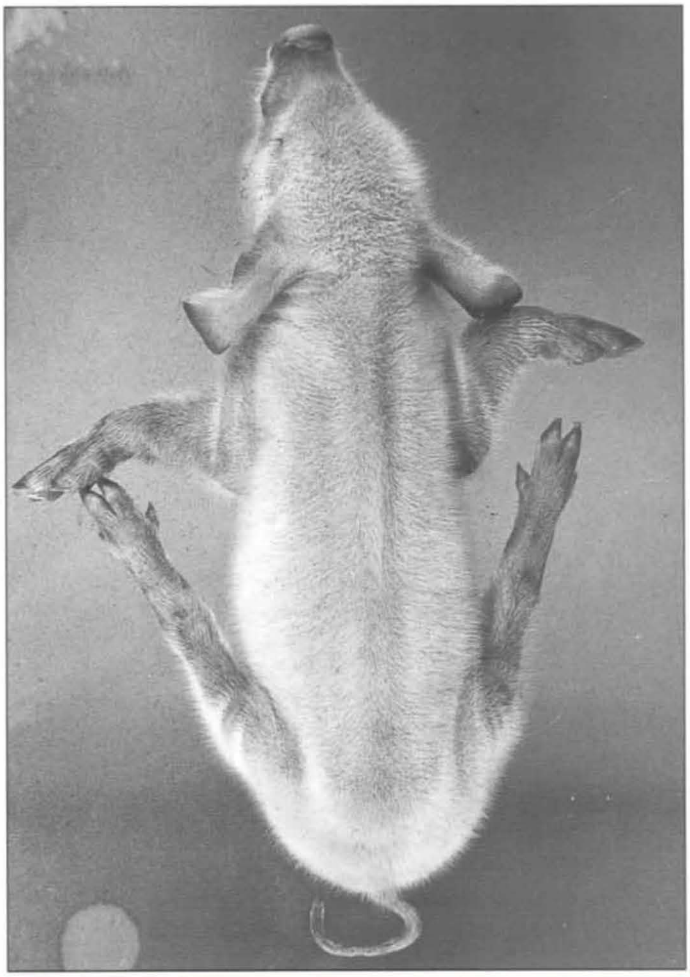

Figure 2.34 Piglet with **splayleg**. (Courtesy of TJ Hulland.)

The clinical signs of splayleg reflect muscle weakness. Not all piglets suffering from splayleg have primary muscle disease; other conditions cause similar signs, but much less frequently. Developmental abnormalities of spinal closure may be responsible (see Arthrogryposis and dysraphism) and myopathy induced by the injection of saccharated iron may produce a similar syndrome in one or more litters. The splayleg syndrome described here is unrelated to either of the above causes. The most common finding in skeletal muscle of affected pigs is *reduced diameter of myofibers with an abnormally small mass of myofibrils within individual muscle fibers* (Fig. 2.35A, B), and increased cytoplasmic glycogen filling the large extramyofibrillar spaces. It is also possible, however, to find the same histologic picture of apparent myofiber immaturity in clinically normal neonatal piglets. It may be that subtle differences in the degree of myofiber immaturity is the explanation for the variable clinical expression.

In the late intrauterine development of skeletal muscles in pigs, the muscle mass is increased by the *"stem line-template" method of new muscle fiber production.* A large type 1 muscle fiber centrally located within a sublobule (a segment of a primary bundle) of developing

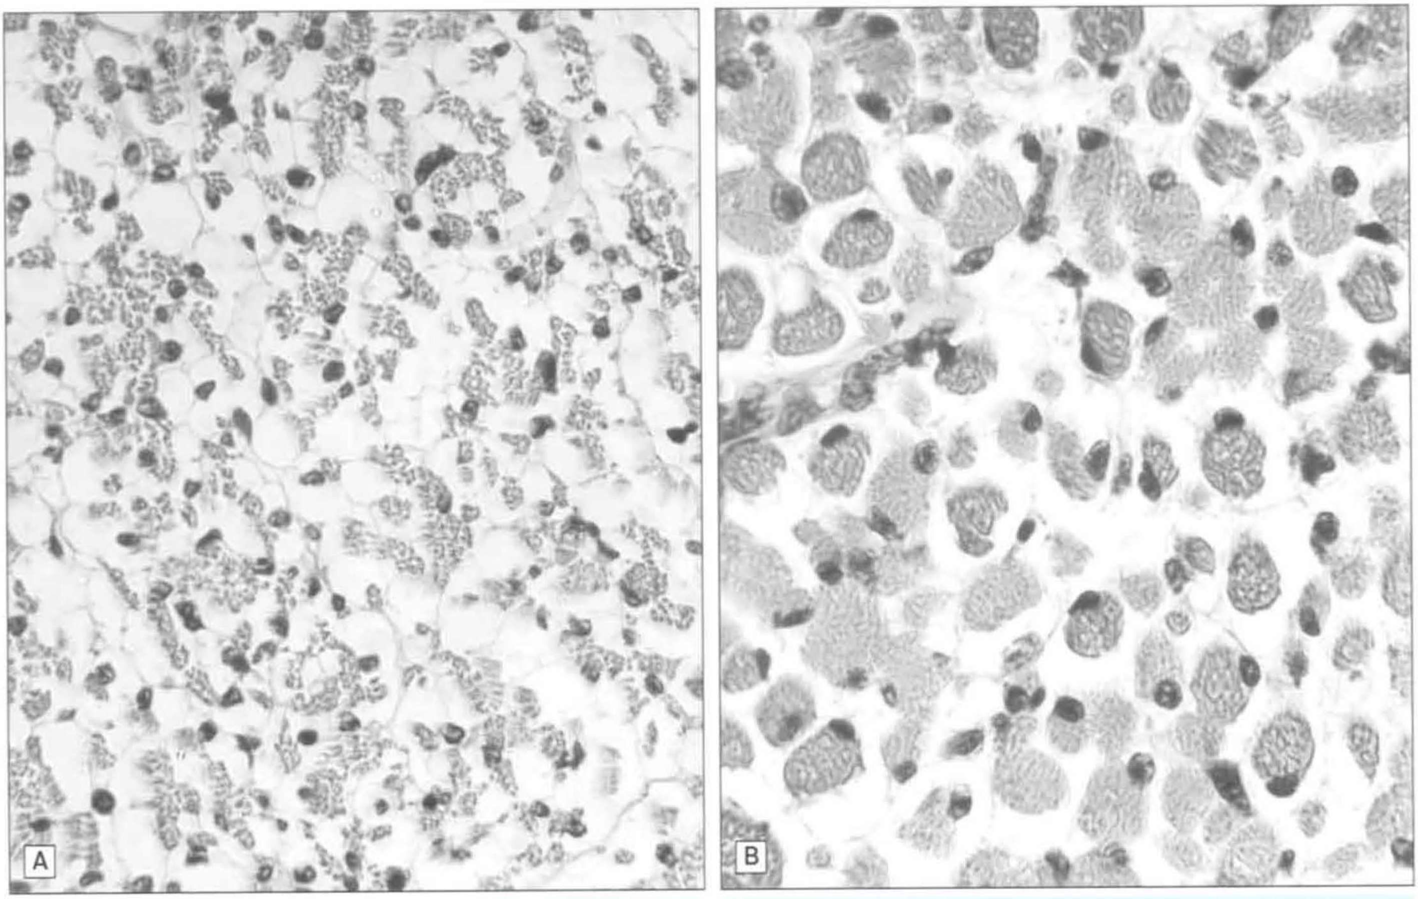

Figure 2.35 A. Reduced diameter of myofibers in a neonatal piglet with **splayleg**. (Courtesy of W Hadlow.) **B. Normal** neonatal piglet muscle. (Courtesy of W Hadlow.)

muscle apparently divides longitudinally to create a smaller daughter fiber, or acts as a template beside which a new fiber evolves from myoblasts. The new fiber has characteristics of a type 2 fiber. The central template fiber continues to spawn new fibers, gradually pushing those formed earlier to the periphery and thereby creating a sublobule of 10–20 fibers. Beginning at about the time of birth, a few of the most recently formed type 2 fibers adjacent to the primary or template fiber take on the characteristics of the central type 1 fiber. This early postnatal period also seems to mark the end of vigorous new fiber production, although some increase may continue in some circumstances. In the critical period just before and just after birth, splayleg pigs show an irregularity or retardation in the transition of type 2 fibers to type 1 fibers in the central sublobular region. *These findings in pigs with splayleg suggest delayed maturation of muscle in utero.* Examination of muscle from recovered piglets indicates that postnatal maturation continues, and the muscles from such pigs are indistinguishable from control piglets.

The characteristic lesions of myofibrillar hypoplasia are only partly revealed by light microscopy. Affected muscles, chiefly the longissimus, semitendinosus, and triceps, are incompletely or irregularly involved, and *the most obvious change is lightness of staining with eosin due to the low volume of myofibrils within outer cell membranes of normal volume.* The remainder of the fiber sheath appears to be empty but sometimes contains a nucleus or thin pink proteinaceous fluid. In longitudinal section, myofibrils appear to be diluted by watery fluid or clear strips of space. PAS staining reveals *marked accumulation of cytoplasmic glycogen.*

Electron microscopic examination of muscle from pigs with splayleg reveals segmental Z-line distortion with dispersal of the electron-dense material (Z-line streaming), loss of register and alignment of sarcomeres, reduced volume of myofilaments, and myofilament splitting and disarray. Glycogen granules are abundant, and there are increased numbers of ribosomes. Although degenerative changes, including increased phagolysosomes and lysis of myofilaments, have been described, this is not a consistent finding.

Myofibrillar hypoplasia has been reported as an isolated case in a *6-week-old calf.* Lesions very similar to those in splayleg pigs were seen. A clinical syndrome similar to splayleg occurs in puppies, and affected pups are known as "*swimmer pups*." Affected pups may have underlying myopathy or neuropathy, but more often this syndrome is seen in rapidly growing, overnourished pups. Dorsoventral flattening of the sternum often occurs. Affected pups often recover completely if measures such as use of a type of harness to help keep legs under the body and assisted exercise are employed.

"Double muscling" (muscular hyperplasia) in cattle

Economic pressure to produce beef cattle with increased muscling has undoubtedly led to perpetuation of multiple genetic defects involving muscle development. The best characterized of these is the defect known as double muscling. This disorder occurs within several beef breeds, including Charolais, Santa Gertrudis, South Devon, Angus, Belgian Blue, Belgian White, and Piedmontese cattle.

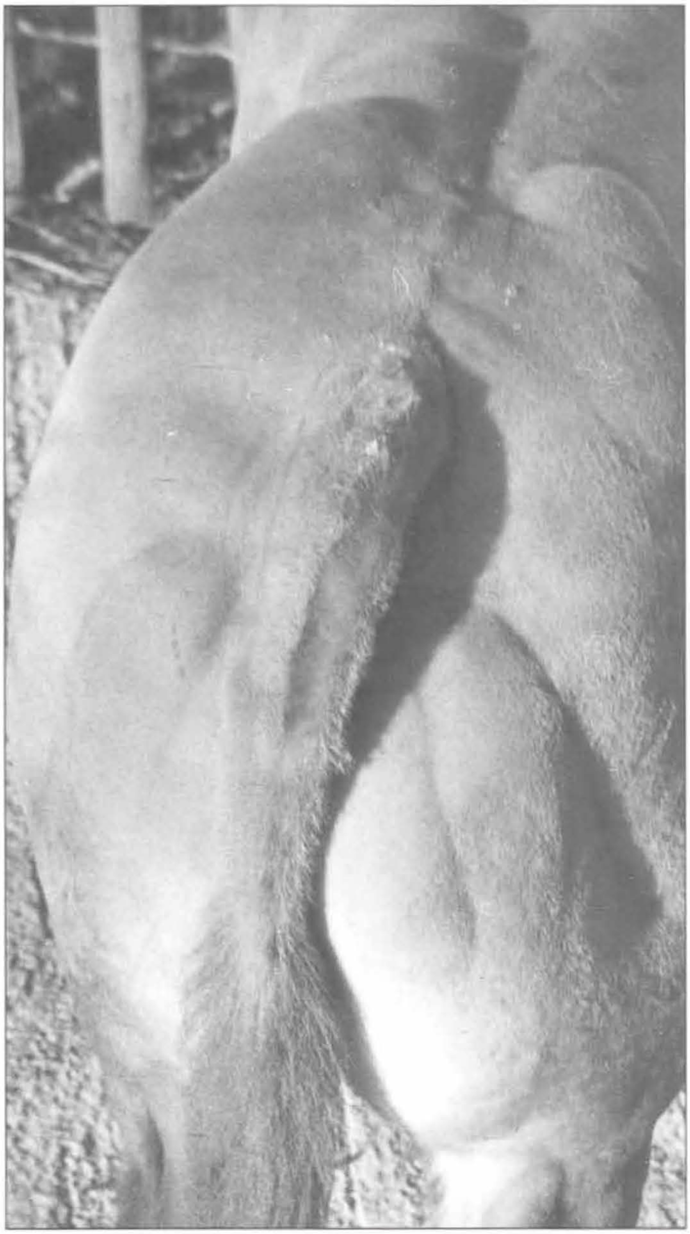

Figure 2.36 Congenital muscular hyperplasia in a calf. (Courtesy of JC MacKellar.)

It is characterized by an *increase in the number of fibers in affected muscles. The individual fibers are of normal size and structure.* This is in contrast to findings in other cattle with increased muscle bulk that are not double-muscled, in which a normal number of hypertrophied muscle fibers is found. In double-muscled homozygotes showing the full effect of the hyperplasia, the increase in gross muscle size is substantial, although not twice normal as the common name "double muscle" might suggest. In fact, the contours of the large muscles are regular and normal except for rather prominent topographical clefts between muscles which are associated with large individual muscle size, reduced body fat proportion and thin skin (Fig. 2.36). Bones may be lighter than normal and are often marginally shorter. Probably all striated muscles of the body are affected to some degree but *the muscles showing the most obvious change are those of the thighs, rump, loin, and shoulder* giving the calf a very athletic appearance and predisposing to dystocia. Some fiber increase is manifested by heterozygotes but the level of heritability seems to be low and subject to capricious variability of penetrance or expression. A higher proportion of type 2B glycolytic fibers and a decreased capillary density are found in muscle from doubled-muscled cattle.

This disorder has been found to be due to *genetic defects in the myostatin gene*, which normally functions to limit skeletal muscle growth. Other genes are likely to be involved in the development of double muscling, as the degree of double muscling in Belgian Blue cattle is significantly greater than in double-muscled Piedmontese cattle, despite the fact that both breeds have genetic defects that apparently result in inactivation of myostatin.

Muscular hyperplasia is also well documented in the *Callipyge phenotype in sheep* – the disease is only seen in heterozygote males and the molecular basis of the defect is associated with a mutation on chromosome 18. The condition is associated with hyperplasia of hindquarters and hindlimb musculature.

Muscular steatosis

Muscular steatosis *is a disease characterized by too much fat deposited within muscles.* It carries an inference that the fat is where muscle once was or ought to have been; effectively, *fat replacement of muscle fibers.* Fat infiltration of muscle is a *common nonspecific finding in chronic myopathic and neuropathic disorders that affect muscle.* The adipocytes that infiltrate muscle are derived from intramuscular mesenchymal cells. Fat infiltration may be accompanied by variable degrees of fibrosis. Steatosis of muscle is *best considered a reaction of chronically damaged or denervated muscle*, rather than a true developmental muscular defect.

The syndrome known as muscular steatosis in livestock is not typically associated with fibrosis. *It appears in clinically healthy animals, and it is usually a problem only in meat inspection.* Although previous damage due to neural lesions, nutritional myopathy, exertional myopathy, ischemia, or trauma are possible underlying causes, in most cases an exact cause is not determined. Studies on steatosis in normal market pig carcasses indicate that about 1–5% of pigs have small steatotic lesions and that a smaller proportion have extensive lesions of the anterior thigh or loin muscles (Fig. 2.37).

Sometimes the steatosis affects several muscles of one limb, but more often it affects only one or several muscles in one region. It may be bilaterally symmetrical or asymmetrical. Rarely does it affect all of one muscle and the dividing line between normal and fatty muscle is not sharp. Surviving muscle fibers in the marginal areas may be normal or smaller than normal but are often angular in fixed tissue as a result of adjacent pressure from turgid lipocytes.

Congenital clefts of the diaphragm

The embryologic development of the diaphragm is complex, with contributions from several different tissues. The septum transversum forms the central tendon, the dorsal aspect of the caudal mediastinum (the dorsal mesoesophagus) forms the diaphragm surrounding the esophagus and aorta, and the right and left pleuroperitoneal membranes fuse to close the pleuroperitoneal canals and form the final complete diaphragm.

Congenital diaphragmatic clefts affect all species either alone or as part of a more generalized malformation. *The most common defect involves the left dorsolateral and central portions of the diaphragm, indicative of failure of closure of the left pleuroperitoneal canal.* The clefts may permit

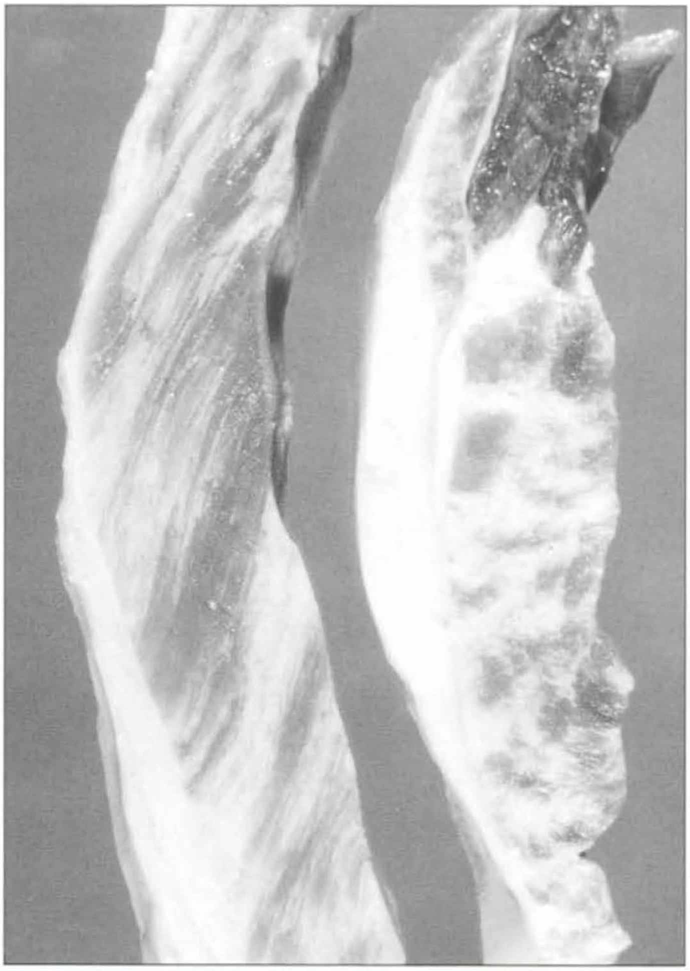

Figure 2.37 Steatosis of the loin muscle of a clinically normal pig. (Courtesy of TJ Hulland.)

the herniation of tissues ranging in size from a small button of liver to extensive displacement of viscera. In very large congenital clefts, the diaphragm may be represented by only a narrow rim of muscle that does little more than mark the diaphragmatic origin. Congenital clefts must be differentiated from acquired but healed lacerations of the diaphragm. The occurrence of congenital diaphragmatic hernia is best documented in the *dog* and in the *rabbit*. In the dog, incomplete closure of the left pleuroperitoneal canal is most common. In the rabbit, both defective closure of the left pleuroperitoneal membrane and absence of the major portion of the left diaphragm have been reported. Autosomal recessive inheritance has been proposed in both dogs and rabbits. The occurrence of congenital diaphragmatic hernias in five of 27 puppies from three father–daughter matings would support this form of inheritance, however further inbreeding of this particular colony of dogs failed to produce any subsequent pups with diaphragmatic hernias, suggesting that the genetic defect is likely to involve multiple genes.

Muscular dystrophy

The muscular dystrophies of humans are defined as inherited progressive myopathies characterized histologically by ongoing muscle fiber degeneration and regeneration. Peripheral nerves and neuromuscular junctions are normal, although a recent study in humans and mice found cognitive disorders and increased susceptibility of the CNS to injury in individuals with Duchenne dystrophy. The advent of molecular genetics has begun to further designate these disorders according to their genetic basis and has aided in validating several animal disorders as true animal models of human disease. Given the high conservation of genes on the mammalian X chromosome, it was suspected that progressive degenerative myopathies inherited as an X-linked recessive trait in animals were likely to be homologs of the X-linked Duchenne and Becker muscular dystrophies of humans. Molecular genetic analysis has proven this to be the case. **True muscular dystrophy**, *homologous to Duchenne and Becker muscular dystrophy of humans, occurs in the dog, cat, and mouse.* Duchenne and Becker muscular dystrophy are X-linked recessive disorders of humans caused by defects in the gene coding for dystrophin, a sarcolemmal-associated cytoskeletal protein. Immunostaining of frozen sections of muscle and Western blot analysis for dystrophin in snap-frozen muscle samples are necessary for confirmation of dystrophin-deficient muscular dystrophy. It is interesting that dystrophin deficiency results in progressive muscle atrophy in most breeds of dogs, but causes marked muscular hypertrophy in the mouse, cat, and Rat Terrier dog. Muscle fiber hypertrophy occurs, especially in early stages of the disorder, but extensive fiber necrosis leads to overall muscle atrophy in most cases. At this time there is no explanation for this phenomenon, although it would appear that muscle hypertrophy is more apparent in animals of small stature.

In animals, a number of muscle disorders have been erroneously designated as "muscular dystrophy," most notably those degenerative myopathies occurring secondary to nutritional deficiency. An inherited progressive myopathy in sheep has been described as a muscular dystrophy and is included in this section, although this disorder might be better classified as a congenital progressive myopathy because cytoarchitectural alterations are the hallmarks of this disorder, and on-going fiber degeneration and regeneration are not typical features. Other inherited myopathies in dogs and cattle, many of which have been described as muscular dystrophies, are considered to be less likely candidates for true muscular dystrophy and are described in the Congenital myopathy section.

Canine X-linked muscular dystrophy

Sporadic reports from around the world of a severe progressive degenerative myopathy affecting young male dogs led to the establishment of a breeding colony of affected Golden Retriever dogs. Although a similar disorder has now been identified in many breeds, including Irish Terrier, Samoyed, Rottweiler, Dalmatian, Shetland Sheepdog, Labrador Retriever, German Shorthaired Pointer, Brittany Spaniel, Rat Terrier, Belgian Groenendael Shepherd, and Schnauzer, *the disease is best characterized in the Golden Retriever.*

Affected pups may be normal or slightly small at birth. Some affected pups may show severe progressive weakness leading to death within the first few weeks of life. This may be particularly true of affected pups in large litters that include normal and carrier pups, and may in part be due to inability to compete for food. Other pups show no signs of disease until approximately 8 weeks of age, when reduced jaw mobility, exercise intolerance, and a stiff-legged gait become apparent. Serum activities of creatine kinase (CK) and aspartate aminotransferase (AST) are, however, markedly increased, indicative of severe myodegeneration, even in neonates with inapparent disease, and levels of CK and AST continue to rise until peaking at about 6 months of age. Serum CK and AST levels in older dogs are always high, but tend to be decreased as compared to younger dystrophic dogs. Serum activities of CK and AST are highest if blood is drawn 4–6 hours after exercise. *Clinical signs of neuromuscular weakness are progressive until approximately 8–12 months of age, when the disease tends to stabilize.* The severity of the disorder is variable, with some dogs developing severe muscle atrophy and contractures by 6 months of age (Fig. 2.38) and others remaining stiff, muscle wasted, and exercise intolerant but without severe impairment of joint mobility. Dystrophic dogs have a characteristic stiff-legged shuffling gait and a thickening of the muscles of the base of the tongue and under the jaw, tend to drool excessively, and develop abdominal breathing and often deformation of the ribcage due to diaphragmatic contracture. Esophageal dysfunction is common, and dystrophic dogs may develop aspiration pneumonia due to regurgitation. The severity of the disease varies among breeds. Although muscle atrophy is more obvious than hypertrophy in the Golden Retriever and Rottweiler, in other breeds such as the Rat Terrier there is progressive development of muscular hypertrophy resulting in obvious increased bulk, particularly involving muscles of the thigh, neck, and shoulder girdle. Breed size may have some role in the type and severity of changes, with larger breeds being most severely affected. Female carriers are clinically normal, although higher than normal levels of serum CK and AST are apparent, particularly in carriers under 6 months of age.

Concentric needle electromyography reveals marked spontaneous activity in the muscles of dystrophic dogs. Although the complex repetitive activity generated by canine dystrophic muscle was initially interpreted as a myotonia, resulting in characterization of this disorder as a myotonic myopathy, careful analysis of the electrical activity indicates that these bursts do not wax and wane but rather start and stop abruptly and are *characteristic of pseudomyotonia.* Although the exact cause of this electrical activity is not known, membrane instability associated with clusters of degenerating and regenerating fibers is suspected.

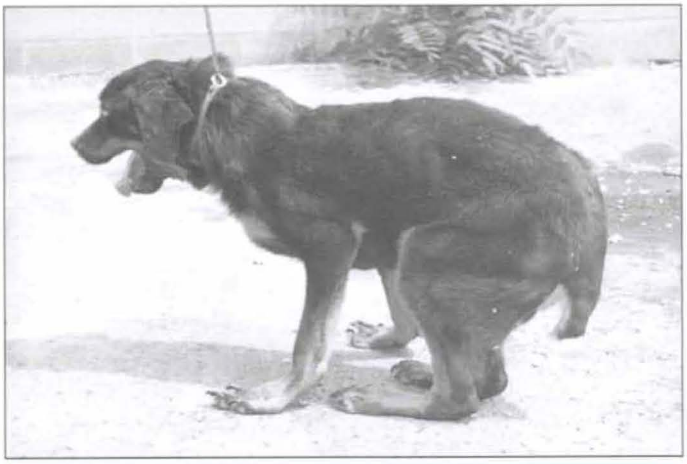

Figure 2.38 One-year-old male Rottweiler dog with severe **X-linked muscular dystrophy**.

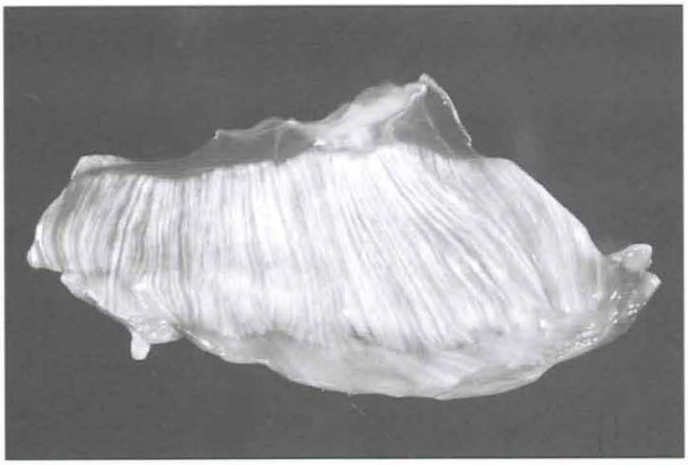

Figure 2.39 Pale streaking of diaphragm muscle due to **massive necrosis** in a neonatal pup with fulminant X-linked muscular dystrophy. (From McGavin MD, Zachary JF. Pathologic Basis of Veterinary Disease. 2006, with permission of Elsevier Ltd.)

Pups dying with fulminant neonatal disease have characteristic gross pathologic findings of severe degeneration of the diaphragm and strap muscles, including the trapezius and sartorius muscles of the limbs, characterized by pale white streaks within affected muscles (Fig. 2.39). Histologic evaluation reveals massive acute muscle fiber necrosis and mineralization, and similar findings are present in tongue muscle. This selective involvement of muscles in neonatal pups may reflect exercise-induced injury in muscles used for breathing, crawling, and suckling and may also involve the susceptibility to injury of more mature, larger-diameter fibers.

Gross pathologic examination of affected dogs that survive the neonatal period typically reveals pale musculature that may be slightly firm, especially true of the sartorius muscles of the hindlimbs. The diaphragm often exhibits the most striking changes, with thickening, contracture, and fibrosis evident (Fig. 2.40). On histologic examination, muscle samples exhibit the characteristic findings of muscular dystrophy. *Numerous swollen and dark staining fibers (so-called large dark*

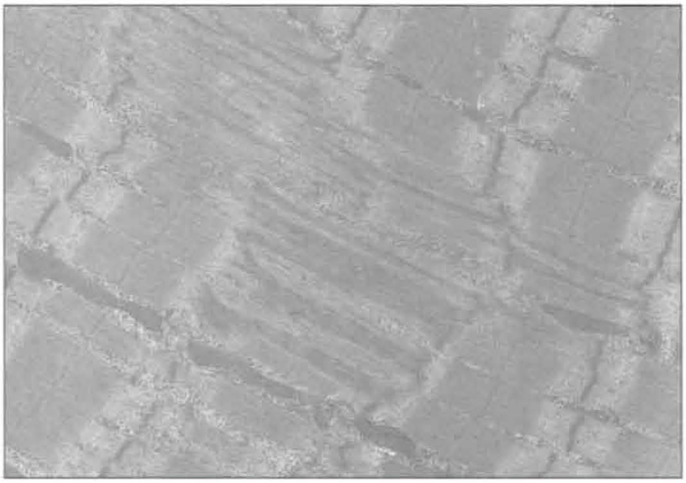

Figure 2.43 Streaming of Z bands in a pup with X-linked muscular dystrophy.

fibers) are seen throughout the sections and are considered to be the earliest stage of muscle fiber degeneration. Small clusters of overtly *necrotic fibers*, either in a coagulative state or macrophage-infiltrated, and of *regenerate fibers* are seen (multifocal, polyphasic necrosis; Fig. 2.41). Scattered *mineralized fibers* are common. The basal lamina of necrotic fiber segments is preserved, resulting in the presence of "empty sarcolemmal tubes" and in the ability to fully regenerate affected fiber segments. Muscle spindles are unaffected. With increasing age the degree of overt fiber necrosis and regeneration decreases. In *older dystrophic dogs*, marked fiber size variation, with internal nuclei, cytoarchitectural changes including nemaline rods, and a type 1 fiber predominance may be seen. Endomysial fibrosis and fat infiltration, the hallmark of advanced Duchenne dystrophy in boys, occurs in some muscles (Fig. 2.42), but is variable and typically less apparent in the dog.

In addition to evidence of fiber necrosis and regeneration, ultrastructural studies of muscle from dystrophic dogs have found small areas of apparent sarcolemmal defects in otherwise normal-appearing fibers. *Non-specific cytoarchitectural changes*, including increased mitochondrial content and Z-line streaming are also seen (Fig. 2.43). Alizarin red staining of frozen sections has confirmed that influx of calcium, probably through defects in the sarcolemma, is an early event leading to muscle fiber necrosis in dystrophic muscle (Fig. 2.44). Although considered to be an essential cytoskeletal protein and known to be part of a membrane-associated complex, *the exact function of dystrophin and the cause of muscle fiber necrosis in dystrophin-deficient muscle is still not clear.*

Cardiac muscle of dystrophic dogs 6 months or older exhibits myofiber necrosis, mineralization, and fibrosis of the myocardium in a subepicardial pattern. The left ventricular wall and right side of the interventricular septum are most severely affected (Fig. 2.45). The development of *progressive degenerative cardiomyopathy* is a hallmark of Duchenne and Becker muscular dystrophy in man, and often eventually results in congestive heart failure in older dystrophic dogs.

Immunostaining of frozen sections for dystrophin typically reveals complete absence of this sarcolemmal-associated protein (Fig. 2.46A, B), although partial expression may be present in Becker-type mutations or in so-called revertant fibers, which are fibers that have undergone genetic mutation allowing dystrophin expression. Cardiac muscle in dystrophic dogs completely lacks dystrophin. Although dystrophin expression has been absent or nearly absent in the dystrophic dogs studied to date, it is possible that animals expressing an abnormal truncated or elongated dystrophin will be found.

Muscle from young female carriers often contains numerous large dark fibers and scattered necrotic and regenerating fibers. The degree of overt necrosis and regeneration appears to be less than the proportion of large dark fibers seen, suggesting that membrane repair in some large dark fibers is possible. By about 6 months of age, evidence of degeneration or regeneration is rare. This reflects the mosaic pattern of dystrophin expression in carrier muscle. This mosaic pattern is most apparent in neonatal carriers, with loss of skeletal muscle mosaicism by about 6 months of age. This phenomenon is thought to reflect up-regulation or translocation of dystrophin throughout the mosaic muscle fiber. Cardiac muscle, composed of uninucleate cells incapable of regeneration, maintains a striking mosaicism for dystrophin for the life of the animal, and carrier females also develop cardiac muscle necrosis and progressive fibrosis in a pattern similar to that seen in dystrophic males. Curiously, although the fibrosis of cardiac muscle in older female carriers is quite striking, overt cardiac failure does not occur.

Feline X-linked muscular dystrophy

As in studies of canine muscular dystrophy, the recognition of a severe progressive degenerative myopathy in young male cats led to breeding studies of affected cats. To date, this disorder has only been reported in cats of mixed breeding. Its occurrence in Europe as well as North America suggests that, similar to canine X-linked muscular dystrophy, the feline dystrophin gene is prone to spontaneous mutation.

Affected cats develop marked muscle hypertrophy, stiff gait, "bunny-hopping" in the rear limbs, reduced activity and difficulty jumping up onto furniture and other objects. Clinical signs may be recognized as early as 5 months or as late as 2 years of age. Thickening of tongue muscle may result in difficulties prehending food and in drooling. Regurgitation due to esophageal dysfunction may also be evident. Given the fairly subtle signs, it is likely that affected cats may not be recognized by owners as being abnormal. Muscular hypertrophy is most evident in the muscles of the neck and proximal limbs (Fig. 2.47). Dystrophic cats are prone to development of a *malignant hyperthermia-like syndrome* associated with restraint or general anesthesia. Serum activities

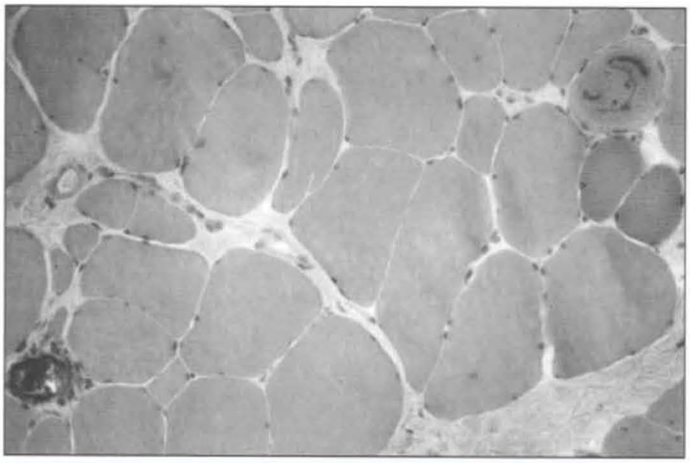

Figure 2.48 Excessive fiber size variation with both atrophy and hypertrophy, internal nuclei, and with scattered mineralized and bizarre fibers, in a cat with X-linked muscular dystrophy. Frozen section H&E. (Courtesy of BJ Cooper.)

of CK and AST are typically very high, and increases can be detected in kittens as young as 3 weeks of age. Electromyographic studies of affected cats reveal bizarre complex repetitive activity similar to that seen in the dystrophic dog.

At necropsy, affected cats have thickening of the muscular wall of the esophagus as well as marked thickening and contraction of the diaphragm. Skeletal muscle is often diffusely pale as well as displaying various degrees of hypertrophy. Pale streaks are often visible in the left ventricular wall and interventricular septum.

Histologic evaluation reveals *marked fiber size variation with numerous hypertrophied fibers often containing multiple internal nuclei.* Scattered clusters of necrotic and regenerating fibers with scattered mineralized myofibers are seen, and fibers with bizarre cytoarchitecture can occur (Fig. 2.48). The degree of myofiber degeneration and regeneration is often less than that seen in dystrophic dogs. Endomysial fibrosis occurs, but is minimal.

Foci of necrosis and mineralization of cardiac myofibers, followed by progressive fibrosis, can be seen in the left ventricular wall and interventricular septum of affected cats in a pattern similar to that seen in dystrophic dogs and in Duchenne and Becker muscular dystrophy. Cardiac lesions are not, however, a consistent finding in dystrophic cats, and clinical signs of cardiac insufficiency have not been reported, although experimental studies using inbred cats demonstrated left ventricular hypertrophy in all affected animals.

Muscular dystrophy, not X-linked, has also been described in cats associated with laminin deficiency. Affected cats developed progressive muscle weakness and atrophy, and also had peripheral neuropathies. In cases that survive for extended periods, fibrous replacement of atrophic muscle is severe.

Ovine muscular dystrophy

Muscular dystrophy of Merino sheep is an autosomal recessive disorder that occurs in widely separated flocks in Australia. This disorder affects about 1–2% of the progeny each year. The sexes are equally affected and *skeletal muscle of affected sheep expresses dystrophin in a normal manner, consistent with the non-X-linked nature of this disorder.* Although similarities to myotonic dystrophy of man have been proposed, there is no compelling evidence that this is the case.

Initial signs are *lack of normal growth and reduced flexion of the hindlimbs* that lead to aberrations of gait or, in mild cases, just stiffness. Subtle clinical signs may be detected in lambs at 3–4 weeks of age. The rate of progression of this disorder is extremely variable but the majority of cases have clear-cut signs of hindlimb gait abnormalities by 6–12 months of age and are severely affected by 2–3 years of age. Under field conditions, the animals often die of inanition at 6–18 months of age. With care, some animals can be maintained for up to 5 years, during which time the clinical disease is slowly progressive. Serum activity of CK is increased at rest in animals with unequivocal clinical signs of muscle dysfunction and is increased further following exercise. No electromyographic abnormalities are found.

On postmortem examination, apart from emaciation, the prominent changes are in the vastus intermedius, soleus, anconeus, and medial head of the triceps, where normal muscle may be replaced by mature adipose tissue. The muscles in advanced cases appear gray, and are hard and atonic. Involvement of other muscles, most often the extensors of the hip, stifle, and hock joints and flexors of the shoulder, carpus, and digits, is limited to microscopic changes only, although these muscles may exhibit some degree of pallor. Affected muscles have a high proportion of type 1 fibers, and it appears that this accounts for the distribution of lesions, as this disorder affects only type 1 fibers.

The initial stages of the dystrophic lesion are heralded by a general hypertrophy of type 1 fibers followed by loss of myofibrils and formation of characteristic sarcoplasmic masses at the periphery or in the central portion of the cell (Fig. 2.49A, B). This is followed by an irregular atrophy of fibers. Fiber proportions remain normal. Compensatory hypertrophy of fibers is often accompanied by fiber splitting, resulting in fiber nesting ("orange section" clusters). A few fibers develop peripheral annular fibrils ("ring fibers," or "ringbinden"). Many fibers acquire internally located nuclei. Hypercontracted fiber segments are observed only sporadically, and regenerative fibers are rare or nonexistent. Muscles undergo progressive loss of fibers which may reach 80–100% in animals over 2 years of age, and undergo progressive fat infiltration and/or endomysial fibrosis (Fig. 2.50A, B, C). In advanced muscle lesions, aggregates of lymphoid and histiocytic cells occur but these seem to be unimportant in the genesis of lesions.

(Courtesy of MD McGavin.)

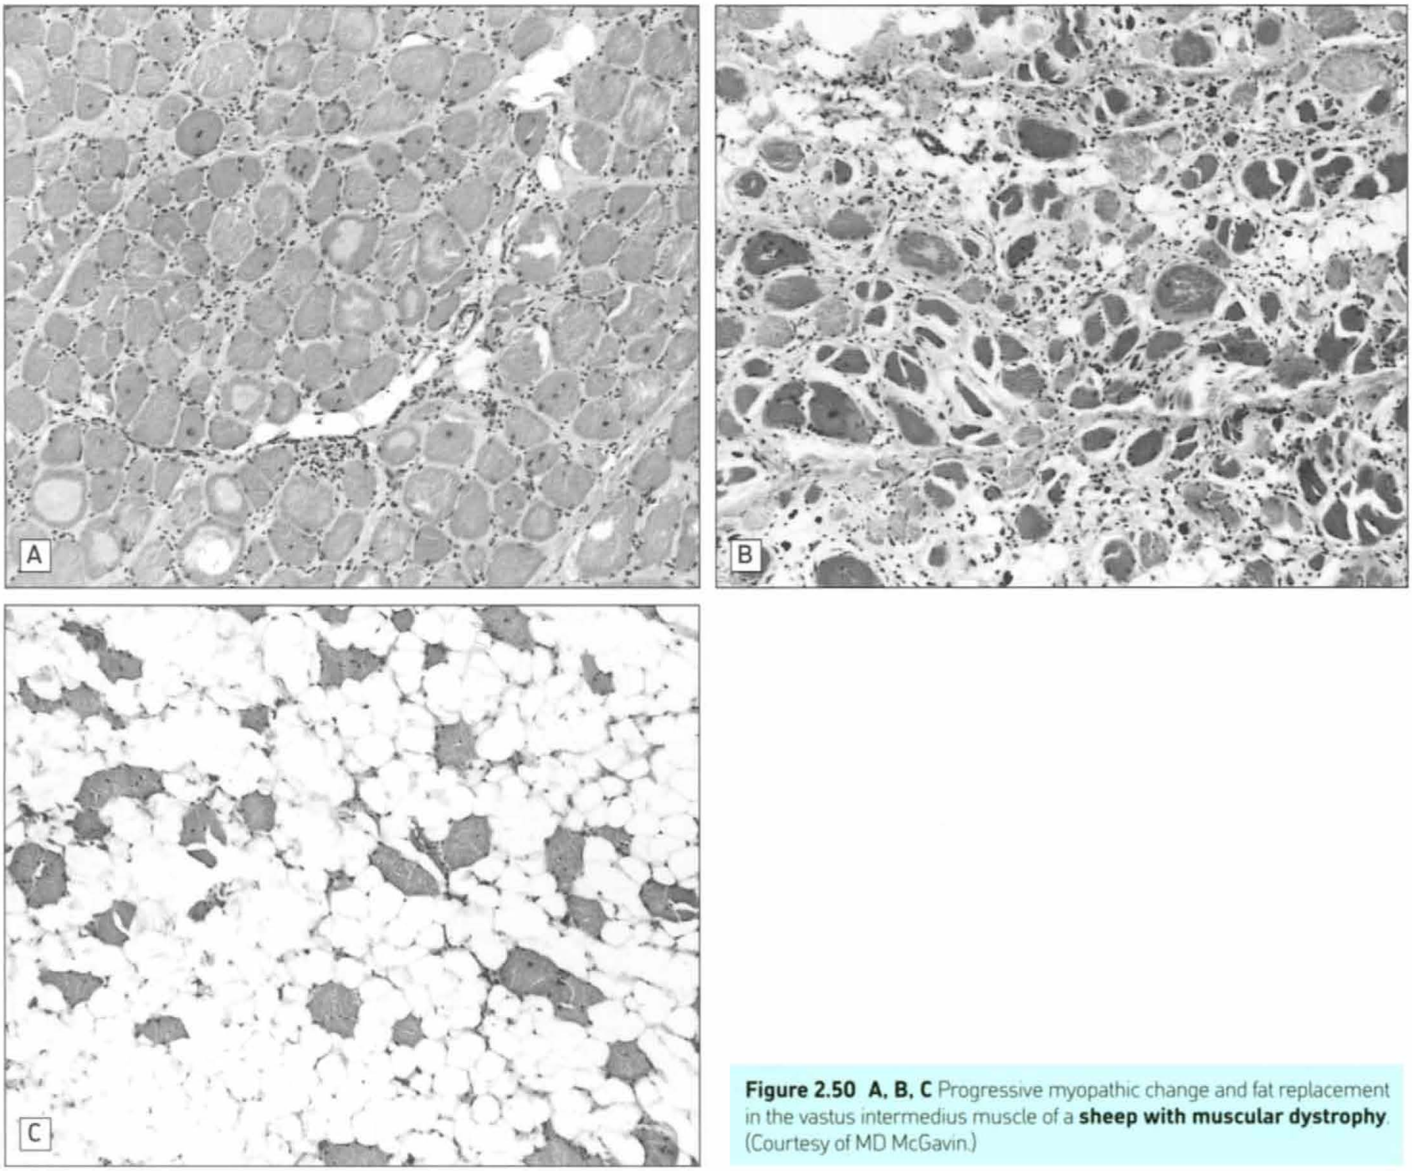

Figure 2.50 A, B, C Progressive myopathic change and fat replacement in the vastus intermedius muscle of a **sheep with muscular dystrophy**. (Courtesy of MD McGavin.)

Ultrastructural findings include *focal myofibril degeneration and Z-line abnormalities, including nemaline rods*. The distinctive sarcoplasmic masses are found to contain a mixture of normal organelles and tubular and fibrillar structures, including abnormal Z-line material. Immunocytochemical studies indicate profound alterations in cytoskeletal elements, including *loss of alpha actinin and proliferation of desmin*. Desmin forms the major constituent of the sarcoplasmic masses. Similar abnormal expression of desmin has been demonstrated in a growing number of myopathies affecting people and animals, and the term "myofibrillar myopathy" has been proposed for such disorders.

Inherited and congenital myopathies

Many animal disorders have been compared to similar disorders in humans, but such comparisons are rarely validated. Several disorders are included in this section that have previously been designated as muscular dystrophies; the myopathy of sheep included in the muscular dystrophy section might be better classified as an inherited progressive myopathy. Inherited metabolic disorders are described in the Metabolic myopathies section. *The classification of myopathies in animals, similar to those in people, is subject to modification based on findings of on-going genetic and pathogenetic studies as well as on changes in disease definitions.*

Breed-associated myopathies in the dog

Several myopathic disorders are recognized in dogs that are breed-specific and it is likely that many more will be identified in the future. An inherited basis is suspected, if not confirmed, in most cases of breed-associated myopathies.

Myopathy of Labrador Retrievers

An inherited myopathy in Labrador Retrievers has been reported from Europe, North America, and Australia. The disorder occurs in working dog lines and not in show lines and is inherited as an *autosomal recessive disorder*. Both yellow and black Labrador Retrievers are affected.

Clinical severity is quite variable. Evidence of *stunting, reduced exercise tolerance, and a stiff "bunny hopping" gait* may be apparent soon after birth or may not occur until about 6 months of age. Affected dogs may always have a slightly stiff gait and low head carriage, or may be apparently normal at rest. Exercise in affected dogs leads to increasing signs of weakness and collapse. Clinical signs are exacerbated by cold ambient temperature. Muscle atrophy may or may not be apparent. *The temporalis muscles appear to be particularly prone to atrophy*. Decreased or absent patellar reflexes are a consistent finding in affected dogs. Megaesophagus leading to regurgitation may occur, but is uncommon. This disorder may progress, but often stabilizes by 6 months to 1 year of age, and affected dogs may show some degree of improvement with age. Electromyography reveals bizarre spontaneous, high-frequency activity. Serum activities of CK and AST are normal or only slightly increased.

Gross pathologic examination may indicate normal or slightly reduced muscling. On histological examination, *affected muscles exhibit a marked increase in fiber size variation that is most severe in older dogs*. Although initial reports indicated a type 2 fiber deficiency,

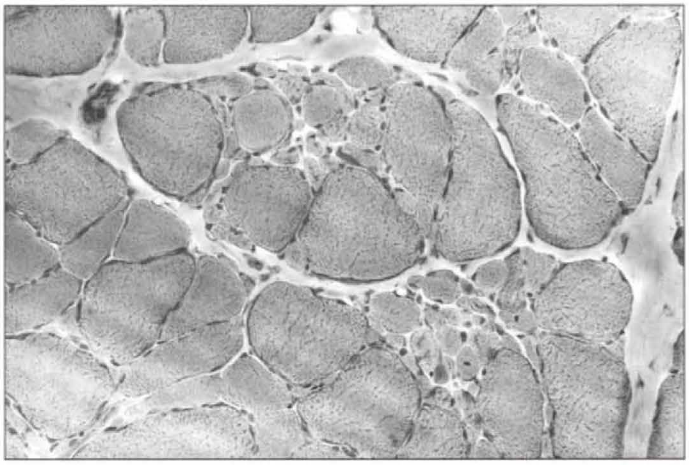

Figure 2.51 Increased variation in fiber diameter with groups of angular atrophied fibers and groups of fibers with rounded atrophy (mimicking denervation atrophy) in a Labrador Retriever with **congenital myopathy**. Frozen section, modified Gomori's trichrome.

subsequent studies indicate that, although alterations in fiber type are typical, atrophy or deficiency of type 2 fibers is variable. Scattered angular atrophied fibers may be seen. Fiber type grouping and small and large group atrophy are common (Fig. 2.51). Alterations in mitochondrial distribution are often striking, with peripheral mitochondrial aggregates and cytoplasmic zones devoid of mitochondria. Fibers with internal nuclei, whorled fibers, and split fibers are seen. There are scattered necrotic and regenerate fiber segments. Endomysial fibrosis is minimal. Despite the angular atrophy and fiber type grouping suggestive of denervation, motor nerve conduction velocities are normal and no abnormalities have been found in the peripheral or central nervous systems.

Myopathy of Bouvier des Flandres dogs

A *degenerative polymyopathy* occurs in the Bouvier des Flandres dog. Although the inheritance is not known, both sexes are affected. *Esophageal and swallowing muscles appear to be preferentially involved*, although generalized weakness occurs and histopathologic changes are seen in multiple muscles.

Affected dogs may not be recognized until 1–2 years of age when regurgitation due to megaesophagus becomes apparent. Clinical severity is variable, however, and affected pups may be slightly stunted and display locomotor and swallowing difficulties as early as 7 weeks of age. Generalized muscle atrophy, weakness, and a peculiar paddling gait are characteristic. Serum activities of CK and AST are typically moderately increased. Bizarre high-frequency activity is seen with concentric needle electromyography.

Gross pathologic findings are *generalized muscle atrophy and pallor and megaesophagus*. Histopathologic changes include moderate to severe increase in fiber size variation with rounded atrophy and hypertrophy of both fiber types. Severe cytoarchitectural changes are seen, including whorled fibers, split fibers, and fibers with internal nuclei. Multifocal myofiber necrosis and regeneration occurs, but is generally not striking. Endomysial and perimysial fibrosis occurs, but is relatively mild. Cardiac myofiber degeneration and fibrosis may also be present.

Canine dermatomyositis

A syndrome of crusting and alopecic skin lesions and associated myositis has been described in *Shetland Sheepdogs, Collies* and in a Pembroke Welsh Corgi dog. Canine dermatomyositis is thought to be inherited as an *autosomal dominant disorder* based on genetic studies in the Collie dog. This disorder has been likened to human dermatomyositis, which is thought to involve autoimmune mechanisms. In people, characteristic findings are a skin rash of the face, upper chest, and skin overlying joints, and muscle weakness with perifascicular atrophy and immune complex deposition and damage in skeletal muscle capillaries. Dogs with dermatomyositis develop distinctive skin lesions with basal cell degeneration and subepidermal cleft formation, but muscle lesions are not consistently found. Serum activities of CK and AST are normal. Nonsuppurative inflammation and atrophy of temporal and masseter muscles have been seen in affected dogs, however *electrodiagnostic and histologic studies of a group of affected Shetland Sheepdogs did not reveal convincing evidence of a primary myositis*. Muscle inflammation, when present, appeared to represent extension of inflammation from overlying ulcerated and inflamed skin lesions.

Other canine myopathies

A juvenile-onset distal myopathy occurs in Rottweiler dogs. Both males and females are affected, and clinical signs of muscle weakness and plantigrade and palmigrade stance are evident at about 2 months of age. The disorder is progressive, and is characterized histopathologically by *marked myofiber atrophy and fat infiltration with mild myonecrosis and endomysial fibrosis.* Serum activities of CK and AST are normal or only slightly increased. Electromyographic studies reveal rare fibrillations and positive sharp waves. The finding of decreased serum and muscle carnitine levels and improvement following carnitine supplementation suggest that *this may be a form of metabolic myopathy involving lipid metabolism*.

A *polymyopathy* with involvement of esophageal musculature occurs in association with dyserythropoiesis and cardiomegaly in *English Springer Spaniel dogs*. Findings in affected skeletal muscle include marked increase in fiber size variation with both rounded atrophy and hypertrophy and many fibers with internal nuclei. Central linear or irregular granular inclusions within myofibers that are visible on H&E and Gomori trichrome-stained frozen sections are characteristic. Inclusions are often associated with fiber splitting.

A myopathy with scattered degenerate and regenerate fibers and intramyofiber core-like structures has been seen in a young adult *Great Dane dog* with muscle weakness and atrophy. Ultrastructural evaluation revealed that the cores consist of disarrayed myofilaments and thickened Z-lines similar to nemaline rods.

Nemaline rods within myofibers occur as a nonspecific change in various canine myopathic conditions, and have been described in dogs with *X-linked muscular dystrophy*, hypothyroidism, and Cushing's syndrome. *Nemaline rods are formed by expanded Z-lines and are visible only in frozen sections stained with Gomori's trichrome stain or on ultrastructural evaluation.* Ultrastructurally, nemaline rods are electron-dense structures with periodicity similar to the Z-band material from which these structures arise. Congenital nemaline myopathy has been described in a 10-month-old Border Collie dog and adult-onset nemaline myopathy occurred in an 11-year-old Schipperke dog. Affected dogs displayed exercise intolerance and muscle weakness.

Endocrine myopathies are well recognized in humans, but in dogs are uncommon conditions sporadically associated with hypothyroidism, hyperadrenocorticism, and diabetes mellitus.

Inherited and congenital myopathies of cats

Primary congenital myopathies are less commonly described in cat than in dogs. Some are better characterized than others. It is possible that, given the relatively sedentary life of most house cats, a subtle neuromuscular dysfunction could be overlooked.

Nemaline myopathy of cats

An apparently inherited congenital myopathy characterized by intramyofiber nemaline rods occurs in mixed-breed cats. Both males and females are affected. This congenital myopathy is similar to congenital nemaline rod myopathy of people.

Affected cats exhibit signs of *progressive neuromuscular dysfunction* characterized by reluctance to move, a crouched "jerky" and hypermetric gait, muscle twitching, muscle atrophy, and hyporeflexia. Serum activities of CK and lactic dehydrogenase are mildly increased. No abnormalities are detected on electromyographic studies.

Muscle atrophy most severe in the proximal limb muscles and muscles of mastication is seen on gross examination. Characteristic histopathologic findings are seen with frozen section histochemistry, and include *atrophy of type 1 and type 2A fibers and presence of nemaline rods.* Nemaline rods are only visible with Gomori's trichrome stain (Fig. 2.52) and occur primarily within atrophied type 1 and 2A fibers and only rarely in type 2B fibers. Nemaline rods are also seen in toluidine blue-stained Epon-Araldite embedded sections and in sections examined by electron microscopy (Fig. 2.53). Fiber size variation and marked fiber splitting are also seen. Fiber typing is often indistinct in areas in which myofibers exhibit extensive fiber splitting. Fiber necrosis and regeneration are uncommon but may be seen, especially in younger cats.

Other feline myopathies

A syndrome of *feline hyperesthesia* has been recognized for many years. Detailed studies of frozen section muscle biopsies of epaxial muscle from affected cats have found numerous rimmed vacuoles. The contents of these vacuoles stain with monoclonal antibodies to paired helical filaments and beta amyloid, and this disorder has been likened to *human inclusion-body myositis.*

A myopathy causing spasticity has been reported in Devon Rex cats. Autosomal recessive inheritance is suspected. Affected cats exhibit neuromuscular dysfunction from an early age, typically from 3 to 23 weeks of age. Ventroflexion of the neck, exercise intolerance, megaesophagus, a hypermetric forelimb gait, muscle tremors, and collapse with exercise are characteristic. Serum activities of CK and AST are normal. Electromyographic studies indicate that abnormal spontaneous activity is rare and motor nerve conduction and repetitive nerve stimulation studies are normal. Sudden death due to laryngospasm is common. Histopathologic findings are consistent with a primary myopathy and are characterized by excessive fiber size variation due to rounded and angular atrophy and marked hypertrophy, internal nuclei, fiber splitting, and scattered necrotic and regenerate fibers. Endomysial fibrosis occurs in older affected cats.

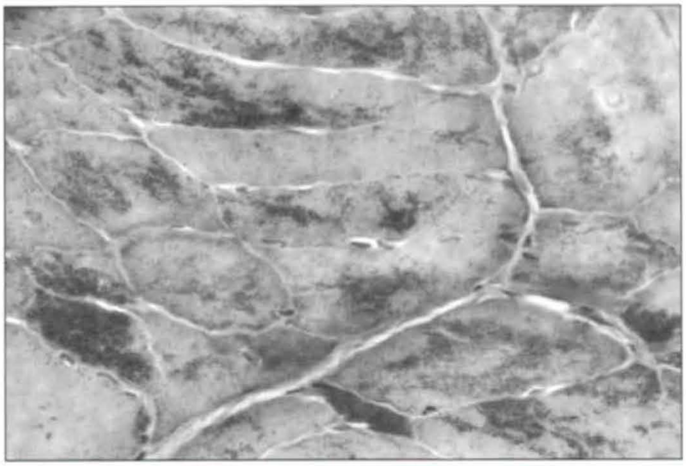

Figure 2.52 Numerous aggregates of dark staining nemaline rods in muscle from a cat with **congenital nemaline myopathy**. Frozen section, modified Gomori's trichrome.

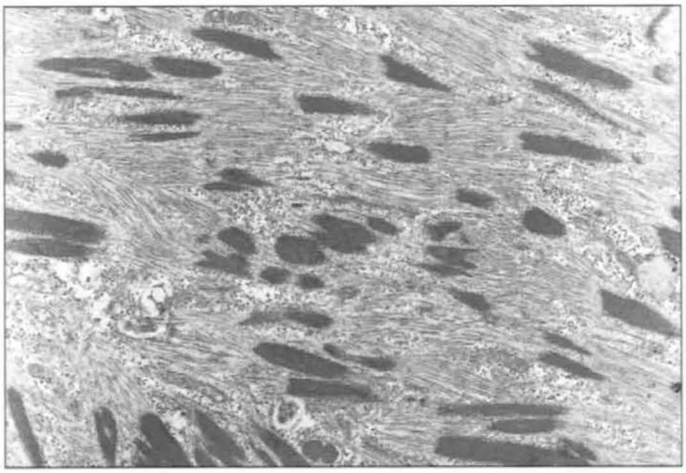

Figure 2.53 Dense staining elongate bodies composed of Z-disk material with associated myofilaments characteristic of nemaline rods in a cat with **congenital nemaline myopathy**. (Courtesy of BJ Cooper.)

Inherited and congenital myopathies of cattle

Congenital and inherited myopathies have been described in beef and dairy breeds. Double muscling in beef breeds, a genetic defect in the myostatin gene, is discussed under the heading Congenital and inherited defects. Myopathy due to glycogen storage disease is described in the Metabolic myopathy section.

Myopathy of the diaphragmatic muscle (diaphragmatic dystrophy)

An inherited myopathy affecting primarily diaphragmatic and intercostal muscles has been described in *Meuse-Rhine-Yssel cattle in The Netherlands and in Holstein-Friesian cattle in Japan.* The disorder in these two breeds appears to be identical. The disorder affects males and females, and is suspected to be transmitted as an autosomal recessive trait.

Clinical signs in affected cattle occur in adults from 2 to 10 years of age and include *loss of appetite and condition, decreased rumen activity, and recurrent bloat.* Serum activities of CK, AST, and LDH are normal.

Abnormal spontaneous activity was not seen in an electromyographic study of the diaphragm of affected Meuse-Rhine-Yssel cattle, although subtle changes in motor unit potentials were found.

The most severe gross pathologic changes are found in the *diaphragm, which is swollen, pale, and inflexible.* Similar changes are seen in intercostal muscles. Microscopic changes of myopathy occur in many other muscles and become more obvious as the disease progresses. Affected fibers exhibit marked cytoarchitectural alterations including vacuolar change, sarcoplasmic masses, atrophy and hypertrophy of fibers, numerous internal nuclei, marked fiber splitting, and central core-like lesions. *These core-like lesions are the most distinctive finding in this disorder.* Frozen section histochemistry studies demonstrate lack of mitochondrial enzyme staining within the cores, but strong staining at the periphery, similar to the cores and rimmed vacuoles described in several human myopathies. Scattered necrotic fiber segments are seen, often with macrophage infiltration. Endomysial fibrosis occurs and appears to be progressive. *Myocardial fibers contain distinctive centrally located inclusions* that are intensely acidophilic on H&E stain and dark green with Gomori's trichrome stain. On ultrastructural examination, the core-like lesions in skeletal muscle and the inclusions within cardiac myocytes consist of *disordered myofilaments with streaming of Z-line material.* Immunohistochemical studies of affected Holstein-Friesian cattle demonstrate that the core-like lesions in skeletal muscle contain actin and ubiquitin, but lack alpha actinin, desmin, and vimentin. Similar studies of myocardial fibers found variable ubiquitin reactivity of cardiac inclusions, and increased desmin reactivity on the periphery of the inclusions. It is proposed that this bovine disorder *may be a form of myofibrillar myopathy.*

Other bovine myopathies

Congenital myopathy occurs in *Braunvieh × Brown Swiss calves.* Both males and females are affected. These calves are abnormal at or soon after birth, with rapidly progressive muscle weakness and recumbency developing within 2 weeks of birth. Histological findings are marked fiber size variation due to fiber atrophy and hypertrophy, fiber splitting of hypertrophied fibers, disorganization of myofibrils, nemaline rods, internal nuclei, and peripheral eosinophilic inclusions. Fiber necrosis, regeneration, and endomysial fibrosis are not seen. Ultrastructural evaluation reveals that peripheral inclusions consist of tightly packed filamentous structures. Myofibrillar and mitochondrial disarray are also seen.

A congenital myopathy has been reported in a single Friesian calf that showed progressive weakness from birth. Muscle fibers were poorly developed and often exhibited lack of adequate myofibrils similar to myofibrillar hypoplasia of piglets. The most striking abnormality was the absence of Z-lines and presence of intracytoplasmic electron dense inclusions.

A degenerative myopathy characterized by necrotizing vasculopathy within skeletal muscle occurs in *young Gelbvieh cattle* (Fig. 2.54). The cause of this disorder is not known, although both immune-mediated and vitamin E deficiency-associated vasculopathy have been proposed.

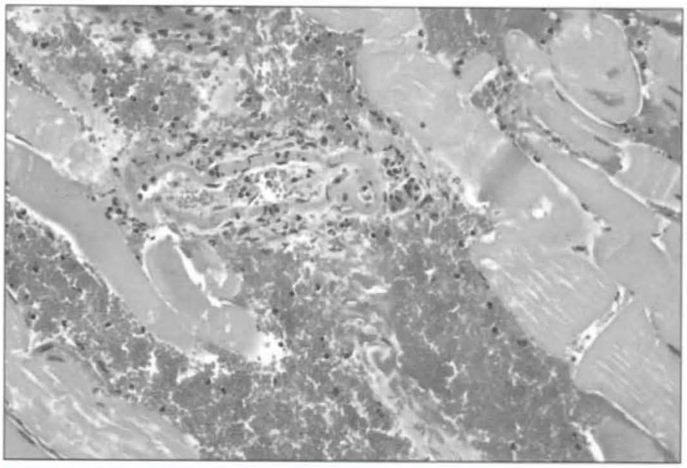

Figure 2.54 Necrotizing vasculitis and hemorrhagic necrosis of muscle in a Gelbvieh steer. (Courtesy of BJ Cooper.)

Inherited and congenital myopathies of sheep

The progressive inherited myopathy of *Merino sheep* in Australia has been described in the Muscular dystrophy section. A suspected autosomal recessive congenital myopathy has been described in *Border Leicester sheep.* At birth, affected lambs have clinical signs similar to lambs with cerebellar cortical atrophy ("daft lambs") but central nervous system lesions are absent. Clinical signs consist of difficulty or inability to rise and a peculiar arching of the neck with the head pressed back in an opisthotonos-like position. Pathologic findings in muscle are primarily within the cervical muscle and consist of abnormal fiber size variation due to fiber atrophy and hypertrophy. It has been proposed that small-diameter fibers represent delayed myofiber differentiation and maturation rather than atrophy. Ultrastructural abnormalities, including electron-dense bodies within axons of intramuscular nerves, suggest that myofiber lesions may reflect functional deficits of peripheral nerves rather than a primary myopathic process.

Myotonic and spastic syndromes

Myotonia *is defined clinically as a temporary inability of skeletal muscle fibers to relax, resulting in transient uncontrollable muscle tension as a result of voluntary muscle contraction, and is manifested clinically as muscle stiffness.* Electromyographically, myotonia is characterized by waxing and waning spontaneous electrical activity ("dive bomber" sounds) evident following needle insertion or muscle percussion during concentric needle electromyography. In many, but not all, myotonic syndromes, prolonged focal muscle contraction may be elicited by muscle percussion, a phenomenon known as "*dimpling*" (Fig. 2.55). Myotonia may be inherited or acquired. Myotonia is most obvious on initiation of muscle contraction and often improves with continued exercise. Affected individuals may be normal between episodes or have persistent muscle stiffness resulting in a stiff gait. Myotonic syndromes reflect muscle membrane electrical abnormalities, most often associated with *ion channel defects*. Ion channel disorders are a diverse group of disorders, collectively termed the *channelopathies*, and many involve the abnormal regulation of chloride and sodium ions.

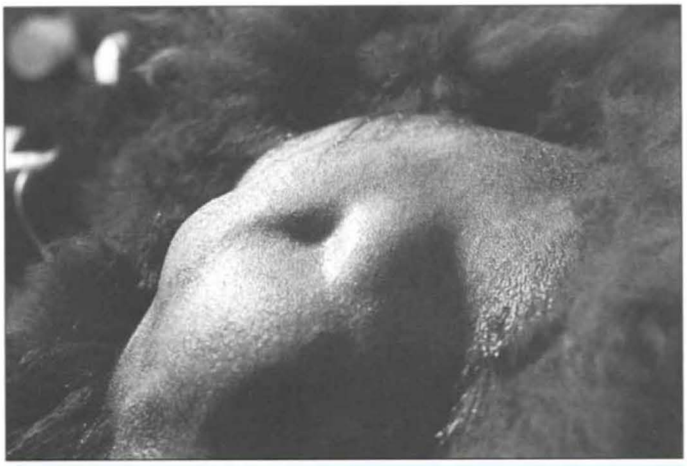

Figure 2.55 Dimpling following percussion in a Chow Chow dog with **congenital myotonia**. (Courtesy of L Fuhrer.)

In animals, confirmed or suspected inherited myotonias are most common. Drug- or toxin-induced myotonia occurs in humans, and a report of transient myotonia in a dog following ingestion of a phenoxy herbicide indicates that such induced forms of myotonia are possible in animals. Hypercortisolism due to endogenous or exogenous corticosteroids can induce a myotonia-like syndrome in dogs, although this disorder is best classified as a *pseudomyotonia*. Pseudomyotonic electrical discharges are also a feature of X-linked Duchenne-type muscular dystrophy in the dog and cat, and the canine disorder has been erroneously described as a myotonic myopathy.

Several syndromes involving *episodic spasticity of limb movements* are recognized in animals. The cause of these spastic syndromes is poorly understood, although an inherited basis is often suspected. Although primary myopathy is suspected in some cases, it is also possible for abnormal peripheral or central nervous system activity to result in episodic spasticity.

Myotonia in the dog

A *congenital myotonic syndrome* has been described in several breeds of dog, including Chow Chow, Staffordshire Terrier, and Miniature Schnauzer dogs. A suspected *adult-onset myotonic syndrome* has been described in the Rhodesian Ridgeback and Boxer dog. Clinical signs in myotonic dogs are often misinterpreted as a shifting leg lameness. Myotonia has been best characterized in the Chow Chow and Miniature Schnauzer dog.

Myotonia in the Chow Chow

This disorder occurs in Chow Chow dogs worldwide, including North America, Europe, Australia, and New Zealand. It may be that breeding for heavy muscling has concentrated the trait in this breed. Myotonia in Chow Chows affects both sexes, and is likely to be an *autosomal recessive trait*. Mildly affected animals, however, may go undetected. The specific muscle defect leading to myotonia in the Chow Chow is still not known.

Clinical signs of stiff gait and muscular spasm on initiation of movement may be apparent as early as 6 weeks of age. Electromyographic evidence of myotonia precedes obvious clinical signs and persists for the life of the animal. Laryngospasm is common, causing episodic collapse or cyanosis, and affected dogs often have a weak or hoarse bark. Muscular contraction occurring when affected dogs attempt to rise often results in transient splaying of the forelimbs followed by sufficient relaxation to allow the dog to stand and ambulate, although affected Chow Chows often have a persistent stiffness of gait. Affected dogs may have a stiff "bunny hopping" gait in the pelvic limbs, and muscular hypertrophy is evident in early stages. Percussion of limb or tongue musculature results in dimpling (Fig. 2.55). Serum activity of creatine kinase may be mildly increased. Muscle atrophy may develop in older animals.

In young myotonic dogs, the muscles may appear hypertrophied. In older affected dogs, muscle atrophy may be more obvious, and muscles may appear slightly pale. Histopathologic findings in affected muscle are minimal in early stages of the disorder. Only rare necrotic fibers are seen. With time, *progressive myopathic changes*, including excessive fiber size variation due to both hypertrophy and atrophy, internal nuclei, and mild endomysial fibrosis may be apparent. *Chronic myopathic changes, in particular numerous fibers with one or more internal nuclei, are the most consistent finding in muscle from older myotonic Chow Chows.*

Myotonia in the Miniature Schnauzer

Myotonia in the Miniature Schnauzer, reported as "myotonic myopathy," is also suspected to be due to *autosomal recessive inheritance* and appears to be clinically and histopathologically similar to myotonia in the Chow Chow. Abnormal muscle membrane chloride conductance in the Miniature Schnauzer is due to mutations in a skeletal muscle voltage-dependent chloride channel, CIC-1.

Myotonia in the cat

A suspected inherited congenital myotonia occurs in mixed breed cats. Clinical signs include a *crouched and stiff hindlimb gait and marked hypertrophy of proximal appendicular muscle evident at about 4 months of age*. These clinical signs of myotonia resemble those of male cats with muscular dystrophy, however serum activities of CK and AST in myotonic cats are normal. Vocalization is weak, facial muscle spasms may be seen, and transient laryngospasm may occur. Electromyography reveals characteristic waxing and waning myotonic activity. Muscle percussion induces "dimpling." *Increased variation in fiber size due to prominent fiber hypertrophy is the primary histopathologic finding.* Fibers with multiple tiny clear cytoplasmic vacuoles may be seen, especially in plastic-embedded sections. Ultrastructural evaluation reveals mild dilation of T-tubules and terminal cisternae of the sarcoplasmic reticulum (Fig. 2.56). Clinical signs are apparently not progressive. Both males and females are affected, and the underlying defect is as yet unknown.

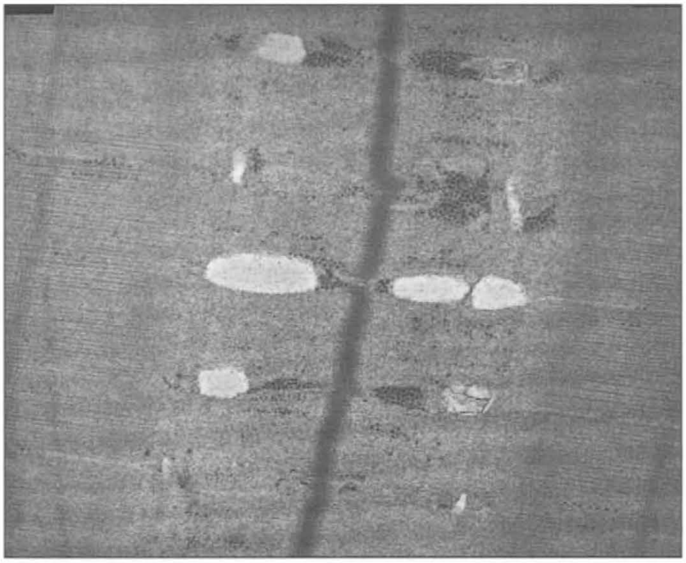

Figure 2.56 Dilated sarcotubular elements in muscle from a cat with **congenital myotonia**. (Courtesy of JF Cummings.)

Myotonia in the goat

Congenital myotonia in the goat has been recognized for many years. *The myotonic goat is said to be the oldest recognized animal model of an inherited human skeletal muscle disease.* In fact, these so-called "*fainting goats*" are prized by certain breeders. If nothing else, the advantages of keeping such goats include the difficulty myotonic goats have in jumping fences due to muscle spasms associated with initiation of muscle contraction.

Myotonia in goats is inherited as *an autosomal dominant trait, with probable incomplete penetrance*. This disorder has been shown to be due to mutation in a skeletal muscle voltage-dependent chloride channel, CIC-1, which causes decreased skeletal muscle chloride channel conductance. This condition is very similar to congenital myotonia (Thomsen's disease) in humans.

Affected goats show clinical signs of myotonia within 2 weeks of birth. Attacks are most often initiated by startling an affected goat. Affected goats assume a "sawhorse" stance and often fall over. Myotonic episodes are transient and affected goats are normal in between episodes. Percussion induces a prolonged muscle "dimpling," and concentric needle electromyography reveals characteristic waxing and waning myotonic potentials. Serum activities of CK and AST are normal.

There are no gross abnormalities in myotonic goats, and affected goats do not appear to be heavily muscled. Histopathologic changes in muscle examined by light microscopy are minimal, with only mild increase in fiber size variation due primarily to fiber hypertrophy and, in some cases, increased internal nuclei. On ultrastructural examination, dilated and proliferated sarcoplasmic reticulum and T-tubules are evident.

Periodic paralyses

The periodic paralyses are a group of inherited muscle disorders. In humans, hypokalemic, normokalemic, and hyperkalemic periodic paralyses are recognized. Although electrical myotonia and pseudomyotonia is a feature of many of the periodic paralyses, the transient attacks of paralysis are associated with muscle hypotonia rather than hypertonicity. These disorders are *sometimes referred to as paramyotonias* rather than true myotonic syndromes. The periodic paralyses are *due to ion channel defects that affect muscle sodium channel activity* and alter the muscle membrane potential. To date, only hyperkalemic periodic paralysis has been recognized in animals. The most common and the best-characterized syndrome occurs in horses. A similar disorder has been seen in a young American Pit Bull dog.

Hyperkalemic periodic paralysis in horses

Hyperkalemic periodic paralysis (HYPP) occurs in horses related to the Quarter Horse stallion "Impressive" and is inherited as an autosomal dominant trait. Homozygotes exhibit more severe signs of muscle dysfunction than do heterozygotes. The diagnosis of HYPP in horses can be confirmed by DNA testing.

Foals homozygous for HYPP often exhibit a peculiar respiratory noise due to *laryngospasm*, and may develop dysphagia and emaciation during the first 2 years of life. Laryngospasm and pharyngeal collapse associated with exercise is common. Such horses must be considered nonviable as performance animals. Heterozygotes may appear to be clinically normal, but are prone to transient attacks of paralysis. Initial signs include muscle fasciculations, flashing of the third eyelid, muscle spasm, and inspiratory stridor. In severe attacks, these signs will be followed by collapse to sternal or lateral recumbency associated with limb hypotonia. Attacks typically last from a few minutes to a few hours. Electromyography performed when animals are apparently normal reveals myotonic discharges and complex repetitive activity (pseudomyotonia).

Serum chemistry analysis often reveals higher than normal potassium levels in affected horses, particularly during attacks of weakness, but this finding is variable. Serum activities of CK and AST are normal or only very slightly increased. Clinical signs of weakness can be induced in HYPP horses with an oral potassium challenge test, high potassium feeds such as alfalfa or molasses-containing feeds, stress, or cold weather. *Sudden death* may occur in HYPP horses, perhaps due to effects of increased blood potassium on cardiac function. Attacks may also be precipitated by inhalant anesthetic agents, and may resemble malignant hyperthermia.

The underlying defect in HYPP in horses, as in man, is a mutation in the muscle sodium channel leading to increased open time. The increased influx of sodium through defective channels results in compensatory loss of muscle potassium, hence the hyperkalemia. Increased concentration of potassium ions outside the cell may further activate the abnormal sodium channels. The alteration in resting muscle membrane potential can lead to increased muscle action potentials and muscle fasciculations and spasms as well as to complete depolarization with inactivation of sodium channel activity and collapse.

There are no gross findings in horses with HYPP, other than frequent heavy and well-defined muscling. Although a vacuolar myopathy similar to humans with hyperkalemic periodic paralysis has been reported, in most cases of equine HYPP, *abnormalities are not found on light microscopy*. Ultrastructural findings of dilated sarcotubular elements are characteristic of HYPP, and are similar to those seen in myotonia in the cat and goat. DNA testing is now available on cells obtained from mane hairs rather than on blood, which is a boon for the pathologist who can now obtain the appropriate sample for testing in cases of otherwise unexplained death in Quarter-Horse-related breeds.

Myotonic dystrophy-like disorders in dogs and horses

Myotonic dystrophy is the most common inherited myotonic disorder in humans, affecting approximately 5 per 100 000 people, and is inherited as an autosomal dominant condition. Onset of obvious clinical signs is most often in late childhood, although this is quite variable, and a congenital form is also recognized. Myotonic dystrophy is a multisystem disorder associated with a constellation of signs, including cataracts and testicular atrophy. Muscle dysfunction is progressive, although the clinical signs of muscle dysfunction remain relatively mild. Findings in muscle biopsies include selective atrophy of type 1 fibers, hypertrophy of type 2 fibers, internal nuclei, ring fibers, and sarcoplasmic masses. However, these histopathologic findings are not specific for myotonic dystrophy. Attempts have been made to classify a group of animal disorders as animal models of myotonic dystrophy based on some similarities in clinical and pathologic findings, but the evidence for this is unconvincing. In particular, the involvement of other organ systems is generally lacking. The genetic defect in human myotonic dystrophy has been shown to be an abnormal expansion of a trinucleotide (CTG) repeat in a gene coding for a serine-threonine protein kinase. Similar molecular studies are lacking in animals. Myotonic dystrophy-like disease has been reported in a Rhodesian Ridgeback dog and in a Boxer dog. The best characterized of the myotonic dystrophy-like disorders occurs in the horse.

Myotonic dystrophy-like disease in the horse

A progressive early-onset myopathy associated with clinical and electrical myotonia and profound cytoarchitectural alterations in muscle occurs sporadically in horses. Breeds affected include Quarter Horse, Thoroughbred, and Standardbred, and both males and females appear to be equally represented. Although the early onset of clinical signs suggests that this disorder is congenital, to date there is no proof that it is inherited, and affected foals appear to occur only sporadically.

Affected foals may have difficulty standing at birth or, more commonly, develop a *progressive stiff gait with marked prominence of proximal limb muscles*, especially the gluteal muscle, evident at about 1 month of age. Percussion of muscle induces prolonged muscle dimpling. Affected foals become progressively weaker and have difficulty rising, with later development of muscle atrophy. Serum activities of CK and AST may be mildly increased. Concentric needle electromyography reveals characteristic myotonic and pseudomyotonic discharges.

At necropsy, affected muscles are often hypertrophied (Fig. 2.57) and may contain fibrous tissue and linear streaks due to fat

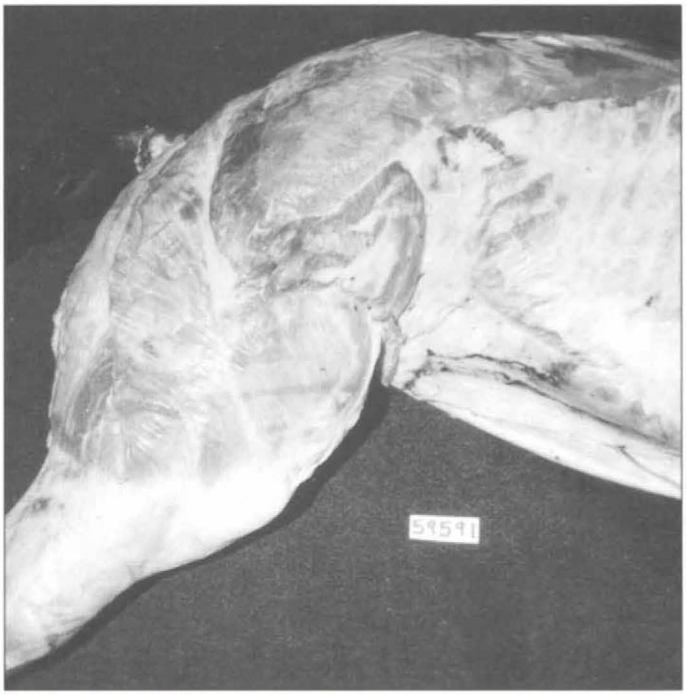

Figure 2.57 Muscular hypertrophy of the hindquarters in a foal with **myotonic dystrophy-like disease**. (Courtesy of TJ Hulland.)

infiltration. Severe lesions are pale and yellow-white. Atrophy of affected muscles may also be seen. There is a selective involvement of muscle, with *the most severe lesions found in the longissimus, iliopsoas, medial gluteal, biceps femoris, semitendinosus, semimembranosus, and sartorius muscles.* The triceps brachii and rectus femoris are less severely affected.

Histopathologic findings are a marked increase in fiber size variation with fiber hypertrophy as well as rounded atrophy and severe cytoarchitectural changes including pale-staining peripheral sarcoplasmic masses, internal nuclei, and small clear vacuoles (Fig. 2.58). Ring fibers and fiber splitting can also be seen. Only scattered necrotic and regenerate fibers are seen. Alterations in fiber type distribution in affected muscles include type 1 fiber predominance and fiber type grouping. Peripheral and intramuscular nerves, however, are histologically normal. Endomysial and perimysial fibrosis occurs, but is variable.

On ultrastructural examination, sarcoplasmic masses are composed of ribosomes, mitochondria, and disarrayed myofibrils.

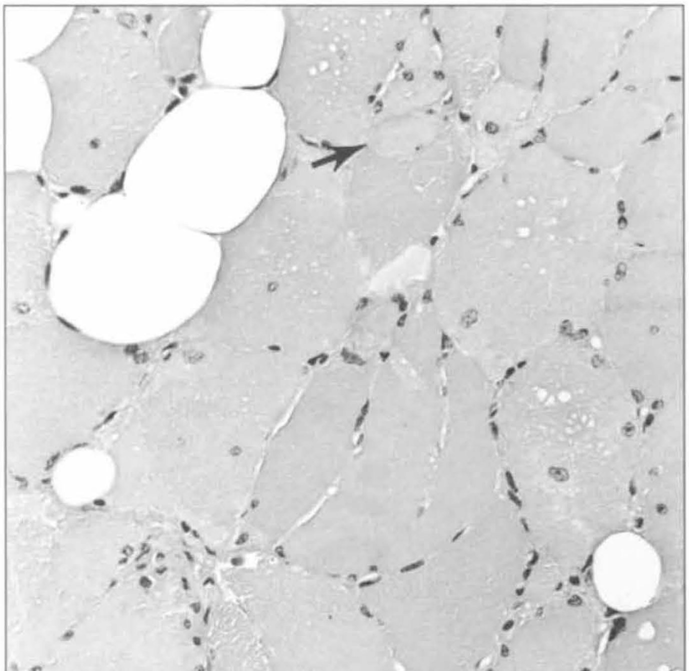

Figure 2.58 Excessive fiber size variation, pale peripheral sarcoplasmic masses (arrow), internal nuclei, fine cytoplasmic vacuoles, and fat infiltration in muscle from a **foal with myotonic dystrophy-like disease**.

Other myotonic-like disorders in the horse

A syndrome resembling *stiff-man syndrome* occurs in the horse. *Affected horses exhibit periodic muscle stiffness and spasms.* Muscle spasms are initiated by voluntary movement. Muscle hypertrophy may be evident. Electromyography reveals persistent motor unit activity, but no abnormal primary spontaneous activity of muscle is seen. Muscle biopsy samples are reported to be normal. A disorder involving *autoantibodies to glutamic acid decarboxylase*, resulting in a neuromyotonic syndrome similar to that occurring in humans, is proposed.

A syndrome of episodic painful muscle spasms associated with prolapse of the third eyelid has been described in horses with ear tick (Otobius megnini) infestation. Percussion of affected muscle groups results in muscle dimpling. Serum activities of CK and AST are often moderately to markedly increased. Electromyographic studies are normal unless muscle contracture occurs secondary to needle placement. No abnormalities have been reported in muscle biopsy samples. Clinical signs resolve following removal or insecticidal treatment of the ear ticks.

Spastic syndromes

"Scotty cramp" is an episodic motor disease, primarily of Scottish Terrier dogs. This disorder most often begins at 2–6 months of age, but adult onset is also possible. It is characterized by *hindlimb and pelvic muscle hypertonicity* along with upward arching of the back for periods of 1–30 minutes, and is precipitated by exercise or excitement. No consistent gross or histologic abnormalities are found in the central nervous system, peripheral nerves or skeletal muscles.

Muscle hypertonicity precipitated by exercise or excitement has been described in several *Cavalier King Charles Spaniels.* Vacuolation of scattered muscle fibers and several minor ultrastructural changes occur, but there is no clear indication of the cause.

"Dancing Doberman" disease has been described as a spastic disease of *one or both hocks* in Doberman Pinschers of any age. The animals are reluctant to bear weight continuously and exhibit a peculiar shifting hindleg action resembling dancing. This appears to be a nonspecific sign, since some of these dogs apparently have a localized myopathy and others have evidence of a neuropathy.

A congenital myopathy in *Devon Rex cats* results in spasticity and is described in the section on Inherited and congenital myopathies.

Spastic paresis of cattle affecting one or both hindlegs is usually seen in calves 3–7 months of age, although onset of signs can occur in adults. The disease appears first as an exaggerated straightness of the hock that increases to the point of *inability to flex the hock.* In the later stages, in animals with unilateral involvement, the affected limb may swing stiffly like a pendulum or be held out in an abnormal cranial or caudal position. The disease, also called *"contraction of the Achilles tendon," "straight hock," or "Elso heel"* (the latter derived from the name of the Friesian bull, some of whose progeny, had the disease), is worldwide in distribution. It affects primarily Holstein-Friesian cattle but has been found in several other dairy and beef breeds, and has a distinct familial pattern. Deafferentation (cutting of the sensory nerve root) of the gastrocnemius muscle relieves the effect, suggesting that the defect is an *unmodulated or uncontrollable sensory-motor reflex loop.*

A related syndrome, referred to as *"spastic syndrome," "crampy spasticity," or "stretches"* affects mature animals, usually *bulls*, and causes periodic and sudden extension and stiffening of both hindlegs. During episodes the back is arched and the neck is extended. Episodes last for a period of seconds to minutes. The disease is progressive and it is reportedly associated with straight hocks and a variety of other abnormalities of bone, joints, or spinal column.

Metabolic myopathies

Abnormal skeletal muscle metabolism leading to neuromuscular dysfunction is most often due to inborn errors of metabolism, but can occur due to acquired metabolic defects. In some disorders, a metabolic defect is suspected based on clinical and pathologic findings but an exact cause remains elusive. Metabolic defects can affect multiple organ systems, with metabolically active organs such as skeletal muscle, cardiac muscle, nervous tissue, and liver being most severely compromised. Muscle dysfunction can, however, be the primary or the only clinical sign. In some such cases, the occurrence of tissue-specific isozymes of enzymes involved in metabolism can explain selective organ dysfunction, and in other cases the cause is not clear.

In *humans*, metabolic myopathies are broadly classified into four groups according to the type of metabolism affected:

- carbohydrate metabolic disorders,
- disorders of lipid metabolism,
- disorders of mitochondrial metabolism ("mitochondrial myopathies"),
- disorders of adenine nucleotide metabolism (myoadenylate deaminase deficiency).

Clinical signs of progressive muscle weakness, or of exercise-induced muscle cramping, contracture, and rhabdomyolysis are most common. Skeletal muscle dysfunction may occur due to inadequate energy production, to disruption of myofibrillar structure due to storage of carbohydrate or lipid, or to a combination of these factors. To date, the confirmed or suspected metabolic myopathies in animals that have been identified include disorders of carbohydrate metabolism, mitochondrial function, and lipid metabolism.

It should be noted that the terminology regarding *periodic acid-Schiff (PAS) positive, amylase-resistant inclusions* that occur within myofibers in some metabolic disorders is confusing. Terms such as *amylopectin, amylopectin-like, polyglucosan bodies, Lafora bodies, and complex polysaccharide have all been applied to this material.* Until detailed biochemical analysis of this type of stored material is available it is safe to say that *all these terms describe a similar type of material.*

Metabolic myopathies of the dog

Glycogen storage disease type II in Lapland dogs

A canine model of Pompe's disease due to acid maltase (acid α-glucosidase) deficiency has been recognized in the Lapland dog. Massive glycogen storage occurs in multiple organs, but skeletal, myocardial, and smooth muscle are most severely involved. The disorder is inherited as an autosomal recessive trait.

Clinical signs of progressive weakness and regurgitation due to megaesophagus are present from about 6 months of age. Myocardial dysfunction is also a feature. Affected dogs typically die at 10–18 months of age.

Overall muscle atrophy and megaesophagus are found on gross pathologic examination. Histologic examination reveals massive glycogen storage in multiple organs. Stored material is visible in routine preparations as clear vacuoles. This material stains positively with PAS stain and is digested by amylase (diastase), consistent with glycogen. Ultrastructural studies indicate that *the stored glycogen is membrane-bound within lysosomes.*

Phosphofructokinase deficiency (glycogenosis type VII) in English Springer Spaniels and American Cocker Spaniels

Phosphofructokinase (PFK) is a rate-controlling glycolytic enzyme. Quantitative and qualitative alterations in PFK activity can significantly alter energy metabolism in cells such as erythrocytes and skeletal muscle cells that rely heavily on glucose metabolism for energy. PFK is a tetramer composed of liver, muscle, and platelet type subunits in tissue-specific patterns. *The genetic mutation is a point mutation in the muscle isozyme of PFK, and a PCR-based test can detect affected and carrier animals.*

In English Springer Spaniels and American Cocker Spaniels, deficiency of the muscle isozyme of PFK results in *recurrent hemolytic episodes due to defective erythrocyte carbohydrate metabolism.* Variable hematocrit and persistent high reticulocyte counts are typical findings. Episodes are most often initiated by exercise or excitement, as PFK-deficient erythrocytes are particularly sensitive to lysis associated with a mildly increased pH of blood (alkalemia) resulting from hyperventilation. Skeletal muscle cells are apparently protected to some degree by up-regulation of the liver isozyme of PFK. Exercise intolerance, exercise-induced muscle cramps, and progressive muscular atrophy and weakness can occur, however, particularly in older PFK-deficient dogs. Erythrocyte PFK activity is markedly reduced in affected dogs, and moderately decreased in heterozygotes.

In humans with PFK deficiency, clinical signs are entirely due to muscular dysfunction, with exercise-induced cramps and myoglobinuria being most common. Late-onset progressive muscle weakness may also occur. The differences in clinical signs in affected dogs reflect the sensitivity of canine erythrocytes to alkalosis-induced lysis and possibly also to the high reliance of canine muscle on oxidative metabolism and less reliance on anaerobic glycolysis.

In older PFK-deficient dogs, examination of skeletal muscle may reveal *chronic myopathic changes including excessive fiber size variation and intramyofiber vacuoles and inclusions of material* that is stained lightly by hematoxylin in H&E-stained sections. This material is *intensely PAS-positive* and resists digestion by amylase (diastase), consistent with an amylopectin-like complex polysaccharide. Accumulation of this material appears to be a function of age. Ultrastructural studies indicate that this material is composed of nonmembrane-bound granular filamentous and amorphous material. Other findings at necropsy include marked extramedullary hematopoiesis and hemosiderosis due to recurrent hemolysis.

Other canine metabolic myopathies

- *Mitochondrial myopathy* causing episodic weakness and exercise-induced lactic acidosis has been described in a litter of Old English Sheepdogs.
- *Familial myoclonic epilepsy* with polyglucosan bodies in skeletal muscle occurs in miniature wire-haired Dachshunds.
- Neuromuscular weakness associated with *increased lipid accumulation and decreased carnitine activity* within skeletal muscle has been described as an acquired disorder in a variety of dog breeds.
- *Lipid storage myopathy* is thought to reflect abnormal lipid metabolism. It should be noted that increased intramyofiber lipid is normal in pups up to about 2 months of age and should not be interpreted as a lipid storage myopathy.

Metabolic myopathy of the cat

Metabolic myopathy in Norwegian Forest cats

A glycogen storage disease type IV due to deficiency of glycogen branching enzyme occurs as an autosomal recessive trait in Norwegian Forest cats. Although glycogen storage occurs in multiple organ systems in the cat, it is dysfunction of skeletal muscle, cardiac muscle, and nervous tissue that characterizes the feline disorder. In contrast, glycogen storage type IV of humans typically results in early-onset and progressive hepatic cirrhosis and liver failure. The molecular basis for this difference between cats and humans is as yet unknown.

Two clinical syndromes have been identified. The most common is the birth of fully developed kittens that are either stillborn or that die within a few hours of birth. Affected kittens that survive the neonatal period develop *progressive neuromuscular weakness, muscle atrophy, and cardiac dysfunction* beginning at about 5–7 months of age. Affected cats are often mildly febrile, exhibit generalized muscle tremors and a "bunny hopping" pelvic limb gait. *Progression to tetraplegia is rapid*, occurring within about 2 months following onset of clinical signs. Electromyography reveals abnormal spontaneous activity in multiple muscles. Cardiologic abnormalities include concentric left ventricular hypertrophy, left atrial dilation, decreased relaxation of the left ventricular wall during diastole, and focal hyperechoic areas in the subendocardial region of the left ventricular wall. Serum activities of CK and ALT are often increased. Glycogen branching enzyme activity in muscle, liver, and leukocytes is markedly reduced in affected cats, and moderately to severely reduced in clinically normal parents of affected cats.

Gross pathologic findings are absent in stillborn kittens or kittens dying soon after birth. In older affected animals, *severe generalized skeletal muscle atrophy* is evident. Fibrous replacement of muscle may be seen. *Left ventricular hypertrophy and left atrial dilation* are typical, and foci of fibrosis may be evident within the left ventricular myocardium.

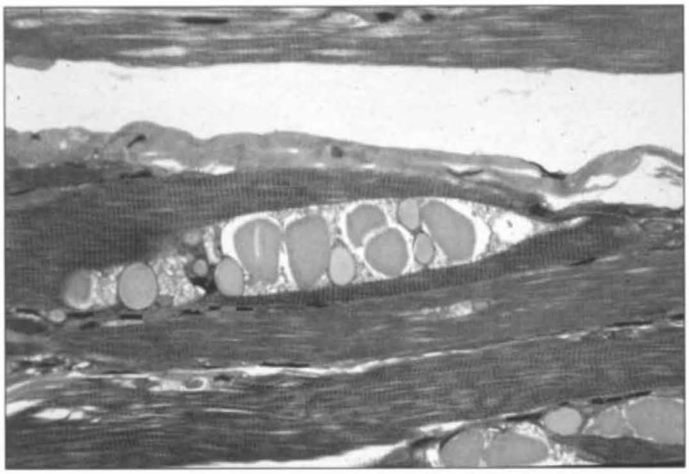

Figure 2.59 Multiple spherical to ovoid pale hyaline inclusions of complex polysaccharide in muscle from a Norwegian Forest cat with **glycogen branching enzyme deficiency** (glycogenosis type IV). (Courtesy of TJ Van Winkle.)

Characteristic histopathologic findings are nonmembrane-bound inclusions of *pale blue material within cells of many organs* (Fig. 2.59). This material is PAS-positive and amylase-resistant. Skeletal muscle, cardiac muscle, and central and peripheral nervous tissue are most severely affected and accumulation of stored material in these organs is accompanied by severe degenerative changes.

Metabolic myopathies of the horse

Equine polysaccharide storage myopathy

A glycogen storage myopathy occurs in many breeds of horses. This disorder has been recognized sporadically for many years. Only recently have studies begun to reveal the variety of clinical disorders associated with polysaccharide storage myopathy in horses as well as the wide range of breeds affected.

Equine polysaccharide storage myopathy is most common in draft, warmblood, and Quarter-Horse-related breeds. In draft-related breeds, a prevalence of over 50% has been reported. This disorder has also been recognized in virtually all other breeds, including ponies and miniature horses. Clinical signs range from recurrent exertional rhabdomyolysis, to progressive weakness that may or may not be accompanied by overt muscle atrophy, to mechanical lameness of the pelvic limbs. Subclinical cases are common. Serum activities of CK and AST may or may not be increased in affected horses. Although *an inherited basis is suspected*, the nature of the inheritance is still unclear.

Gross pathologic findings vary from no significant findings to obvious pale streaks within affected muscle. Muscle atrophy may or may not be evident. Red staining of muscle due to myoglobin release may be seen at postmortem examination of horses dying due to rhabdomyolysis. Careful evaluation of the diaphragm is indicated in animals dying with respiratory failure following clinical rhabdomyolysis, as *severe diaphragmatic necrosis can occur.*

Histopathologic findings are variable. In the most severe cases numerous round to irregularly shaped *blue-gray inclusions are seen within skeletal muscle fibers* on H&E-stained sections (Fig. 2.60). *Inclusions may be single or multiple and are segmental, replacing up to 90% or more of the cross-sectional area of affected fiber segments* (Fig. 2.61). These

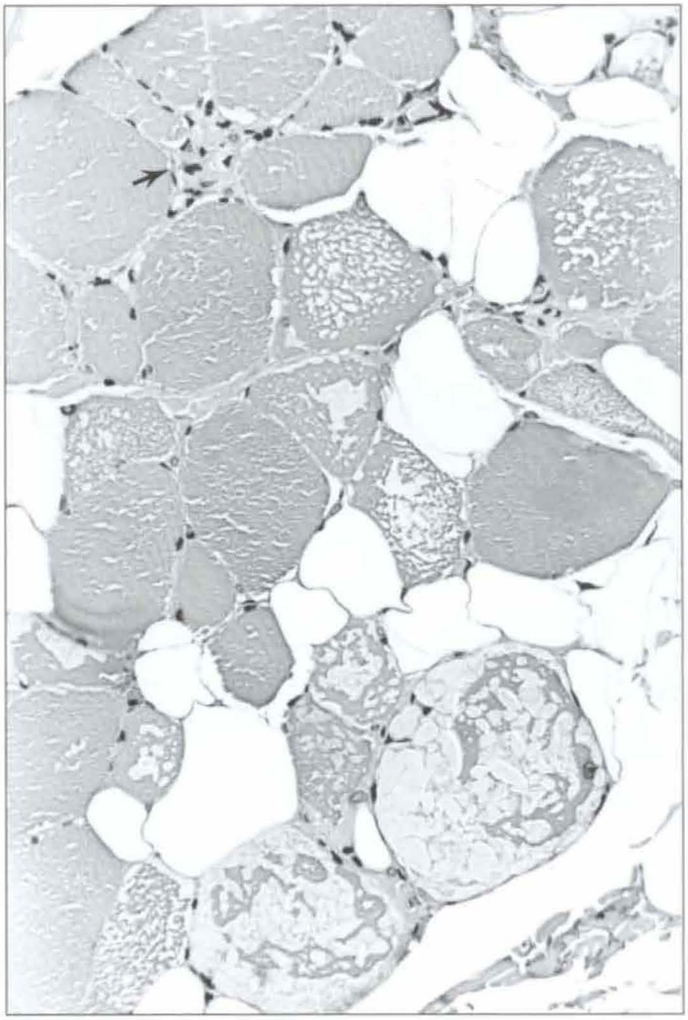

Figure 2.60 Marked fiber size variation with numerous fibers containing multiple vacuoles and inclusions of pale complex polysaccharide in a draft horse with severe chronic **polysaccharide storage myopathy**. A focus of interstitial macrophages (arrow) is indicative of previous segmental necrosis.

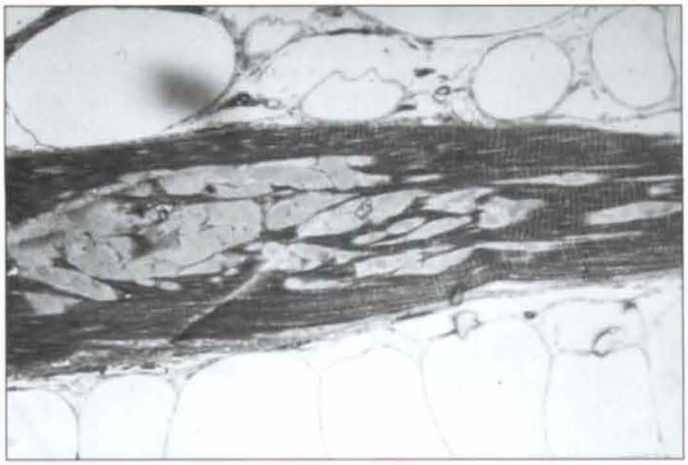

Figure 2.61 Multiple pale inclusions of complex polysaccharide replace large portions of fiber segments in a horse with **polysaccharide storage myopathy**. (Courtesy of JF Cummings.)

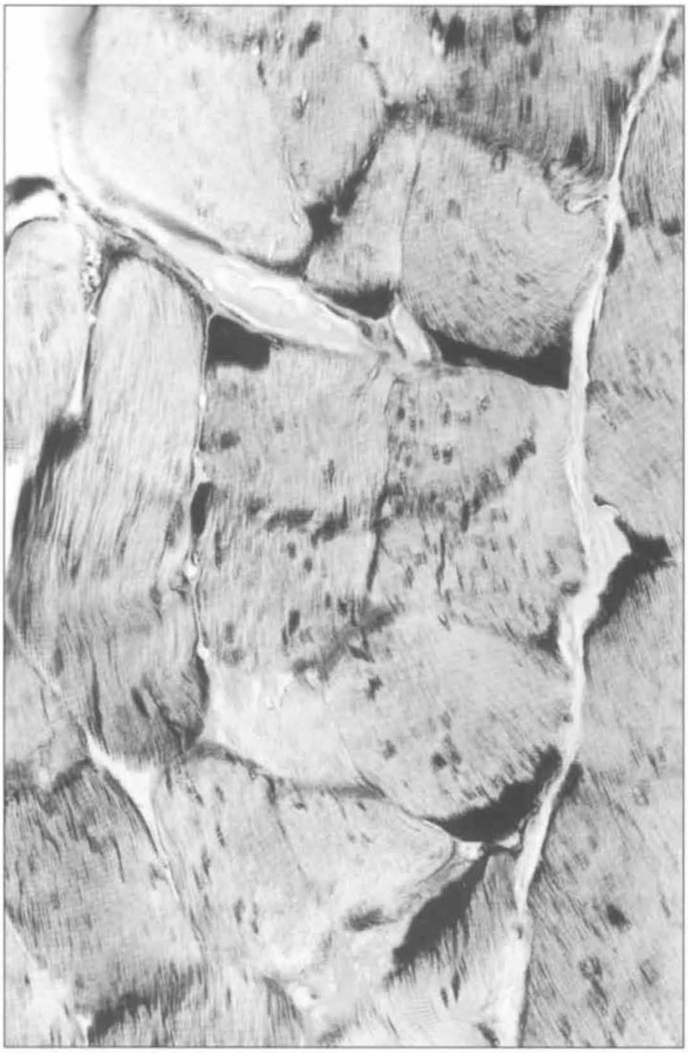

Figure 2.62 Multiple fibers with peripheral aggregates of densely stained glycogen in muscle from an Arabian horse with **polysaccharide storage myopathy**. Fibers also contain increased coarse granular glycogen. Periodic acid-Schiff.

inclusions are PAS-positive and amylase-resistant, consistent with a form of *complex polysaccharide. Inclusions occur only in type 2B glycolytic and 2A oxidative-glycolytic fibers.* Muscles that are strongly type 2 in composition, including semimembranosus, semitendinosus, gluteal, longissimus, and pectoral muscles, are most severely affected. In all cases in which inclusions of complex polysaccharide are seen, other fibers contain subsarcolemmal rounded vacuoles that are either clear or that contain pale pink hyaline material on H&E-stained sections. This material is PAS-positive and amylase-sensitive, consistent with *glycogen.* Fibers with complex polysaccharide or glycogen inclusions often occur in clusters, particularly at the periphery of fascicles. A more subtle pathologic change, involving only subsarcolemmal inclusions of glycogen, is seen in horses believed to have a form of the same disorder (Fig. 2.62). Numerous clear vacuoles within the fiber interior as well as in a subsarcolemmal location can also be seen. Aggregates of glycogen and of amylase-resistant material often contain ubiquitin. *Chronic myopathic changes* are often found, especially in older affected horses, and include excessive fiber size variation due to fiber atrophy and/or hypertrophy and increase in internal nuclei within myofibers. Scattered myofiber necrosis or regeneration may or may not be seen. Macrophages within necrotic fiber segments or found as small clusters within the interstitium often contain PAS-positive, amylase-resistant complex polysaccharide. In very severe cases, to date only documented in draft-related horses with apparent sudden onset of inability to rise, massive replacement of skeletal muscle by infiltrating adipose tissue can be seen. Other organs, with the exception of rare cases with inclusions of complex polysaccharide within cardiac myofibers, are unaffected.

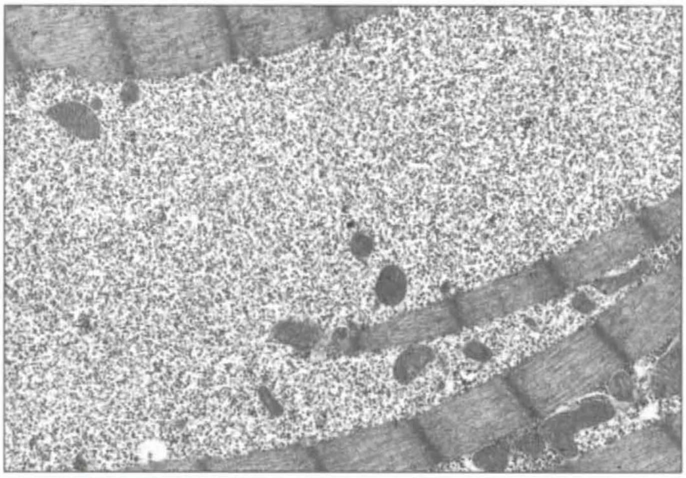

Figure 2.63 Aggregates of granular glycogen with attenuation of myofibrils in a horse with **polysaccharide storage myopathy**. (Courtesy of JF Cummings.)

Ultrastructural examination of affected muscle indicates that *glycogen storage is not intralysosomal but rather is dispersed within the cytoplasm.* Loss or attenuation of myofibrils occurs (Fig. 2.63). Organized inclusions of PAS-positive, amylase-resistant material are composed of tangled fibrillar material studded with glycogen particles.

Despite the clinical and pathologic similarities to myopathies due to carbohydrate metabolic defects in people, dogs, and cats, extensive studies have failed to document a defect in either glycolytic or glycogenolytic pathways in muscle from affected horses. However, diets designed to minimize starch and sugar intake and maximize fat intake have proven to be extremely successful in controlling clinical signs of skeletal muscle dysfunction, *suggesting that this equine disorder involves an as-yet unknown abnormality in carbohydrate metabolism.* Curiously, studies of a small number of horses indicate that pathologic findings are not obviously altered by dietary therapy.

Other metabolic myopathies of horses

A *mitochondrial myopathy* due to deficiency of complex 1 respiratory chain enzyme has been described in an Arabian. Profound exercise intolerance and exercise-induced lactic acidosis without evidence of exercise-induced muscle necrosis were seen.

Glycogen brancher enzyme deficiency occurs in Quarter Horse foals. Affected foals may be aborted or stillborn, or develop weakness and die of cardiac failure in the first few months of life. Characteristic spherical or ovoid inclusions of PAS-positive amylase-resistant amylopectin are seen within skeletal and myocardial fibers, particularly Purkinje fibers (Fig. 2.64). Similar material is seen to a lesser degree in many other organs.

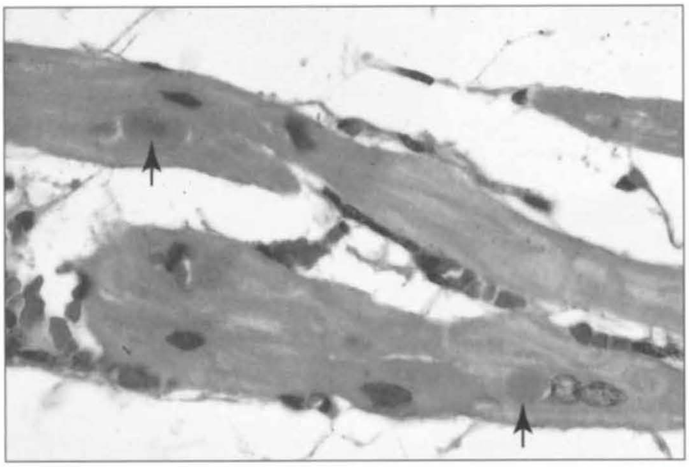

Figure 2.64 Spherical-to-ovoid bodies of complex polysaccharide within Purkinje fibers and cardiac myocytes in a Quarter Horse foal with **glycogen branching enzyme deficiency**. (Courtesy of BJ Cooper.)

Metabolic myopathies of cattle and sheep

Biochemical abnormalities leading to abnormal glycogen storage within skeletal muscle occur in sheep and cattle. In some cases, the disorder is generalized and in others it is confined to skeletal muscle. *Clinical signs of neuromuscular weakness in young sheep and cattle due to metabolic myopathy must be distinguished from the more common nutritional myopathies.*

Bovine metabolic myopathy due to myophosphorylase deficiency

Glycogen phosphorylase is an essential glycolytic enzyme. Tissue-specific isoforms exist, and the skeletal muscle isoform is known as myophosphorylase. *An autosomal recessive defect in the myophosphorylase gene similar to McArdle's disease in people occurs in Charolais cattle, and results in metabolic dysfunction confined to skeletal muscle.* Clinical signs of exercise intolerance and exercise-induced collapse can be seen in affected cattle as young as 7 weeks of age. Increased serum activities of CK and AST are characteristic. Subsarcolemmal vacuoles due to glycogen storage within myofibers are characteristic, and biochemical and histochemical studies reveal a *complete lack of myophosphorylase activity.* Testing of DNA from peripheral white blood cells will detect homozygotes and heterozygotes.

Glycogenosis type II (Pompe's disease) in cattle

Glycogen storage disease due to acid maltase (acid α-glucosidase) deficiency occurs as an autosomal recessive trait in Shorthorn and Brahman cattle. Two clinical syndromes are reported in Shorthorn cattle. An *early-onset form* results in intralysosomal glycogen storage within skeletal, cardiac, and smooth muscle, and in neurons of the central and autonomic nervous systems. Clinical signs of cardiac dysfunction predominate, leading to death due to cardiac failure. A *late-onset form* develops clinical signs predominantly of muscle weakness. Serum activity of CK is often increased, sometimes markedly. In Brahman cattle, glycogenosis type II results in early-onset signs of poor growth and neurologic dysfunction.

Glycogen storage diseases of sheep

A *generalized form* of glycogen storage disease occurs in sheep. Glycogen storage confined to skeletal muscle due to *myophosphorylase deficiency* also occurs, and is similar to the disease in cattle.

Metabolic myopathies of other species

Acid maltase deficiency (glycogenosis type II) resulting in generalized glycogen storage occurs in *Japanese quail.* These birds have been studied as an animal model of acid maltase deficiency of people. Clinical signs of muscle dysfunction predominate, and include inability to right themselves following placement in dorsal or lateral recumbency, and poor wing movements. Weakness is progressive. Abnormal accumulation of membrane-bound glycogen particles occurs as early as day 16 of embryonal development. Progressive glycogen storage resulting in *vacuolar myopathy*, with formation of autophagic vacuoles followed by fiber loss and fatty replacement, are characteristic. Abnormal glycogen storage also occurs in cardiac and smooth muscle as well as in neurons in the brain and spinal cord.

Congenital myasthenia gravis

Two clearly defined types of myasthenia gravis occur in humans and animals; both congenital and acquired myasthenia gravis have been described in dogs and cats.

- The *congenital disease* is due to an inherent defect in acetylcholine end-plate receptors.
- The more common *acquired disease* is an immune-mediated disorder due to circulating anticholinesterase receptor antibodies and is discussed in the section on Immune-mediated conditions.

Canine congenital myasthenia

In the dog, congenital myasthenia gravis has been described in Jack Russell Terriers, Springer Spaniels, Smooth Fox Terriers, and the Gammel Dansk Hønsehund. The disorder is inherited as an *autosomal recessive trait*. Affected dogs are clinically normal at birth but develop clinical signs of *exercise-induced weakness and collapse* at an early age. Clinical signs are apparent at about 5–8 weeks of age in affected Springer Spaniels and Jack Russell Terriers, and at about 12–16 weeks of age in the Gammel Dansk Hønsehund. Clinical signs are progressive in growing Jack Russell Terriers and Springer Spaniels, often leading to recumbency. The disorder is not progressive in the Gammel Dansk Hønsehund. Esophageal dysfunction leading to megaesophagus may occur in the Springer Spaniel and Smooth Fox Terrier. A decremental response occurs with repetitive nerve stimulation studies. Circulating antibodies to acetylcholine receptors are not found, but affected dogs improve with anticholinesterase therapy.

No abnormalities are seen in the motor end plate by light microscopy. Ultrastructural evaluation reveals *decreased density of postsynaptic acetylcholine receptors and shallow secondary clefts in the end-plate synaptic gutters*. Studies in the Jack Russell Terrier have shown a decreased rate of insertion of acetylcholine receptors into the postsynaptic membrane. Young animals are apparently able to function normally, but with growth this reduced acetylcholine receptor density results in neuromuscular weakness.

Feline congenital myasthenia

Myasthenia gravis is less commonly described in cats. This disorder has been described in Siamese and in domestic shorthaired cats. Mode of inheritance is not known. Clinical signs of *episodic weakness* are first noted at about 4–5 months of age. Affected cats may have a weak voice and the disorder may progress to tetraplegia. Megaesophagus has not been reported. A decremental response is seen with repetitive nerve stimulation, and circulating antibodies to acetylcholine receptors are not found. Clinical improvement can be seen with oral or intravenous anticholinesterase therapy. Acetylcholine receptor density was found to be 66% of normal in one cat studied.

Malignant hyperthermia

Malignant hyperthermia (MH) *is a condition that results in a sudden increase in myoplasmic calcium concentration leading to prolonged myofiber contraction and muscle rigidity, hypermetabolism, tachycardia, dyspnea, metabolic acidosis, and life-threatening hyperthermia. Severe acute rhabdomyolysis is the primary histopathologic finding.* Episodes are triggered by a variety of circumstances, including stress and pharmacologic agents such as halothane anesthesia. Malignant hyperthermia is an inherited disorder in humans, pigs, and some dogs. *The defect is in the ryanodine receptor*, a calcium-release channel of the sarcoplasmic reticulum that serves a critical role in triggering release of calcium from the sarcoplasmic reticulum during excitation–contraction coupling. Malignant hyperthermia in humans may be due to more than one genetic defect involving the ryanodine receptor. Other myopathic disorders leading to susceptibility to MH occur, and therefore *MH is best regarded as a syndrome rather than a single entity*. Susceptible individuals may have mildly increased serum CK activities and increased erythrocyte fragility. Testing for MH susceptibility classically involves in vitro exposure of muscle biopsy samples to various concentrations of caffeine and halothane. Muscle from MH-susceptible individuals exhibits contraction at relatively low concentrations of these pharmacologic agents as opposed to normal individuals.

Malignant hyperthermia-like episodes also occur in *anesthetized horses*, although an inherited basis has not been documented in the horse. Ryanodine receptor defects have been documented in a small number of cases. It may also be triggered in horses by injection of succinylcholine. Malignant hyperthermia-like episodes may also occur in people or animals with other underlying myopathies. This is certainly the case in cats with X-linked muscular dystrophy, in which anesthesia or the stress of restraint can trigger episodes of fatal hyperthermia. Underlying HYPP has been associated with malignant hyperthermia-like episodes associated with anesthesia in horses, and it is possible that other myopathic conditions may predispose horses to this disorder.

Malignant hyperthermia in pigs (porcine stress syndrome)

Malignant hyperthermia in pigs renders them susceptible to episodes associated with stresses such as handling, transportation, or fighting, and *may result in sudden death*. The meat of affected pigs is usually *pale, soft, and exudative (PSE pork)*. Porcine stress syndrome has been recognized in Europe and North America for a long time as "*herztod*" or *back muscle necrosis* of pigs. *Susceptible pigs exhibit intense, immobilizing limb and torso muscle rigidity, respiratory difficulty, tachycardia, acidosis and, often, rapid death.* Heavy-muscled pigs seem to be most susceptible to the clinical disease. Prior to identification of the ryanodine receptor gene defect, a large body of literature accumulated regarding various biochemical abnormalities detected in affected muscle and in affected animals. Recently, *a single point mutation in the skeletal muscle ryanodine receptor (ryr1) at locus HAL-1843 leading to increased channel open time has been shown to be the cause of MH* in domestic pigs, including Pietrain, Yorkshire, Poland China, Duroc, and Landrace breeds. DNA testing of peripheral blood for the HAL-1843 gene defect is available commercially. Genetic studies point to a single affected founder pig followed by widespread dissemination of the gene, and it has been suggested that these pigs have been selected for based on their heavy muscling and decreased body fat. Malignant hyperthermia occurs in all pork-producing countries of the world. It has been estimated that 2–30% of purebred breeding pigs are susceptible to malignant hyperthermia. A similar syndrome of MH appears to occur in *Vietnamese pot-bellied pigs*. In one case of a pot-bellied pig dying due to anesthesia-induced hyperthermia, a gene defect at HAL-1843 was detected. Testing of parents of another pot-bellied pig with suspect malignant hyperthermia, however, did not reveal HAL-1843 defects, suggesting that in pigs, as in humans, *more than one gene defect may lead to MH.*

Postmortem examination of the muscles of susceptible pigs that have not endured an episode of hyperthermia recently reveals normal muscles. *Pigs dying of hyperthermia have pale muscles that are wet and apparently swollen. Rigor mortis develops unusually rapidly.* In addition to lesions of skeletal muscle, *lesions of acute heart failure*, such as pulmonary edema and congestion, hydropericardium, hydrothorax, and hepatic congestion, often are present. The muscles most likely to be affected are those of the *back, loin, thigh, and shoulder.* Although both type 1 and type 2 myofibers undergo necrosis, muscles with a high proportion of type 2 fibers such as longissimus, psoas, and semitendinosus are most extensively and most frequently affected, and these should be examined histologically. Hemorrhages sometimes are present in muscles, and in the warm carcass a marked lowering of muscle pH to 5.8 or lower can be detected. On cooling, the pH rises rapidly towards neutrality. Myocardial pallor involving the ventricular muscles sometimes occurs but the clinical signs of tachycardia are probably related to acidosis.

Microscopic examination of malignant hyperthermia susceptible animals not recently affected by hyperthermic episodes reveals normal muscle fibers, or there may be a few degenerate fibers. *There is nothing distinctive about the appearance of the degenerate fibers.* In pigs dying acutely of malignant hyperthermia, *muscle fibers are separated by edema fluid.* This is evident in rapidly fixed specimens only and may be lost in processing. Changes in muscle fibers are widespread and are typically characterized as *multifocal monophasic injury*. It is possible, however, to find polyphasic injury in pigs with recent non-fatal episodes of MH, and underlying chronic myopathic changes may also be observed. Degenerative changes vary from segmental hypercontraction (Fig. 2.65) to overt coagulative necrosis. *Hypercontraction* is the most common lesion in skeletal muscle. Myocardial lesions include multifocal granular degeneration of myocytes, contraction band necrosis, and myocytolysis.

Malignant hyperthermia in dogs

There are sporadic reports of *MH-like episodes* in various breeds of dogs. *Exercise-induced hyperthermia* has been seen in English Springer Spaniels and in Labrador Retrievers. *Ingestion of hops* can trigger a MH-like episode in susceptible dogs, and this condition has been most commonly seen in Greyhounds. Studies of a breeding colony of mixed-breed dogs susceptible to anesthesia-induced MH determined that the disorder was inherited as a dominant trait with variable severity. A genetic defect has yet to be identified in MH-susceptible dogs and *it is possible that MH in dogs is a heterogeneous disorder.* Chronic myopathic changes including internal nuclei, increased fiber size variation, and fiber hypertrophy may be seen in muscle from MH-susceptible dogs. Histologic lesions in dogs dying due to

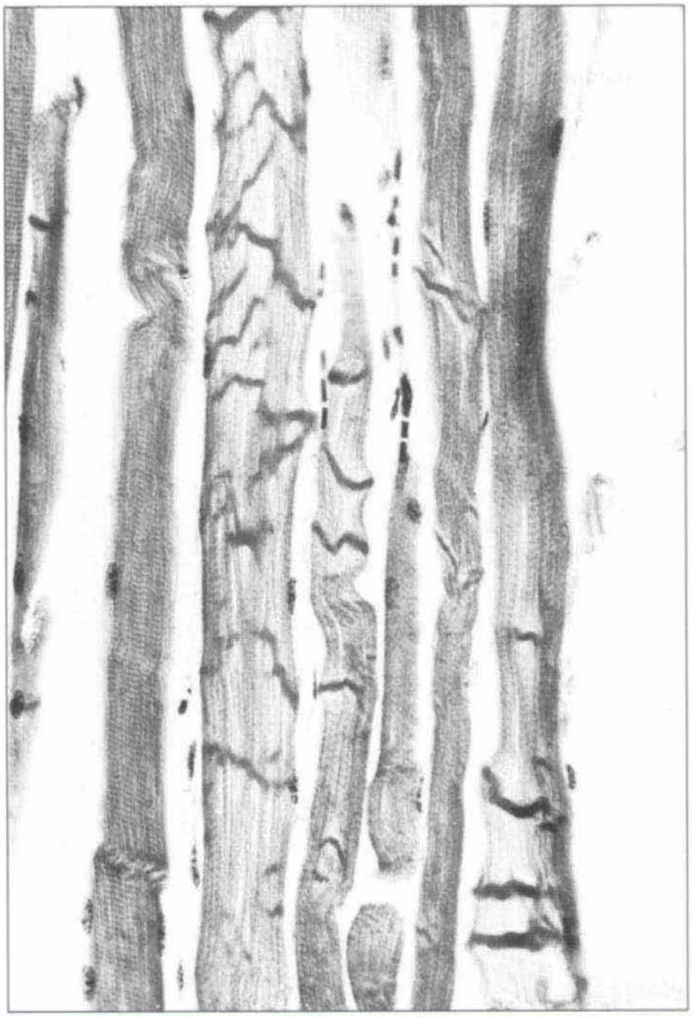

Figure 2.65 Acute myopathy in a pig with malignant hyperthermia (porcine stress syndrome) with characteristic **segmental hypercontraction**. (Courtesy of TJ Hulland.)

hyperthermia are similar to those seen in other MH-susceptible species.

CIRCULATORY DISTURBANCES OF MUSCLE

Skeletal muscle is a highly vascular tissue with an abundant capillary bed that forms an extensive system of anastomoses. It is generally not possible to induce muscle fiber necrosis by ligation of, or damage to, intermuscular arteries, because most muscles receive small collateral arterioles from tendons, fascial sheaths, and major nerve trunks. Naturally occurring examples of ischemic muscle necrosis are most often due to vascular occlusion secondary to pressure. Occlusion of major arteries such as aortic-iliac thrombosis ("saddle thrombi") can also cause ischemic muscle necrosis.

Each muscle fiber is served, at any given level, by three to 12 capillaries that run mainly longitudinally in the endomysium. Type 1 fibers are served by slightly more capillaries than are type 2 fibers of comparable size. Muscles such as those of mastication are particularly well supplied; nearly twice as many capillaries serve each of these fibers than is the case for the major thigh or shoulder muscles.

Maximum myofiber diameter is limited to some extent by the distance from the capillary to the center of the fiber(s) supplied. When the distance becomes abnormally great, the fiber is likely to form a longitudinal cleft down one side (*fiber splitting*) into which a capillary slips, effectively serving the fiber interior (Figs 2.16, 2.17). Complete or incomplete longitudinal fiber division appears to be a mechanism primarily initiated to improve the capillary-to-fiber ratio.

Ischemic damage to muscle fibers, and the capacity to repair, will depend on the completeness and duration of oxygen and nutrient deprivation.

- Least damaging is *transient hypoxia* of a few hours duration, which causes coagulation of muscle contractile proteins but does little harm to the other cellular components or to the satellite cells. Muscles are ordinarily restored to normal function in about 16–20 days by myoblast activation, division and fusion to form myotubes (see Degeneration and repair of muscle, Fig. 2.22) that mature to myofibers.
- The next level of injury is induced by *episodes of ischemia lasting 6–24 hours*, which cause death of both myofiber and satellite cell nuclei and coagulative necrosis of long segments of myofibers. The capacity for regenerative muscle fiber repair is lost or greatly reduced and reaction is largely local proliferation of fibroblasts and endothelial cells within the endomysium. The repair process is quite rapid but leads to a randomly distributed mixture of regenerated or original fibers interspersed with fibrosis.
- The *third level of ischemic injury is that lasting for more than 18–24 hours*, which leads to death of all cells within an area of muscle. The tissue response in this case is confined to a slow peripheral sequestration followed by phagocytic removal of dead muscle and fibroblastic proliferation that can take months to complete. The end result is a mass of scar tissue that can include adipose tissue, with a peripheral narrow zone of distorted muscle fibers.

During the *acute phase of ischemic muscle destruction*, a relatively orderly sequence of functional and morphological changes can be expected. After as little as 1 h of ischemia, the ability of the muscle fiber to contract in response to any stimulus is lost. Ultrastructurally, changes in subcellular components begin after about 6–7 h of ischemia when the tubular systems become dilated and begin to disintegrate. Some mitochondria may show evidence of swelling and disarray at 8 h, but even after 24 h many mitochondria may be well preserved. Z bands begin to disintegrate at about 12 h. Other components of the sarcomere, including thick and thin myofilaments, remain intact for at least 48 h, and it is only after this time that an amorphous hyaline mass forms, free of cross or longitudinal striations. Degeneration of the fiber at the Z bands occurs after 48 h and may be an extension of the earlier Z band disintegration.

Regardless of the duration and extent of the ischemic change, *the muscle fiber plasma membrane becomes permeable to enzymes and myoglobin*. Serum creatine kinase activity is markedly increased but often returns to near normal in 4–5 days, even when destruction of muscle is extensive. Myoglobin is released from damaged muscle and the amount released will vary directly with the severity and extent of damage. When a large mass of muscle is physically injured or when ischemic degenerative changes are extensive, large amounts of myoglobin are released into the bloodstream. Much of this is excreted by the kidneys. Myoglobin has a direct toxic effect on convoluted tubules leading to nephrosis. Perhaps more importantly, renal ischemia due to shock will contribute to the potential for severe renal damage and renal shutdown. Hyperkalemia due to massive muscle fiber breakdown can result in acute heart failure.

Four syndromes of ischemic muscle necrosis are recognized in humans and animals, namely, compartment syndrome, downer syndrome, muscle crush syndrome, and vascular occlusive syndrome. The distinctions among these syndromes are not always clear. In veterinary medicine, *hypotensive myopathy in anesthetized horses constitutes a fifth syndrome.* In the compartment syndrome, the downer syndrome, and the muscle crush syndrome, ischemia is caused by increasing intramuscular pressure. The vascular occlusive syndrome results from physical obstruction of the blood supply to muscle, and hypotension leading to poor muscle perfusion is thought to be the cause of hypotensive myopathy in horses.

Compartment syndrome

Muscles that are surrounded by either a heavy aponeurotic sheath or by bone and sheath are vulnerable to ischemia when muscle fibers are subjected to moderately vigorous but not exhaustive contraction. This syndrome occurs in well-conditioned athletes, but nowhere is the syndrome more clearly primary and specific than in the infarction that occurs in the *supracoracoid muscles of some breeds of broiler chickens and in some breeds of turkeys*. In these birds, a brief, vigorous flapping of the wings increases intramuscular pressure of the supracoracoid muscle within the inelastic breastbone and the outer muscle sheath. Muscle in full contraction increases in volume up to 20% and this causes partial or transient collapse of the venous outflow. At the same time, muscle activity increases arterial blood flow to the muscle. Subsequent muscle contractions tend to build internal pressure until the intramuscular pressure exceeds first venous and then arterial blood pressure. Metabolites of the muscle fibers exerting an increased osmotic tension coupled with increased arteriolar blood pressure cause accumulation of interstitial water early in the process and this further increases intramuscular pressure. Once blood flow has stopped, ischemic changes of both muscle and vessels begin, and further water escapes from damaged endothelial cells. Pressure builds for 1–4 h after muscle exercise and the extent and severity of damage to muscle increases with time. In both humans and birds, early fasciotomy releases intramuscular pressure and restores the potential for complete regenerative repair.

The so-called *spontaneous rupture of the gastrocnemius muscle of Channel Island breeds of cattle* may represent an example of compartment syndrome leading to ischemia and subsequent rupture (Fig. 2.66). Similarly, the swelling of muscle that can occur in dogs and horses with *masticatory myopathy*, and in horses with *exertional rhabdomyolysis*, may occur at least partly due to compartment syndrome, with initial muscle damage leading to increased pressure against thick overlying fascia.

Downer syndrome

Humans and most of the domestic species share a muscle ischemia syndrome that is initiated by external pressure of objects or by pressure created by the weight of body, torso, or head on a limb tucked under the body for prolonged periods. This condition in humans is usually related to drug overdose, while in animals it is induced by prolonged anesthesia, muscle, joint, or bone damage causing prostration, or metabolic or neurologic disease causing paresis. Absolute size and body weight has some influence on the incidence of the disease. Animals in good condition are particularly susceptible, and thin animals seldom suffer from ischemic muscle necrosis. Rams and heavy ewes, boars and sows, and even large dogs are occasionally susceptible, but this disorder does not occur in cats. *Cows are the species most frequently affected*, partly because of their weight and their muscle bulk and

partly because they are subject to diseases in which paresis is common (Fig. 2.67).

The pathogenesis of the downer syndrome depends upon the fact that the weight of the body can cause pressure within muscles to rise to levels considerably higher than both venous and arterial pressure. Muscles of limbs in a flexed or tucked position are particularly susceptible. The intramuscular pressure soon serves to collapse veins of the fascial sheaths and skin, causing congestion, and then collapses arteries. In cows and horses, extensive ischemic lesions are sometimes created by a period of inertia as short as 6 h, while some cows seem to be able to tolerate 12 or even more hours of immobility with minimal residual lesions. As time passes and as the pressure is removed, the affected limb continues to swell as edema fluid increases under returned arterial flow. *Reperfusion injury is likely to contribute to ischemic damage in the downer syndrome.* The extent of lesions within a muscle mass is quite variable but seldom involves more than half of the mass. The degree of damage will reflect the extent, duration, and severity of the ischemic episode as well as the extent and rapidity of reflow.

The clinical presentation of downer syndrome can be complicated by *pressure-induced peripheral nerve injury*. Even 6 h of anesthesia or comparable inactivity in horses and cows can cause sciatic or other nerve damage leading to *peroneal nerve paralysis* and a flexed rear fetlock, or a dropped shoulder and elbow due to *radial paralysis*. This neuropathy is, however, more often due to nerve conduction block than to structural nerve damage, allowing for the possibility of a relatively rapid recovery. If there is actual structural damage to nerves, effective recovery and mobilization may be delayed until nerves to muscles are regenerated, and complete recovery is not always possible.

Muscle crush syndrome

This form of muscle ischemia has characteristics in common with downer syndrome. *It is usually initiated by acute accidental trauma, often including bone fracture.* It occurs less frequently in animals than in humans, but has been seen in the dog and perhaps the cow. Initial events center on the *traumatic laceration of muscle*, which leads to a combination of high osmotic tension and hyperemia that result in accumulation of abundant edema fluid in the area. Edema causing increased pressure can exacerbate the muscle damage. If the damaged muscle and bone are still confined within a relatively firm sheath, conditions resembling those of compartment syndrome are set up. The limb swells and extends, and becomes turgid. Ischemia of variable extent ensues but, because of the great amount of myoglobin released, *renal dysfunction* may dominate the syndrome.

Vascular occlusive syndrome

When a *major vessel to a limb is occluded* the limb becomes cool, the arterial pulse is lost, skin over the limb loses its ability to sweat, and some limitation of movement may be apparent. When this occurs as a result of *aortic-iliac artery thrombosis in the horse* the effects are usually transient, apparently due to effective collateral circulation. Some muscle degeneration probably occurs but is repaired rapidly and completely. In the *cat with aortic-iliac thrombosis* associated with underlying cardiomyopathy, more of the aorta is likely to be occluded than is the case in the horse, and collateral circulation may be less effective at restoring circulation to hindlimb muscles. Muscle lesions vary from mild to severe (Fig. 2.68). The *anatomic pattern of degeneration* varies from one case to another and more distal muscles are not necessarily more vulnerable. Hindlimb muscle from cats with aortic-iliac thrombosis can also exhibit chronic myopathic changes indicative of previous bouts of subclinical ischemic myopathy.

An ischemic lesion of muscle seen in *sheep in advanced pregnancy* appears also to be caused by arterial occlusion. Ewes carrying twins or triplets sometimes suffer from ischemic necrosis of the internal abdominal oblique muscle without evidence of congestion or hemorrhage. This muscle does not have a confining sheath thus the necrosis is not part of a compartment syndrome. The arterial supply to the abdominal oblique is via a tortuous branch of the internal iliac artery which turns back on itself inside the iliac tuberosity, and it may be vulnerable to stretch and/or trauma. Ischemia of the muscle is followed by rupture, and subsequently the other abdominal muscles also rupture. In spite of all of this, the ewes sometimes lamb at term without difficulty.

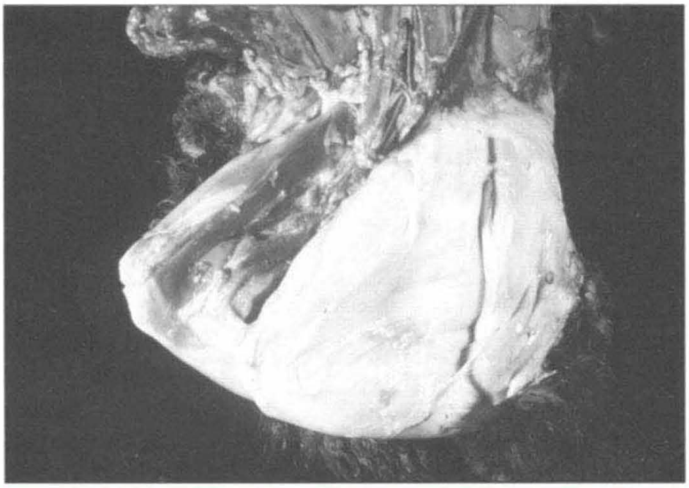

Figure 2.68 Pale thigh muscle due to infarction in a cat with **ischemic myopathy** due to aortic-iliac thrombosis.

Postanesthetic myopathy in horses

Postoperative weakness due to neuromuscular dysfunction occurs with some regularity in horses. A *variety of etiologies* are possible. Heavily muscled horses anesthetized and laid on poorly padded surfaces can develop *pressure-induced ischemic damage* to muscle similar to downer syndrome. *Compartment syndrome* affecting selected muscles can also occur. Cases of compartment syndrome in which a hemorrhagic infiltrate is prominent suggest predominantly venous occlusion. Pressure-induced neuropathy is a frequent complication. Horses with underlying myopathy, such as hyperkalemic periodic paralysis (HYPP) (see Myotonic and spastic syndromes) and polysaccharide storage myopathy (see Metabolic myopathies) are particularly prone to postanesthetic myopathy. A hyperthermia-like condition is also possible, especially in horses with HYPP.

A syndrome of ischemic myopathy due to hypotension and decreased muscle perfusion occurs in horses, most often associated with *halothane anesthesia*. This syndrome can be reproduced experimentally. Marked increases in serum CK and AST activities and lactate concentration occur. Swelling is most common in downside muscles, with increased intracompartmental pressure indicative of associated compartment syndrome.

Fibrotic myopathy

Fibrotic myopathies occur in a number of species including horses, dogs, cats, and humans, and most commonly involve the semitendinosus muscles. *Fibrotic myopathy is nonspecific and may be a consequence of intramuscular injections, primary myopathies, or peripheral neuropathies.* It may occur spontaneously in Quarter Horses and Greyhounds that rupture muscles upon explosive exercise, but is predisposed in conditions such as hemophilia where repeated hemorrhage into muscles leads to extensive fibrosis. *Affected muscles are replaced by contracted bands of dense scar tissue.*

PHYSICAL INJURIES OF MUSCLE

Traumatic injuries of muscle (*laceration, contusion, tearing, penetrating wounds*) are common and may be the result of external trauma, or they may be a result of a muscle rupture or tear of the fascia as occurs occasionally in violent contraction, rarely in overextension. The effects of external trauma are very variable and depend on the qualities of the applied force, the presence or absence of concomitant fracture of the adjacent bones, and especially on the degree of hemorrhage, injury to blood vessels, and injury to motor nerves. The principles governing the outcome of these types of lesions have been discussed above.

Violent contraction of muscle may result in either hernia or rupture with hemorrhage. A hernia occurs when the belly of the muscle protrudes through a rent in the overlying fascia and epimysium. The hernia can be reduced by pressure when the muscle is relaxed and it hardens and bulges further when the muscle contracts, providing thereby a point of useful distinction between hernia and tumor of soft tissue.

Actual rupture of muscle tissue may also occur during violent exercise and is probably more common than rupture of the tendon. The muscle bulges at the end opposite to that which is torn. Such ruptures are not necessarily complete from the outset, but may become so later from additional strain or degeneration caused by infiltrating hemorrhage with pressure and ischemia. Regeneration in large defects is ineffective and the gap is filled in by scar tissue. The muscle most frequently ruptured in animals is the *diaphragm*. Trauma, with acute abdominal compression, is the usual excitant in the dog. In cattle, it tends to follow diaphragmatic myositis secondary to traumatic reticulitis. In horses it is a consequence (in foals) of abdominal compression at parturition, and diaphragmatic rupture occurs occasionally with acute gastric dilation. *Acquired ruptures must be differentiated from congenital and postmortem ruptures by attention to the edges of the cleft and the disposition of abdominal viscera.* Muscles subjected to continuous pressure undergo degeneration, necrosis, and fibrous replacement. It is possible that pressure can have a direct effect on the fibers by disorganizing their internal structure, but the principal effect is to interfere with circulation.

The histologic appearance of traumatic injury depends on the age of the lesions. Initially it includes sarcolemmal rupture with adjacent intact fibers showing hyaline and granular degeneration, accompanied by edema and hemorrhage and neutrophilic infiltration. Reparative changes are conventional, but if the endomysial tubes are extensively disrupted, regeneration will be by "budding" with accompanying fibrosis. Bleeding into muscle, whether caused by trauma or spontaneous hemorrhage, as in some hemorrhagic diatheses, is often sufficient in volume to result in hematoma, the fate of which will depend largely on its volume. Metaplastic bone may form in the capsule of the hematoma. Severe trauma-induced swelling in muscle will result in secondary ischemic injury, which causes muscle necrosis. Primary healing is by regeneration by budding and extensive fibrosis because endomysial tubes are transected.

Ossifying fibrodysplasia

Also termed *myositis ossificans or fibrodysplasia ossificans*, this infrequent condition of the dog, cat, pig, and horse represents heterotopic mineralization within the connective tissues of skeletal muscle. It occurs as either a localized or a generalized form. The generalized form is described under Fibromatous disorders of tendons and aponeuroses.

The *localized form* of myositis ossificans occurs in the dog and horse. In the dog, the lesion often, but not always, occurs secondary to trauma and results in firm swollen areas in the affected muscles generally in the caudal hip, shoulder, quadriceps, or neck. Microscopically, the lesion typically has *three zones* – a central area of actively proliferating undifferentiated connective tissue, a middle zone with osteoid and immature bone, and an outer zone of mature trabecular bone.

Strains/tears/ruptures/fibrotic myopathies/contractures

Strains are the result of *overstretching of muscles* that have disrupted muscle fibers, most commonly at the muscle–tendon junction. The severity of damage varies from mild localized disruption to complete rupture of muscle fibers. Hemorrhage and edema accompany the muscle damage and healing is by fibrosis.

Fibrotic myopathy of the semitendinosus, semimembranosus, and gracilis muscles occurs most often in Quarter Horses performing sliding halts. Physical tearing and hemorrhage from these abrupt maneuvers initiates the damage with fibrous replacement as an outcome. Additionally, some cases are the result of denervation injury.

Several syndromes of limb muscle dysfunction, possibly associated with trauma, are described in dogs. A variety of names have been applied including *infraspinatus contracture, quadriceps contracture, gracilis contracture, fibrotic myopathy of semitendinosus, and gracilis-semitendinosus myopathy*. The contractures are the result of functional shortening of affected muscles following injury and healing by fibrosis. German Shepherds, especially males, are involved with the gracilis/semitendinosus fibrotic myopathy. The affected muscle may contain a thin fibrous band.

A myopathy of the tail muscles in hunting dogs ("limber tail" or "frozen tail") appears to be associated with overwork and environmental stresses.

NUTRITIONAL MYOPATHY

Nutritional myopathies (also named nutritional myodegeneration, nutritional muscular dystrophy, white muscle disease, stiff-lamb disease) are *principally diseases of calves, lambs, swine, and foals.* They infrequently affect carnivores. *The nutritional deficiencies are principally selenium and vitamin E.* Various environmental factors may, at times, also contribute to the muscle lesions historically associated with selenium/vitamin E deficiency. The clinical syndrome was first produced experimentally in 1928 in the suckling young of female rats fed a diet deficient in vitamin E but the skeletal muscle lesions were not identified until further studies in 1938 when the disease was incorrectly called a "dystrophy," a term appropriately applied to some inherited diseases of muscle. Selenium was established as an essential nutrient and implicated in nutritional myopathy in the late 1950s. Muscle fiber degeneration, as seen in nutritional myopathy, was discussed earlier (see Degeneration and repair of muscle); *it is a selective, segmental polyfocal and polyphasic degeneration of contractile components of the muscle cell* which leaves the ensheathing basal lamina and satellite cells intact, and therefore enables a rapid and efficient regenerative repair to take place. Myoglobinuria is usually absent in the enzootic disease of young animals but may occur in the sporadic cases in young adult animals, as those have a higher concentration of myoglobin in skeletal muscle. Frequently, skeletal muscle damage is concurrent with myocardial lesions.

Etiology and pathogenesis

Nutritional myopathy is a problem around the world but it occurs most often in those countries with intensive livestock agriculture operations. *Selenium moves through a soil–plant–animal cycle.* Sedimentary rocks provide most of the Se that becomes incorporated into soils. Alkaline and well-aerated soils provide much higher amounts of Se available to growing plants than acid, poorly aerated soils. This difference in availability from soils is related to the chemical form of Se and not to the Se concentration in the soil. *Soluble selenates* predominate in alkaline soils, and sparingly soluble *selenites* complexed with iron salts are in acid soils. As Se moves from soils into growing plants, it is largely incorporated into organic compounds, mainly in those selenoproteins with abundant selenomethionine. The Se content in the lush forage of heavily fertilized and watered soils is low because of dilution by the abundant plant tissue. Surveys of plants grown in soils throughout the USA and other countries have provided data and have been used to map areas of Se deficiency and excess. Deficient areas include the southeastern, northeastern, midwestern, and far northwestern portions of the US. The prevalence of Se-E deficiency diseases in animals throughout the USA correlates closely with the areas having low (<0.05 ppm dry weight) plant Se concentrations. Animals are able to utilize Se from inorganic salts (selenites and selenates) as well as from the organic forms in plants. Further, the Se of compounds in feedstuffs of plant origin has a much higher biological availability than Se found in compounds of animal products (e.g., fish meals). Other inorganic Se sources, elemental Se, and selenides, have little or no biological value for animals. In most of the studies that compared the efficacy of various chemical forms of Se to prevent deficiency disease in animals, *organic Se was found to have greater protection than inorganic Se (selenite).* However, because selenite is readily available and inexpensive, this form is commonly used as a dietary Se supplement.

Selenium is distributed widely in animal tissues, and the concentration is directly related to dietary intake. Highest concentrations are found in kidney and liver, intermediate amounts are found in heart and skeletal muscle, and low content is found in blood and fat. Animals fed rations in which small amounts (0.1–0.2 ppm) of Se are added to meet their nutritional requirements do not develop large increases in tissue Se content; therefore, human consumption of the tissues of animals so fed offers no risk of causing Se toxicosis.

Selenium deficiency in animals may be induced by the incorporation of high but nontoxic amounts of certain elements that antagonize Se. *Copper, silver, tellurium, and zinc in rations can induce typical lesions of Se-E deficiency in animals fed diets containing amounts of Se ordinarily considered adequate.* Also, a role for high amounts of dietary sulfur as a Se antagonist has been claimed. The importance of Se antagonists in field, rather than laboratory, conditions remains to be established. However, such a mechanism should be considered when animals fed a selenium supplement develop lesions of Se-E deficiency.

Vitamin E content of compounded animal feeds is generally low because many of the feedstuffs used are poor sources of that vitamin. Rich sources of vitamin E include wheat bran, many vegetable oils, and legumes such as alfalfa. The biological activity of vitamin E is concentrated in the α-tocopherol fraction, and thus determinations of total tocopherol content of feeds may be of limited value for determining their vitamin E potency, to prevent deficiency disease. Diets that contain large amounts of polyunsaturated fats (e.g., those in fish oils) will require greater amounts of vitamin E, which limits oxidation and the development of rancidity. Also, if diets with low Se content are fed, vitamin E supplements will need to be increased to prevent deficiency disease.

Of the domestic mammals, *cattle, sheep, and pigs are most susceptible to nutritional myopathy*. Horses and goats are moderately susceptible, and occasional cases have been reported in dogs and cats. Most zoo ungulates should be regarded as susceptible to the disease. Historically, nutritional myopathy has been thought of as a disease of young animals, particularly the very young. *Rapid postnatal growth seems to predispose*, a problem perhaps of outgrowing a scarce resource or of biochemical transition as fiber types develop into the adult patterns. Although nutritional muscle degeneration does occasionally occur in mature animals, it is rare.

In cattle, spontaneous nutritional myopathy may occur in utero in 7-month-old fetuses, and muscle lesions are seen in lambs and calves at birth. However, lesions may not occur in calves or lambs born of cows or ewes, which themselves have extensive lesions of nutritional myopathy prior to, or at the time of, parturition. It is equally true that dams of calves or lambs with extensive lesions seldom show clinical disease or even clinicopathological evidence of muscle fiber breakdown.

Nutritional myopathy occurs in all of the susceptible domestic species on widely variable planes of nutrition. Neonatal disease usually affects the thrifty, well-grown suckling animal and the sporadic disease in yearlings and adults usually occurs in animals in good physical condition. The adult disease affects animals fed marginal-quality rations, such as turnips or poor-quality hay, and can appear as clinical or subclinical disease in animals in very poor condition because of neglect or chronic disease. Animals with nutritional myopathy often lose condition rapidly and appear to be very unthrifty even when the muscle disease is not clinically severe.

One of the most perplexing aspects of these myopathies is the irregularity and unpredictability of their occurrence. Natural disease is seldom a serious problem in consecutive years, yet sometimes it will occur in most years in any given region. A good deal of correlative and circumstantial evidence indicates that climate-related conditions, such as the length and the amount of sunshine of the growing season, and the length of the housing season, may be very important. Since the disease often occurs while animals are consuming stored feeds, the condition and duration of storage of the fodder can be relevant. Detailed investigation sometimes reveals comparable concentrations of vitamin E and selenium in forage from one year to the next, yet the incidence of nutritional myopathy in animals consuming it may be quite different. Grazing of dry pastures may be associated with an increase in the incidence of disease and may also have an influence later through the stored hay or grain harvested from them. On the other hand, ingestion of lush pasture may also cause problems. The leaves of some pasture plants have moderately high levels of polyunsaturated fatty acids and these fatty acids are absorbed largely intact in herbivores. They are almost certainly antagonistic to selenium and vitamin E, thus the requirements for these nutrients may be raised considerably when animals first graze new pasture. *In most parts of the world, nutritional myopathy occurs in late winter or early spring*, but in sheep it may occur more often in the fall, in both pastured and feedlot animals that are immature.

The patterns of nutritional myopathy seem, in a general way, to obey the rules of straightforward deficiency of one or two essential nutrients. The metabolism of vitamin E and selenium is incompletely understood. Understanding of factors involved in membrane integrity and membrane alterations in disease has elucidated the role of the subcellular changes, which seem to be a basic result of deficiency of these substances.

In many cells, *vitamin E- and selenium-containing enzymes are required as physiologic antagonists to a group of chemically varied substances known as free radicals.* **Free radicals** are molecules with an odd number of electrons; they can be either organic or inorganic. Some free radicals are products of normal cell function, and several participate in, or are products of, oxidative metabolism. They may also be produced outside the cell as products of tissue radiation, drug reactions, and inflammation. One of the major sources of free radicals is the cell detoxification process, which renders materials less harmful by converting them to epoxides. Many intracellular and extracellular free radicals contain oxygen, and are involved in electron transfer reactions. They are highly reactive and this is responsible for their rapid alteration (instability), which occurs in oxidation-reduction reactions within a wide range of cellular structures and enzyme systems.

Free radicals may initiate cellular injury by causing peroxidation of membrane lipids and by causing physicochemical damage to protein molecules including those of mitochondria, endoplasmic reticulum, and cytosol. Protection against the effects of free radicals is provided partly by the constant presence of *small scavenger molecules* such as tocopherols, ascorbate, and beta-carotene. These "quench" free radicals, but both free radicals and scavengers are consumed in the process. Protection is also provided in part by selenium-containing enzymes of the *glutathione peroxidase/glutathione reductase system*. This system is capable, under normal circumstances, of more or less constant renewal by a complex sequence that makes use of several enzymes, although some consumption of the selenium-containing component does occur.

From the above, certain conclusions seem to emerge. *Although vitamin E- and the selenium-containing glutathione system perform many similar functions at the cellular level in quenching destructive metabolites and byproducts, they may function independently.* The circumstantial clinical evidence that one can relieve the need for the other in the prevention of muscle disease is also reasonably explained. The need for some of both at all times within the cell, and vitamin E outside the cell, perhaps is explained by the fact that the two mechanisms quench a different array of free radicals and that tocopherol operates both outside and inside the cell while the glutathione system operates only inside the cell. The practical interpretation of deficiency of vitamin E or selenium should relate to the consumption of these elements during a steady intracellular production of free radicals, rather than an interpretation of these nutrients as structural cellular components that may be deficient.

In the absence of sufficient protection by selenium and/or vitamin E, cellular membranes are modified by free radicals, and the ability of those membranes to maintain essential differential gradients for one or more ions is diminished or lost. The normal inward flow of calcium ions from the extracellular compartment to the cytosol, where calcium levels are one quarter to one half as high as extracellularly, causes a greatly increased demand for energy to move calcium away from the calcium-sensitive myofilaments and into mitochondria which act as sumps. As a result, mitochondria may accumulate up to 50 times their normal amount of calcium, and this results in reduction in their ability to produce energy. It also initiates the sequence of events identified earlier (see Degeneration and repair of muscle) as "mitochondrial calcium overload" which proceeds to calcium-induced hypercontraction of myofibrils and degeneration of myofibers.

The explanations of intracellular dynamics and myofiber degeneration outlined above indicate that *segmental muscle fiber degeneration with mineralization is not a specific lesion.* Any event which can trigger the cascade of degenerative events in the muscle fiber could produce a similar lesion. Starvation, or poor-quality rations, or rations in which vitamin E and/or selenium have been destroyed, could produce muscle lesions simply by not providing enough protective scavenger molecules. Metallic toxicants or other chemicals, including therapeutic agents, might produce disease by binding selenium and inducing a higher than normal demand for antioxidant molecules such as tocopherols or glutathione. The relationship between unaccustomed exercise or cold weather and nutritional myopathy, which is frequently observed in all ages and all susceptible species, may be explained by an energy depletion at the intracellular level rather than by membrane alteration, especially in those instances of nutritional myopathy in which levels of tissue vitamin E and selenium are near normal. Excepting those cases exacerbated by driving, transport, or other forced exercise, serum and tissue concentrations of vitamin E and selenium generally correlate well with levels in the feed of the animals concerned. *This by itself seems to indicate that the naturally occurring disease is a true deficiency.*

Once the myofiber cell membrane (plasmalemma) has been altered, the stage has been set for leakage of intracellular enzymes into the extracellular space. *The concentration of activity of muscle enzymes in blood is a rough indication of the extent of muscle fiber destruction.* It is clear that increase in concentrations of enzymes in plasma may accompany extensive athletic use of muscles and indicate physiologic disruption of muscle fibers. When monitored by muscle biopsies in animals and man, however, such increase in enzyme concentrations is associated with degeneration of fibers or at least of some fiber segments (segmental degeneration).

The concentration of creatine kinase in plasma is the enzyme that seems to be most specific in indicating muscle damage although, in animals, plasma concentrations of aspartate aminotransferase is quite specific for muscle as well. Its activity in serum tends to rise later and disappear much later than creatine kinase and therefore, its evaluation is most useful in establishing the time and duration of the muscle injury. Serum glutathione peroxidase activities are reliable indicators of selenium availability. Tissue concentrations of selenium may not reflect metabolic availability if selenium is stored in complex form. Mineral supplements often contain a variety of metals as contaminants. Those that have been shown experimentally to have a myopathy-inducing effect include iron, silver, tellurium, cobalt, copper, zinc, and cadmium. The complicity of such metals in the production of natural disease is undetermined but worthy of examination.

Nutritional myopathy of cattle

Clinicopathologic descriptions of the disease in calves appeared in the 1890s and the disease was well known at that time in Germany, France, Switzerland, and Scandinavia. *Nutritional myopathy occurs, sometimes in endemic proportions, in calves, mostly of beef type and 4–6 weeks old.* It is also common in animals up to 6 months of age and occurs sporadically in older cattle. In calves there is often a typical history indicating that the dam has been housed at least 3–4 months and had been fed poor-quality hay or not enough hay. Similar problems occur in calves in the USA, Australia, and New Zealand when legume hay alone or irrigated legume pasture is fed. Sulfur fertilizers applied to the pasture, and copper deficiency in the dam, may be contributing factors. *The precipitating event in many cases is unaccustomed physical activity that converts subclinical to clinical disease.* The feeding of cod liver oil that has become rancid destroys vitamin E in the ration and has been blamed for producing the disease. The presenting sign in calves is often stiffness or dyspnea, but a shuffling gait, a dropping of the chest between the shoulders, and outward rotation of the forelimbs have also been noted. Some calves become recumbent and die rapidly with signs of respiratory failure. Calves over 3–4 months of age may show myoglobinuria.

Postmortem lesions in calves are usually dominated by marked mineralization of necrotic skeletal and/or cardiac muscle. When the heart is extensively affected, intercostal muscles and the diaphragm are usually also affected, but other skeletal muscle lesions may not be widespread. *Heart lesions in calves usually involve the left ventricle more than the right.* Small lesions just under the epicardium or endocardium may appear as scattered white "brush" strokes. The mineralized lesions are creamy white and opaque. Small streaks of hemorrhage may also be seen. Lungs are often filled with pink frothy fluid and an excess of fluid may be present in the thorax indicating heart failure. Acute pneumonic changes sometimes develop as a complication of pulmonary edema. *In those cases where skeletal muscle lesions predominate, the most extensive lesions can be found in the large weight-bearing muscles of the thigh and shoulder,* but many others are affected and the lesions are bilaterally symmetrical.

Suckling animals often have extensive lesions in the *highly active tongue and neck muscles*, and occasionally in the voluntary muscles of rectum, urethra, and esophagus. Affected muscles are pale, irregularly opaque and yellow to creamy-white. The longitudinal divisions of muscle (primary bundles of 40–200 fibers) often have an indistinct appearance in most severely affected areas and sometimes streaks of hemorrhage and moderate local edema are present. Minimal myocardial lesions are sometimes present, but not accompanied by evidence of cardiac failure.

In older calves and young adult cattle, the patterns of disease vary considerably and are unrelated to age. Dairy and beef calves 6–12 months of age show stiffness and lethargy just after winter housing, or sometimes while they are housed. *The disease is often related to poor-quality feed.* In similar circumstances, extensive myopathy occurs in pregnant heifers and they may suffer a high incidence of abortion, stillbirth, placental retention, and parturient recumbency. Feedlot steers fed high-moisture corn, which has been treated with propionic acid to control fungal growth and stored for 6–8 months, show initial signs of diarrhea and unthriftiness and become recumbent for 2 or 3 weeks. Many have lesions in muscles at slaughter. Most mature animals with extensive skeletal muscle lesions have myoglobinuria.

Young adult cattle with bilateral dorsal scapular displacement ("*flying scapula*") have rupture of the serratus ventralis muscle and this may be of sufficient duration to have extensive fibrosis and multifocal osseous and cartilaginous metaplasia underlying the displaced scapulae. Presumably, nutritional myopathy of the subscapular muscles has preceded rupture and displacement.

Histologic lesions of nutritional myopathy are varied only slightly by age of the lesion. The earliest lesion visible by light microscopy is *hypercontraction*, recognizable in fiber segments with tightly contracted sarcomeres or no striations. In cross-section, hypercontracted fibers are large, round, and stain strongly with eosin. This is the change which is usually described as *hyaline*, implying an amorphous structure, but striations may be visible for 3–4 days when examined by electron microscopy. Eventually these hypercontracted fiber segments will be phagocytosed but not as quickly as other fibers that undergo fragmentation with or without mineralization. In both types of degeneration, the processes of degeneration and repair are essentially those described earlier and allowance needs to be made in histological examination for the incremental changes of chronic deficiency. Thus, the typical histologic findings will be a *polyphasic, polyfocal myopathy*.

By electron microscopy, the earliest detectable change is *degeneration of mitochondria* and this is followed by loss of some parts of the sarcomere and then disintegration of the tubular systems. By histochemical examination it can be determined that *type 1 fibers in the interior of primary bundles degenerate preferentially but not exclusively.* Apart from this preference, the pattern of degeneration appears to be random. This random pattern is helpful in distinguishing this from other muscle diseases such as ischemic degeneration.

Changes in *myocardium* are very similar to those seen in skeletal muscle. Mineralization of hyalinized fibers is often pronounced and the coagulated, mineralized myofibrils appear to be rapidly removed by macrophages. Necrotic myocardial fibers are not regenerated; they are replaced by condensed fibrous stroma.

Nutritional myopathy of sheep and goats

Nutritional myopathy in **sheep** *is probably more prevalent in more areas of the world than the disease in cattle.* The disease was first described in Germany in 1925. The names white muscle disease, rigid lamb disease, and stiff lamb disease were coined to describe the most frequently encountered clinical patterns in 2–4-week-old lambs, which very often are *spring lambs, recently turned out onto the first green pasture.* Congenital nutritional myopathy does occur in lambs, but not often. The typical disease may occur as an outbreak among lambs from 1 day to 2 months of age or beyond. Mortality at this stage may be very low or may reach 50%. The next peak of incidence occurs at 4–8 months of age as weaned lambs are put onto lush pastures following mowing or into feedlots. Mortality is not usually very high, but the incidence of minimal clinical disease may be moderately high and that of subclinical disease may be higher. Beyond these age groups, nutritional myopathy in more mature sheep is clinically apparent sporadically, but subclinical disease may involve from 5–30% of a group. Under special circumstances, the incidence of clinical disease and mortality may rise dramatically. Thus, in various parts of the world, the disease has been precipitated by stress from bad weather, prolonged winter feeding, subsistence on root crops, or forced activity, as well as feeding on stubble, legume pastures, dry pastures, and pastures with too much copper. Outbreaks in lambs and yearlings have also occurred on pastures on which copper had been made unavailable by top-dressing with molybdenum.

Deficiency in sheep is attributed to deficiency of vitamin E or selenium, but seldom of both. In certain regions of the world, one nutrient does not seem to be able to replace the other to any extent, while in others the addition of either vitamin E or selenium is rapidly curative.

Lesions and their corresponding clinical signs are as varied as the circumstances under which myopathy occurs. The lesions may be detectable in lamb fetuses at least 2 weeks prior to parturition. In the congenital disease, *tongue and neck muscles* used in suckling movements often contain the most severe lesions. When the lesions occur in lambs a few days older, they are likely to be much more extensive and involve primarily the *major muscles of the shoulder and thigh but also back, neck, and respiratory (diaphragm and intercostal) muscles.* The gross appearance of affected muscles is similar to that described for calves, although *the likelihood of muscle mineralization is probably greater.* Lambs normally have pale muscles, consequently the recognition of the mineralized flecking in primary bundles is almost essential if diagnosis is to be made grossly with any confidence. It is necessary to confirm the gross diagnosis by histological examination.

In older sheep, lesions are more varied in distribution, location, and extent, but some similarity to the distribution in young animals may exist. For example, bilaterally symmetrical lesions of the thigh muscles may occur but they may predominate in or be confined to the intermediate head of the triceps, or the tensor fascia latae. Lesions in pregnant ewes may be more or less confined to the abdominal muscles subjected to increased work load from supporting the pregnant uterus and may rupture allowing viscera to herniate.

Microscopically, the changes seen in affected muscle over a period of several days follow the expected sequence of *necrosis, mineralization, phagocytosis, and regeneration characterized by satellite cell proliferation and myoblast formation.* Because the basal laminae of myofibers are intact, all of this can be completed within about 16–18 days, leaving little in the way of residual lesions, but often repair lesions of several days evolution can be seen side by side with more recent ones (*polyphasic, polyfocal myopathy*). Repair can take place in the face of continuing deficiency, but even normal activity during the early repair phase is likely to lead to more myofiber necrosis.

Reports of nutritional myopathy in **goats** are relatively few but this may be due to the fact that the goat is less often reared under intensive animal agriculture practices. Caprine nutritional myopathy has been observed in Europe, the Middle East, New Zealand, Australia, and North America. In most instances it appears in goats on pasture, and clinical and pathological changes are similar to those seen in sheep.

Nutritional myopathy of pigs

Nutritional myopathy in swine has been reported as a spontaneous disease wherever intensive pig rearing is practiced, but particularly in northern, central and eastern continental Europe, the UK, the US, and Canada. Classical lesions involving only skeletal muscles are less common than some of the other expressions of porcine vitamin E/selenium deficiency such as hepatosis dietetica and mulberry heart disease, but *systematic microscopic study of muscles has revealed a much higher incidence of muscle lesions than was thought to exist.* Since the pig is an easily managed experimental animal, much more is known about experimental vitamin E/selenium deficiency in this species than in others.

Naturally occurring nutritional myopathy is not known to be congenital in pigs but piglets as young as 1 day may have extensive

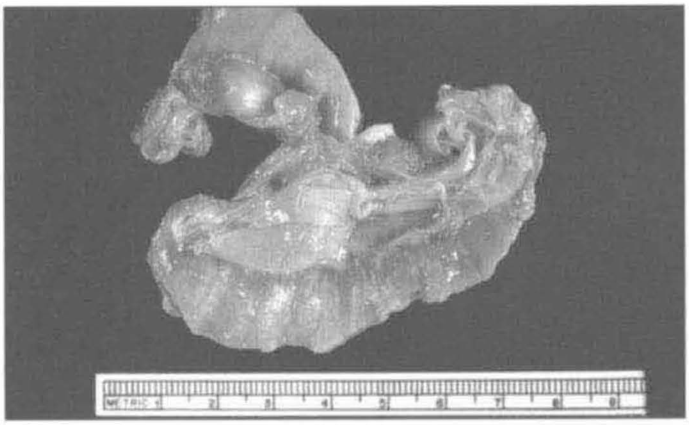

Figure 2.69 White streaks with necrosis radiate in diaphragm from a pig with **nutritional myopathy**.

lesions, which cause paresis or extreme weakness. Growing pigs of all sizes up to 65 kg may be affected in outbreaks, but *most commonly affected are weaned pigs of 6–20 weeks of age.* A special circumstance is that caused in pigs a few days old by the *injection of iron dextran products*, which precipitates acute widespread degenerative and usually fatal myopathy. It is believed that iron acts as a catalyst for lipid peroxidation of cell membranes. Older pigs, and particularly sows that have recently farrowed, are occasionally susceptible to widespread nutritional myopathy of sufficient severity to cause prostration, although more often clinical signs, if present at all, consist of lethargy and slowness of movement.

Apart from deficiencies in diet, the factors that trigger the disease in pigs seem to be relatively few. Unaccustomed exercise does not seem to play a part, but *feeding rancid or oxidized fish liver oils, which destroy vitamin E, may do so.* Newly harvested grain sometimes seems to contain a myopathy-inducing factor, and pigs fed quantities of peas (*Pisum sativum*) may be particularly prone to the disease. Metals occurring as contaminants in ground mineral mixes can induce an increased requirement for vitamin E and/or selenium. Silver, copper, cadmium, cobalt, vanadium, tellurium, and zinc, and possibly other metals, in some way bind selenium or prevent its participation in free radical protective activities. This leads to a two-fold or greater demand for selenium to prevent lesions that can be only partly alleviated by vitamin E supplementation.

Mineralization of degenerate fibers is often not abundant and even when it is present and visible, it is difficult to detect grossly in the naturally pale muscles of the pig. This, and the fact that lesions in heart and liver are much more dramatic, may explain why there are relatively few reports of skeletal muscle lesions in natural outbreaks of vitamin E/selenium deficiency disease. In the experimental disease in pigs, gross lesions may be seen (Fig. 2.69) but many skeletal muscle lesions are microscopic, while the liver and heart lesions are grossly visible.

Microscopic muscle lesions are similar to the polyphasic, polyfocal myopathy seen in lambs and calves (Figs 2.70–2.75). Type 1 fibers are principally affected and in view of the orderly central arrangement of type 1 fibers within muscle fascicles in the pig, this leads to a *distinct central degeneration of primary muscle bundles.* Regeneration is often rapid and complete in surviving piglets, but the mortality rate may be as high as 80% of a litter, and usually 100% when secondary to iron injection. The survival rate for older pigs is higher except in those instances in which the cardiac lesions are prominent. Relatively few pigs survive mulberry heart disease.

Myocardial degeneration (mulberry heart disease) is the most common manifestation of vitamin E/selenium deficiency in growing weaned pigs 6–20 weeks of age. It is described in Vol. 3, Cardiovascular system.

The liver lesions associated with vitamin E/selenium deficiency are referred to as *nutritional hepatic necrosis or hepatosis dietetica* and are described in Vol. 2, Liver and biliary system.

Nutritional myopathy of horses

A disease in *foals* that is, in many respects, comparable to vitamin E/selenium deficiency myopathies in other species, has been recognized for many years. *The usual age range is 1 day to 12 weeks and it may be present at birth.* Cases have been reported from North America, Europe, and Australia in most breeds of light horses and in pony, zebra, and donkey foals. The similarities of lesions and circumstances of the equine syndrome and nutritional myopathy of ruminants has led to the conclusion that the disease is due to a deficiency of vitamin E and/or selenium, but this has not been confirmed. Tissue concentrations of selenium and glutathione peroxidase in affected foals are often no lower than those in healthy foals, however, and selenium and vitamin E appear to have little or no curative value, and in a few instances, little or no preventive value. Serum creatine kinase concentrations may be very high; over 2 million IU/L in nonsurviving cases, and as high as 200 000 IU/L in surviving animals.

Postmortem lesions of nutritional myopathy in foals are similar in many respects to those in calves and lambs – a *polyphasic, polyfocal myopathy*. Foals dying acutely may have myocardial lesions. In the *subacute syndrome, shoulder, neck, and thigh muscles* may be bilaterally and extensively involved and this usually accounts for an inability to rise or to assume certain postures such as the one for suckling. Involvement of the lingual, pharyngeal, and masticatory muscles results in dysphagia. Involvement of digital flexors and extensors may be more frequent than in calves but typical lesions are the *chalky opaque flecking of muscle*. Myoglobinuria may be present and reflects the severity of muscle damage. Sometimes in poorly nourished stabled horses, there is involvement of the masticatory and tongue muscles. This lesion has been called *masticatory myositis* in foals and *polymyositis* in older animals, but based on clinical and pathological grounds *the syndromes seem to be part of nutritional myopathy.*

The distinction between true nutritional myopathy and other diseases is more difficult in older horses than it is for foals, because circumstances and lesions are not as distinctive and because the history is often fragmentary. Nutritional myopathy occurs in animals ranging from less than 1 year to middle age. *The clinical signs may be nonspecific* and may be mistaken for evidence of colic, cardiac failure, wry neck, or general depression, but *the most common features are stiffness and muscular weakness.* Lesions are seldom widespread enough to cause severe crippling although lethargy may be secondary to skeletal muscle degeneration. A willingness to eat is retained in downer animals. *The most convincing indications of nutritional myopathy are the myocardial lesions that are similar to those seen in other species. The presence of myocardial necrosis separates the syndrome from the exertional and ischemic myopathies.*

As is the case with foals, the vitamin E and/or selenium status of older horses with lesions is sometimes difficult to reconcile with information in other species. Low concentrations of blood selenium or glutathione peroxidase are not always present in horses with lesions. Blood tocopherol and glutathione peroxidase concentrations do not seem to be related in individual animals, and selenium and vitamin E may not be curative or, in some cases, not preventive. There is, however, indirect evidence of a need for one or both of the nutrients for optimal muscle function.

Histologic lesions in both foals and older horses are similar to those seen in calves or pigs – a *polyphasic, polyfocal myopathy*. The repair process in foals is rapid and usually complete in 2 weeks if the foal survives, but some lasting retardation of growth may result. Older animals may have the same capability for regeneration especially in subclinical disease, but it is expected that in older animals the repair process may be less effective, and healing will be by scarring in severely affected muscles and this may be responsible for limitations of gait or deviation of the neck.

Steatitis is apparently not seen in older horses with nutritional myopathy but it is common in foals and may, in the healing stage, lead to lumpiness in subcutaneous adipose tissue, especially along the nuchal crest and over the gluteal muscles and the abdominal wall. The affected fat is firm and yellow-brown. Microscopically, neutrophilic infiltration and necrosis and mineralization of fat cells are present.

Nutritional myopathy of other species

Nutritional myopathy is unusual in carnivores and primates. Clinical, morphological, and therapeutic evidence suggests that it does occur. There are several reports in dogs fed prolonged diets unusually low in vitamin E and selenium, and dogs with chronic biliary fistulas developing nutritional myopathy and myocardial damage. *Cats fed vitamin E-deficient diets develop steatitis (yellow fat disease).*

Nutritional myopathy in *ranch mink*, usually accompanied by steatitis, had been a periodic but costly problem. With the introduction of commercial feeds in which vitamin E is added to counteract the effects of oxidized fish oils or other lipid peroxides, it has largely disappeared. It is unlikely that the disease occurs in wild mink.

A number of *zoo animals* appear to be susceptible to nutritional myopathy, but details are scarce and evidence largely circumstantial. A small nocturnal wallaby, the Rottnest quokka (*Setonix brachyurus*), and the nyala (*Tragelaphus angasi*) seem to be exquisitely susceptible. Problems of diagnosis arise in such populations in which capture myopathy is a complication (see Exertional myopathies), but cases that circumstantially appear to be due to nutritional myopathy are reported in several species of gazelle and antelope in Africa, roe deer in Scotland, and white-tailed deer and Rocky Mountain bighorn sheep in North America.

TOXIC MYOPATHIES

A large group of chemical and biological agents are recognized as producing skeletal muscle degeneration and necrosis, either experimentally in laboratory animals or as sporadic clinical occurrences in human patients treated with various therapeutic agents. However, in veterinary medicine, naturally occurring toxicities are largely limited to disease syndromes associated with ingestion of *ionophores, toxic plants, and plant-origin toxins.*

Skeletal muscle susceptibility to toxicants appears in part related to the specialized metabolism of muscle and the increased demands on the metabolic process from contraction. In addition, sensitivity to toxicants may be enhanced because many of the substances tend to bind to skeletal muscle fibers. Skeletal muscle dysfunction or damage has been induced by altered neurogenic function (increased motor nerve activity, neuromuscular blockade, acetylcholine accumulation, and denervation atrophy); immunologic modulations; alterations in various subcellular sites centered on cell membranes, myofilaments, lysosomes, microtubules, and sarcoplasmic reticulum; altered intracellular calcium concentration; altered protein synthesis; and altered muscle cell differentiation. Some agents, such as oxytetracycline, cause direct local injury at injection sites.

Clinical expression of myotoxicities is highly variable and ranges from lack of overt clinical signs but elevated serum concentrations of skeletal muscle origin enzymes, stiffness and muscle pain with or without myoglobinuria, and severe muscle weakness accompanied by recumbency usually with myoglobinuria. Mortality rates may be high in severely affected animals; death is often caused by concurrent myocardial damage by the same toxin.

Ionophore toxicosis

Ionophores *used in agriculture are monensin, lasalocid, salinomycin, narasin, and maduramicin.* Ionophores are compounds that alter membrane permeability to electrolytes by influencing transmembrane transport. In excess, all of these agents damage skeletal and cardiac muscle but *horses are uniquely susceptible.* Most reports of toxicosis involve monensin, an ionophore used widely for years.

Monensin, an antibiotic produced by the fermentation of *Streptomyces cinnamonensis*, has a growth-promoting effect in ruminants and is an efficient coccidiostat in birds and other animals. Monensin is produced commercially in very large quantities in North America and Europe where it is added, as a concentrated premix, to pelleted or bulk feeds fed to cattle, sheep, and other ruminants. Toxicity develops when monensin is fed to monogastric animals, which have a much reduced tolerance for the drug, or when human or mechanical error leads to concentrations of monensin in the ration that are abnormally high for the species being fed. Toxic effects have been recorded in horses, donkeys, mules, zebras, cattle, sheep, dogs, wallabies, camels, blesbok, Stone sheep, turkeys, and chickens. Many episodes of monensin poisoning have been caused by mixing errors in packaged, pelleted, commercial animal feeds, either concentrates or final mix which has put hundreds or thousands of animals at risk, sometimes over wide geographic areas. In North America alone, such mixing errors have been reported in horse, cattle, dog, and zoo feeds. Some indication of susceptibility of different species is provided by the *estimated LD_{50} for different animals*. Horses and other equids that are sensitive have an LD_{50} of 2–3 mg of monensin/kg body weight. LD_{50} values for other species are: dogs, 5–8 mg/kg; sheep and goats, 12–24 mg/kg; cattle, 50–80 mg/kg; and various types of poultry 90–200 mg/kg. Pigs, which may be given the drug for its coccidiostatic properties or are exposed by mistake, have an LD_{50} of 16–50 mg/kg body weight. The toxic effects of monensin or salinomycin are potentiated by the addition of tiamulin, triacetyloleandomycin, or sulfonamides to the ration, usually for therapeutic purposes.

Ingestion of **maduramicin**, an ionophore antibiotic utilized as a coccidiostat in poultry, has caused *cardiotoxicity in cattle and sheep*. Cases occurred in South Africa and Israel where dried poultry litter was used as a source of protein for ruminants. The clinical and pathological features of this toxicosis are similar to those of monensin cardiotoxicity.

When a single large toxic dose of an ionophore is fed to an animal, clinical signs of *lethargy, stiffness, muscular weakness, and recumbency* occur within 24 hours. Horses and other equids are likely, in the early stages, to show marked signs of colic, apprehension, shifting or fidgeting, sweating, myoglobinuria, and muscle tremors. Dogs show apprehension and progressive weakness. If sublethal doses are fed, the toxic effect will be cumulative, and the clinical onset may be delayed for 2–3 days to weeks depending on the total amount and the period over which it is fed, but the debility is likely to be more pronounced. Animals on low-level toxicity experiments often have delayed progression of the toxic signs because consumption of these feeds is reduced. These animals frequently scour and lose weight. At dose levels capable of inducing clinical signs of toxicity in a few days, many animals show evidence of *progressive cardiac failure due to a high incidence of myocardial lesions*. Animals recovering from the acute disease may subsequently develop within several months signs of progressive cardiac insufficiency from myocardial fibrosis, and sometimes renal failure, in addition to poor growth or poor weight gain, although the signs referable to skeletal muscle injury may disappear.

Postmortem lesions of ionophore toxicity may be difficult to detect in acute cases dying within 24 hours. *In horses, myocardial damage predominates, in sheep and swine the skeletal muscles are the main site of damage and myoglobinuria is generally present* (Figs 2.76, 2.77), *and in cattle skeletal and cardiac muscle are about equally affected*. Skeletal muscle may lack normal rigor, and ill-defined pale streaks may be visible in both myocardium and skeletal muscle. Later, the white streaking and local atrophy of affected skeletal muscles becomes more prominent. Hindlimb muscles may be the sites of major degenerative changes. Cases with terminal cardiac damage will have features of congestive heart failure including fluid accumulations in body cavities, pulmonary congestion and edema, and hepatic congestion.

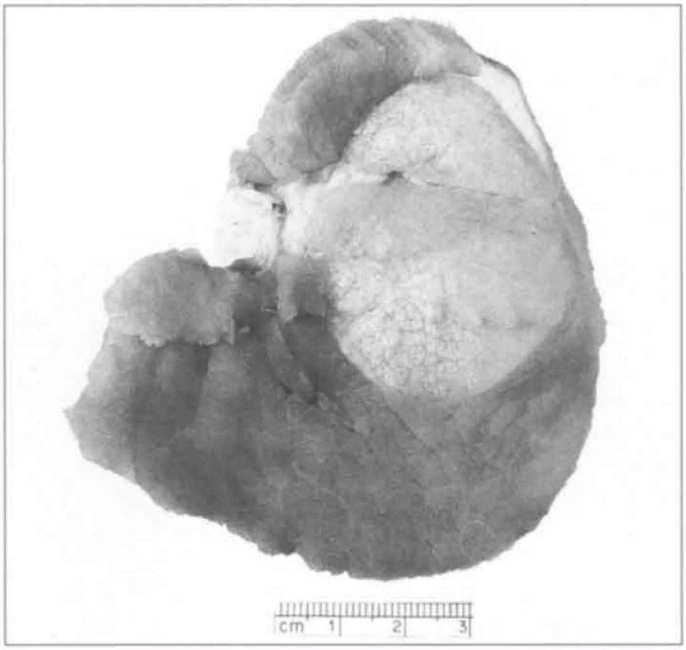

Figure 2.76 Pale area of necrosis in cross-section of caudal thigh muscles from a pig with **monensin toxicosis**. (Reprinted from Van Vleet JF et al. Am J Vet Res 1983;44:1460.)

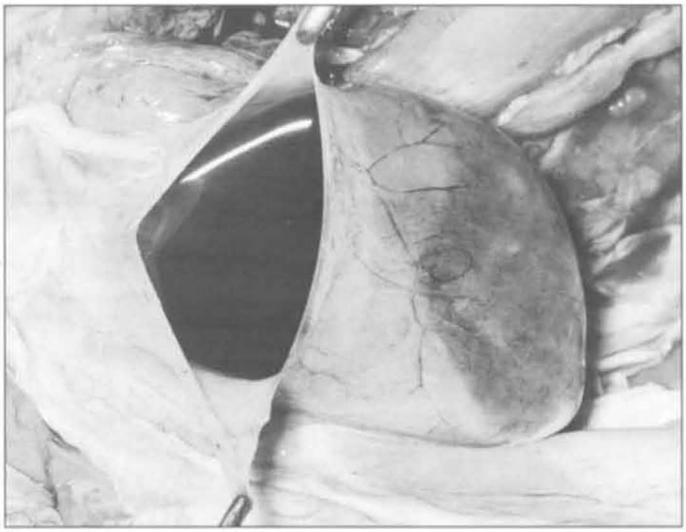

Figure 2.77 Myoglobinuria in a pig with monensin toxicosis. (Reprinted from Van Vleet JF et al. Am J Vet Res 1983;44:1460.)

Microscopic lesions of ionophore toxicity typically are *monophasic, multifocal degeneration* by 48 hours after exposure and thus differ from the polyphasic, multifocal lesions of nutritional myopathy. One of the earliest electron-microscopically visible lesions in muscle fibers is *marked swelling and disintegration of mitochondria*. Monensin is an ionophore that distorts membrane transport of sodium and potassium. This apparently leads to distortions of the electrolyte-modulated calcium gating mechanism and then mitochondrial failure, energy exhaustion, failure of calcium ion removal from the cytosol, and eventually myofibrillar hypercontraction and segmental degeneration. *Both type 1 and type 2 fibers are involved with hyaline necrosis and macrophagic infiltration* (Figs 2.78–2.83).

Myofiber nuclei and satellite cell nuclei as well as endomysial cells apparently survive acute toxicity, and the early stages of regeneration

are initiated during the first few days following exposure (Figs 2.82–2.85).

Myocardial lesions in monensin toxicity are not reparable and, particularly in a growing animal, the probability of lasting cardiac insufficiency is high.

Toxic plants and plant-origin toxins

Toxic plants and plant-origin toxins

Cassia spp. toxicity – ruminants

In the southern USA, mature cattle and goats on pasture may ingest the beans of the **senna or coffee senna plant** (*Cassia occidentalis* or *C. obtusifolia*) or **coyotillo** (*Karwinskia humboldtiana*) late in the year, after a killing frost has made the plant more palatable than normal. Horses and pigs may also be affected. After eating the plant for a few days, animals develop diarrhea, show evidence of weakness, and display a swaying, stumbling gait that is related to the developing muscle lesions. The disease progresses rapidly and most of the animals affected become recumbent and develop myoglobinuria and

high concentrations of muscle-origin enzymes in serum. Recumbent animals usually do not recover but may live for several days. The morbidity rate may reach 60%.

Postmortem lesions in recumbent animals consist of *ill-defined pallor of much of the muscle mass*. Histologic changes are typically *monophasic multifocal myopathy*. The destruction of muscle fibers is

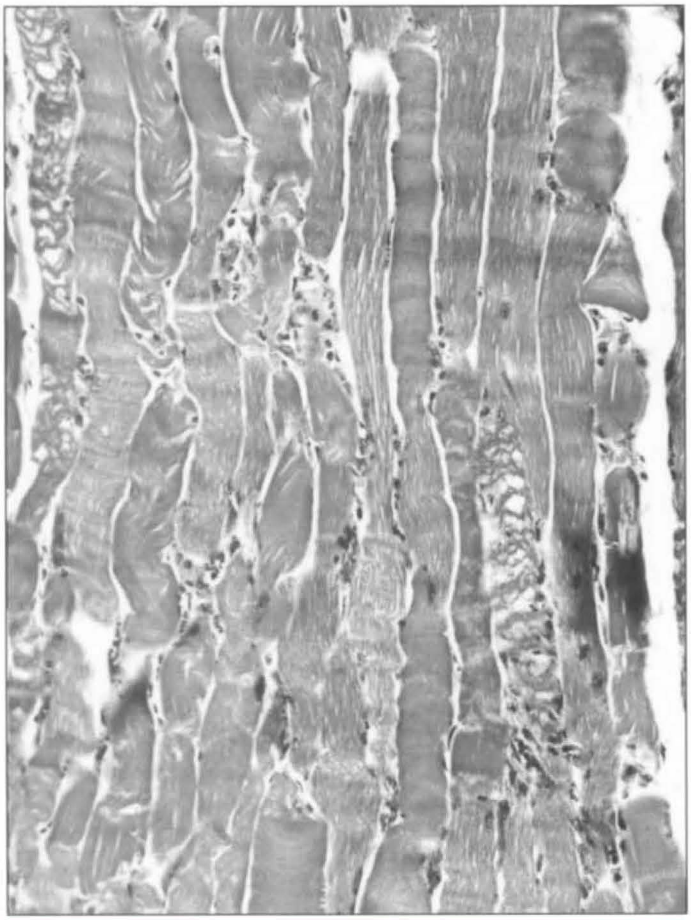

Figure 2.86 Myodegeneration caused by ***Cassia occidentalis*** **poisoning** of a heifer. (Courtesy of KR Pierce.)

segmental, but sarcolemmal sheaths and muscle nuclei remain, enclosing the floccular degenerate contractile elements (Fig. 2.86). Myocardium is not extensively involved but animals dying acutely show some myocardial lesions. Apparently recovered animals have not been examined, and the specific toxin has not been characterized.

Cassia spp. toxicity – swine

Natural outbreaks of toxicity on several pig farms occurred when animals were fed grain contaminated with *C. occidentalis* seeds. Several pigs died after a short period of reduced weight gain and a progressively wobbly, unsteady gait. Experimentally, the clinical disease was reproduced after 40 days with diets with as little as 1% of ground seeds. Postmortem examination revealed no gross lesions, but microscopic degeneration of the myocardium and diaphragm were characterized by *vacuolation and segmental hypercontraction of fibers*. The lesions were unexpectedly limited in the skeletal musculature, considering the marked locomotor clinical signs.

Gossypol toxicity

Gossypol *is a yellow, pigmented, polyphenolic substance present in cottonseeds* (*Gossypium* spp.). It is toxic to swine, and toxicosis occurs when swine are fed cottonseed cake or meal at a concentration of 10% or more of rations to which it is added as a protein supplement.

Lesions occur after feeding such rations for a month or more, which suggests that the toxic effects are cumulative. Gossypol is toxic to experimental lambs and calves at concentrations of less than 450 ppm in the feed (the level of free gossypol permitted in human and some animal foods). Dogs may also be affected. Lesions are present in several organs, including the heart, skeletal muscles, liver, and lungs, and *death is due to cardiac failure*, which causes fluid accumulation in body cavities. Histologically, *segmental necrosis of skeletal muscle and myocardium* is present, the liver has centrilobular necrosis and the lungs are congested and edematous. Affected animals are pot-bellied and poorly grown, and most die acutely. Natural outbreaks of disease in calves and lambs circumstantially linked to cottonseed meal ingestion have similar patterns of poor growth and sudden death. Serum enzyme concentrations are generally not significantly increased, which seems to confirm that the heart is the only striated muscle generally affected. Other circumstantial evidence suggests, however, that in calves, skeletal muscle lesions can be locally extensive but unpredictable in distribution. *Both type 1 and 2 muscle fibers appear to be affected in a selective, segmental myopathy* generally indistinguishable from the lesions of other toxic myopathies except that both myofiber types are equally involved.

Other toxic myopathies

Myopathies are reported in sheep with **lupinosis** (*Diaporthe toxica*), in sheep with **water hemlock** (*Cicuta douglasii*) toxicosis, in calves with **false lupine** (*Thermopsis montana*) toxicosis, in horses with **white snakeroot** (*Eupatorium* spp.) toxicosis, and in pigs, cattle, sheep, and other species with **selenium** toxicosis.

MYOPATHIES ASSOCIATED WITH ENDOCRINE DISORDERS

Hypothyroidism

Some dogs with hypothyroidism may develop clinical signs of weakness, stiffness, reluctance to move, decreased exercise tolerance, and *muscle wasting* in addition to the traditional signs of alopecia and obesity. The likelihood of development of myopathy is increased if concomitant endocrinopathies are present such as diabetes mellitus and hyperadrenocorticism. Peripheral neuropathy with axonal degeneration may also be produced in hypothyroidism (and hyperadrenocorticism) with subsequent atrophy of type 1 and type 2 fibers.

Muscle biopsies reveal *atrophy and loss of type 2 fibers*. The atrophic fibers appear oval or angular in outline and are present throughout all muscle fascicles. Nemaline rods may be found, especially in type 1 fibers. No evidence of muscle fiber degradation or inflammatory cell infiltration is present. Initiation of thyroid hormone replacement therapy leads to resolution of the lesions. Selective involvement of type 2 fibers has been attributed to alterations in carbohydrate metabolism with subsequent loss of energy from glycolysis and glycogenolysis.

Hyperthyroidism

Affected cats may exhibit muscular tremors, ventroflexion of the neck, disturbances in gait, generalized weakness, and collapse. Microscopic alterations usually are absent, but *nonspecific fiber damage may be present.*

Hyperadrenocorticism

Cushing's disease from pituitary-dependent hyperadrenocorticism, adrenal-dependent hyperadrenocorticism, and iatrogenic hyperadrenocorticism may result in muscular weakness, stiff stilted gait, *muscle atrophy,* and inability to walk in dogs. The pelvic limbs are mainly affected.

In muscle biopsies, there are *selective type 2 fiber atrophy, fiber splitting, and focal necrosis.* Medical or surgical treatment of Cushing's disease may lead to resolution of the muscle lesions unless severe atrophy or contracture was present in the pelvic limb musculature. The muscle fiber alterations are attributed to *increased catabolism and inhibited synthesis of muscle proteins from glucocorticoid excess.*

Hypoadrenocorticism

Addison's disease in dogs and cats often results in muscle weakness presumed to be related to accompanying *hyperkalemia*. Muscle alterations have not been characterized.

Increased growth hormone exposure

Beagle dogs given exogenous porcine growth hormone had hypertrophy of types 1 and 2 fibers. However, skeletal muscle alterations have not been described in dogs or cats with acromegaly.

MYOPATHIES ASSOCIATED WITH SERUM ELECTROLYTE ABNORMALITIES

Hypokalemia in cats

In 1984, a *polymyopathy* was identified in cats and in over half of the affected animals, there was a coexisting hypokalemia. Subsequently, a distinct syndrome of **hypokalemic myopathy** was characterized and the disorder was also termed *feline kaliopenic polymyopathy-nephropathy syndrome* and *sporadic feline hypokalemic polymyopathy*.

Clinically, the affected cats had generalized weakness, ventroflexion of the neck, a stiff stilted gait, exercise intolerance, reluctance to walk, and muscle pain. Serum activity of skeletal muscle origin enzymes (CK, AST) was elevated and serum potassium levels were low (<3 mEq/L). Hypokalemia was attributed to low dietary intake or excessive renal loss. Low intake occurred in cats fed potassium-depleted regular diets or high-protein vegetarian diets. Excessive renal loss of potassium was present in cats with chronic renal disease and in those fed acidic diets to prevent urolithiasis. Also, the syndrome reported in Burmese kittens 2–6 months of age with intermittent hypokalemia, is presumed to be heritable.

In general, *the skeletal muscle lesions have been either mild or absent*. Lesions have been described as a *polyphasic myopathy with concurrent necrosis and regeneration*. The skeletal muscle damage was attributed to influx of sodium with a decrease in resting membrane potential and hypopolarization, altered glycogen metabolism in skeletal muscle fibers, and ischemic injury from hypokalemia-induced vasoconstriction. Treatment with potassium supplementation is generally successful but the syndrome may recur unless supplementation is maintained.

Hypokalemia in cattle

In 1997, a hypokalemic syndrome with *muscle weakness and myopathy* was reported. Affected cattle were weak, recumbent, and were unable to elevate their heads off the ground and instead held them against their flanks. They were post-parturient and had moderate to severe ketosis with hypokalemia (1.4–2.3 mEq/L). The animals were treated with isoflupredone, a glucocorticoid with high mineralocorticoid activity. The skeletal muscle damage involved the hindlimbs and included vacuolar degeneration, necrosis with macrophagic infiltration, and variably present secondary ischemic injury.

Hypernatremia in cats

Muscle weakness evident as ventroflexion of the neck has been observed with hypernatremia and hypodipsia in the cat.

Hypophosphatemia in dogs

Muscle weakness occurs in dogs with hypophosphatemia. Necrosis of skeletal muscle with myoglobinuria was present in severe acute phosphorus depletion.

EXERTIONAL MYOPATHIES

The term **exertional myopathy** *is indicative of myofiber damage occurring due to exercise stress.* Acute myofiber injury is precipitated by exercise in a broad group of myopathies, including X-linked muscular dystrophy, nutritional myopathy, metabolic myopathies, malignant hyperthermia, and myopathy due to hypokalemia. In such cases, the initiation of abnormal excitation–contraction coupling, inadequate energy metabolism, ionic imbalance, or simply the mechanical stresses occurring during contraction are thought to lead to myofiber damage of predisposed muscle.

Historically, the syndrome of passage of *myoglobin-pigmented urine (myoglobinuria)* was recognized long before it was determined that massive *skeletal muscle necrosis (rhabdomyolysis)* was the cause. Small wonder that so many names exist for the varying manifestations of exertional myopathy. In a broad sense, *exertional myopathy has included the group of diseases in which acute muscle fiber necrosis is initiated by muscle activity of the major muscle groups but in which the underlying cause is unknown or poorly understood.* Such activity may be intensive or exhaustive, but in susceptible individuals exertional myopathy may occur with only minimal exercise. Continued research into causes of exertional rhabdomyolysis is clearly warranted and, as is true of equine exertional rhabdomyolysis (see below), may lead to better understanding of causes and preventive measures.

Exertional myopathy (rhabdomyolysis) in the horse

Various manifestations of exertional myopathy have been recognized in horses for many, many years. There are numerous names for the disorder, including *azoturia* (presumably named for nitrogen-containing compounds in the urine, and possibly related to the resemblance of myoglobin to the red-purple azo dyes), *black water, paralytic myoglobinuria, Monday-morning disease, set fast, and tying up.* Various classifications have distinguished the disorder in heavy horse breeds that are prone to severe and often life-threatening muscle injury, particularly when worked after a day of rest and full grain ration (hence the term Monday-morning disease), from the often less severe disorder in light horse breeds. Muscle injury severe enough to result in myoglobinuria, profound weakness, and recumbency is common in heavy horse breeds, hence the terms azoturia, black water, and paralytic myoglobinuria. Exertional myopathy in light horse breeds is typically less severe, resulting in episodic muscle pain, sometimes associated with swelling, and reluctance to move, hence the names set fast and tying up. Given the recent recognition of a metabolic myopathy leading to exertional rhabdomyolysis in both heavy and light breeds (see below), it becomes clear that *the same underlying disorder can result in a spectrum of clinical signs.*

It has long been suspected that the clinical disorder represents a syndrome with multiple possible etiologies. It has been proposed that exertional myopathy in the horse be classified as either sporadic exertional rhabdomyolysis or recurrent exertional rhabdomyolysis, with sporadic exertional rhabdomyolysis possible due to muscle exhaustion or electrolyte depletion in any horse, and recurrent exertional rhabdomyolysis occurring in horses somehow predisposed to this disorder. Studies of serum activities of CK and AST following exercise have shown, however, that subclinical exertional myopathy is common in horses. As exertional myopathy can occur without obvious clinical signs other than, perhaps, poor performance, it is possible that so-called sporadic cases really represent recurrent disease, and therefore this classification is difficult to justify based on current knowledge of equine muscle disease.

Previously, *etiologies* proposed for equine exertional rhabdomyolysis have included muscle lactic acidosis, hypothyroidism, electrolyte imbalance, and vitamin E and/or selenium deficiency. Of these, *only electrolyte imbalance, in particular hypokalemia, is still considered possible.* Extensive studies have shown that lactic acid levels in the muscle of exercising horses prone to exertional rhabdomyolysis are no different than those of control horses, removal of thyroid glands results in poor cardiac output and performance without evidence of muscle damage, and vitamin E and selenium status varies widely in affected horses. More recently, a *metabolic myopathy* thought to involve abnormal starch and sugar metabolism (equine polysaccharide storage myopathy, see the Metabolic myopathies section) has been shown to be the most common cause of exertional rhabdomyolysis in many breeds of horses, including Quarter Horse, Warmblood, draft, Arabian, Standardbred, Tennessee Walker, Morgan, and Welsh pony-related breeds. It is possible that a similar metabolic disorder is the cause of recurrent exertional rhabdomyolysis in Thoroughbreds, although this is controversial, with one group reporting evidence for abnormal calcium handling in muscle fibers of affected Thoroughbreds. Defective ryanodine receptor function similar to malignant hyperthermia has not, however, been found in affected Thoroughbreds. Whether the abnormal muscle contracture testing reported in in vitro studies of muscle from Thoroughbreds with recurrent exertional rhabdomyolysis is a primary or secondary abnormality is still unknown. *There is strong evidence that there is an inherited basis for the predisposition to exertional rhabdomyolysis in horses.* Both autosomal recessive and autosomal dominant inheritance have been proposed, depending on the breed studied. Although further studies are needed, *it is now accepted that exertional rhabdomyolysis in horses is most often due to underlying metabolic abnormalities of muscle rather than simply due to poor management of diet and exercise.*

Although diets high in starches and sugars (grains) are associated with increased severity of exertional rhabdomyolysis, clinical signs can still occur in horses fed only forage. Despite differing opinions regarding cause, *almost all horses with recurrent exertional rhabdomyolysis respond positively following a diet change to one that is high in fat, high in fiber, and low in starches and sugars.* Stall rest appears to exacerbate the signs of equine exertional rhabdomyolysis, however the mechanism by which daily exercise benefits such horses is still unknown.

Weakness and/or pain in the hindlimbs occur suddenly, and the animal soon becomes unable or very reluctant to move. This may be accompanied by sweating and generalized tremors. The affected muscles, which are typically those of the *gluteal, femoral, and lumbar groups*, may be swollen and board-like in their rigidity. *Myoglobinuria* can appear early in the disease, causing dark red-brown discoloration of the urine. Severely affected horses become recumbent, a sign that is often a prelude to death from myoglobinuric nephrosis or problems associated with being down and attempting to rise. Considerable variation occurs between cases as to the nature and duration of the initiating exercise and severity of clinical signs. Recovery from mild attacks in quiet animals may occur in a few hours. Recovery from severe episodes may take days. But, if an animal continues to struggle and is unable to rise, death or euthanasia is the most likely outcome. *Atrophy of the gluteal muscles* may be a feature of recovery in moderate to severe cases. Exertional rhabdomyolysis occurs in both males and females, although *females appear to be predisposed.* The activity of the ovarian hormones estrogen and progesterone does not, however, appear to be directly related to onset of exertional rhabdomyolysis in females, and ovariectomy is not an effective therapy.

The apparent pain and muscle swelling associated with many cases of equine exertional rhabdomyolysis is curious, as muscle necrosis per se is neither painful nor does it cause muscle swelling. It is suspected that *increased intramuscular pressure, perhaps exacerbated by oxidative membrane injury, may cause painful muscle injury in this disorder.*

This may explain the often-reported improvement obtained following vitamin E and selenium supplementation in affected horses.

Muscle fiber membrane injury leads to release of sarcoplasmic proteins, most notably myoglobin, creatine kinase (CK), and aspartate aminotransferase (AST). Serum activity of CK peaks at approximately 4–6 hours post-injury and declines rapidly, with a half-life of approximately 6–10 hours. Therefore, if serum CK activity is not reduced by at least 50% every 24 hours this is evidence of continued muscle injury. Serum activity of AST increases more slowly, with a peak at about 48 hours post-injury and a very long half-life that can lead to persistent AST increases for days to weeks. The degree of CK and AST increase does not, however, correlate with severity of clinical signs. It is possible that muscle cramping or stiffness in the absence of overt necrosis may occur in some horses.

Grossly visible changes in muscle may be inapparent. In severe cases they are most obvious in the gluteal, lumbar, and caudal thigh regions but lesions often are widespread. *Muscles may be moist, swollen, and dark, and streaks of pallor may be visible in the more extensively involved muscles.* If ischemic complications occur, the muscles also may show blotchy or linear hemorrhage. In animals that have survived for 2–3 days, muscles may become paler and, although edema may surround larger muscle divisions, the locally damaged areas appear dry compared to normal muscle.

Necrosis affects primarily the strongly glycolytic fibers (type 2B glycolytic and type 2A oxidative-glycolytic fibers; Fig. 2.87), in contrast to the primary involvement of type 1 oxidative fibers in the nutritional myopathies. The timing and sequence of events are not clear, but *damaged fiber segments generally undergo hypercontraction and hyaline degeneration* (Fig. 2.88) *followed by coagulative necrosis.* Mineralization is not typically seen. There is also potential for perpetuation of myofiber injury due to release of free radicals from damaged membranes and subsequent oxidative membrane injury. This sequence of events may reduce the capacity of muscle protein to hold water, consequently water is lost to the interstitial compartment where it raises local pressure and predisposes to ischemia (*compartment syndrome*), particularly if moderate muscle movement is continued (see Circulatory disturbances of muscle). Oxidative injury to muscle capillary endothelium may also contribute to intramuscular edema and increased pressure. Cardiac involvement is rare.

The early irreversible fiber change as monitored by electron microscopy consists of myofibrillar waving and architectural loss, irregular mitochondrial swelling, and interfibrillar edema. After 12 h, more marked sarcomere destruction occurs along with streaming of Z-bands. Histologically, the lesions are characterized by scattered single or small groups of necrotic fiber segments admixed with intact fibers. In the more severe, acute tying-up cases, 1–5% of muscle fibers in a biopsy sample may be affected. In the less severe cases, the amount of fiber damage involves less than 0.2% of fibers in irreversible change but many more fibers can undergo hypercontraction that is potentially reversible. If muscle is examined days after injury, fiber regeneration will be apparent. Lesions are often monophasic and multifocal, but can be polyphasic in horses with repeated bouts of necrosis or on-going injury (Fig. 2.89).

In horses with *polysaccharide storage myopathy*, abnormal inclusions of pale blue-gray complex polysaccharide may be seen within scattered myofibers on H&E stain (see Fig. 2.60). Inclusions may be numerous or very rare, and have been shown to occur only within type 2A and type 2B fibers. *Inclusions stain intensely with periodic acid-Schiff (PAS) for glycogen and resist amylase digestion.* In severe chronic cases, interstitial aggregates of complex polysaccharide-laden macrophages may be seen, indicative of previous necrosis of polysaccharide-laden segments, and marked fatty infiltration is possible (see Fig. 2.60). Subsarcolemmal aggregates of amylase-sensitive glycogen are also a feature of this disorder, and may occur in the absence of complex polysaccharide in some affected horses (see Fig. 2.62). Chronic myopathic changes, including excessive fiber size variation due to fiber hypertrophy and atrophy and increased numbers of internal nuclei are common. Given the high incidence of underlying equine polysaccharide storage myopathy in horses with histories of exertional rhabdomyolysis or postanesthetic myopathy (see below), *PAS staining and careful evaluation of muscle from all such cases for evidence of chronic myopathy and abnormal glycogen and complex polysaccharide storage is warranted.*

Other equine degenerative myopathies

In addition to nutritional myopathy and exertional rhabdomyolysis, *degenerative myopathy can occur in horses recovering from general anesthesia.* This syndrome of **postanesthetic myopathy** has been recognized most often in heavy horse breeds. Although experimental induction of hypotension during general anesthesia will cause postanesthetic myopathy in any horse (see Circulatory disturbances of muscle), recent studies of clinical cases indicate that *many occur due to underlying polysaccharide storage myopathy.* Persistently high CK serum levels can occur in horses with postanesthetic myopathy due to polysaccharide storage myopathy, indicative of on-going muscle injury occurring even after the horse has stood up. A form of malignant hyperthermia has also been proposed as a cause of anesthetic-related myopathy in horses. This may be appropriate for those cases in which hyperthermia occurs during inhalant anesthesia, but most affected horses develop myopathy during recovery rather than during anesthesia. Although such horses may develop dangerously high body temperatures during recovery, this condition is best considered to be a hypermetabolic state rather than malignant hyperthermia. Underlying myopathy of any type may be a predisposing factor in horses that develop life-threatening hyperthermia either during or following general anesthesia.

Nutritional myopathy in horses causes a degenerative myopathy (see Nutritional myopathy), as do various *plant toxins and ionophores* (see Toxic myopathies). A myoglobinuric disease of pastured horses has also been described in Britain, in which extensive myolysis is triggered by an as yet unknown factor.

Exertional myopathy in dogs

Exertional rhabdomyolysis *is recognized as a syndrome affecting racing Greyhounds and racing sled dogs.* Given the vast difference in type of exercise (i.e., sprint vs endurance racing) in these two breeds of dog, there are likely to be differing underlying etiologies.

In *racing Greyhounds*, the disorder primarily affects longissimus, quadriceps, and biceps femoris muscles. Affected dogs may display distress and generalized muscle pain associated with a stiff gait. Myoglobinuria can lead to death due to renal failure. In less severe cases, myoglobinuria is not evident, and muscle pain may only be mild to moderate. Similar to exertional rhabdomyolysis in horses, affected muscles may be swollen as well as painful, indicative of mechanisms besides simple muscle necrosis as a cause of pain and swelling. Predisposing factors proposed include an *excitable nature, lack of physical fitness, hot and humid conditions, and overexertion of physically fit dogs.* Gross lesions are not often seen in affected muscles, although histopathologic evidence of acute degenerative changes is found in susceptible muscles.

Racing sled dogs may undergo massive rhabdomyolysis during racing that can lead to *sudden death.* There is often selective involvement of certain muscle groups; in one case studied there were moderate to severe polyfocal and monophasic necrotizing lesions involving quadriceps, psoas, deep digital flexor, and gastrocnemius muscles, with sparing of triceps brachii, epaxial, and cranial tibial muscles. Gross lesions are not typically seen, and sampling of multiple muscle groups may be necessary to determine the extent of injury. It has been suggested that prolonged endurance-type exercise leads to increased lipid peroxidation and reduced plasma antioxidant concentrations, however vitamin E supplementation does not appear to ameliorate exercise-induced muscle injury in racing sled dogs, and pre-race plasma vitamin E levels do not appear to correlate with risk of exertional rhabdomyolysis. As in horses, dietary management is likely to play a role in canine exertional rhabdomyolysis, as a high-fat and low-carbohydrate diet has been reported to reduce exercise-induced muscle injury in these dogs.

Exertional myopathy in other species ("capture myopathy")

Massive muscle injury associated with exertion reported in other domestic animals such as sheep and cattle can occur due to overexertion. Underlying nutritional myopathy (see the section on Nutritional myopathy) or metabolic myopathy (see the section on Metabolic myopathies) is also possible. *Of special interest is exertional myopathy occurring in wild animals following capture and/or immobilization, an entity known as* "**capture myopathy**." First described in wild ungulates, this disorder has been seen in multiple species, including wild ruminants, captured otters, cetaceans, mustelids, canids, marsupials, and wild birds. Clinically affected animals can exhibit *dyspnea, weakness, muscle tremors or muscle rigidity, hyperthermia, collapse, and, often, death.* Thigh muscle rupture may occur. Those that do not die acutely show myoglobinuria and increased levels of muscle enzymes in the blood and may subsequently die of renal failure. When the animal is down, ischemic complications may be secondary (see Circulatory disturbances of muscle). The muscle lesions are capable of more or less complete repair over a few weeks unless infarction has intervened.

Capture myopathy is associated with stress to the affected animal, and *increased circulating catecholamines may play a role,* particularly in the cardiac damage that can be seen. Hyperthermia and metabolic acidosis have also been associated with capture myopathy. Extreme overexertion likely also contributes. In some cases, marginal selenium status or electrolyte abnormality such as hypokalemia or hyperkalemia may be predisposing factors.

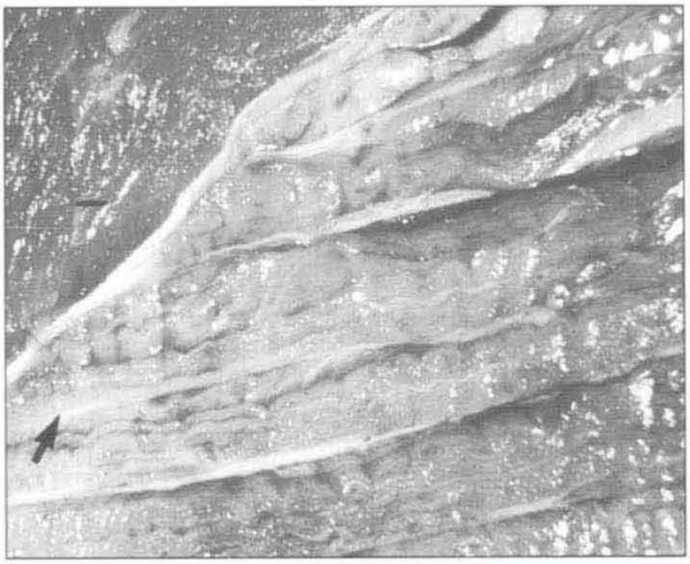

Figure 2.90 Marked pallor of affected muscle (arrow) in **bovine transport myopathy**. (Courtesy of TJ Hulland.)

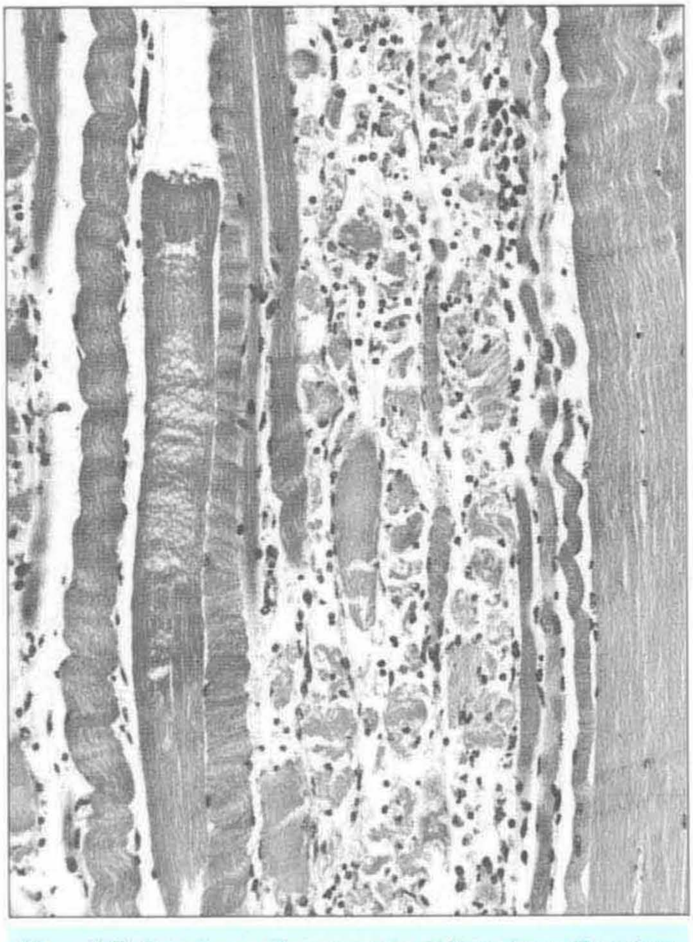

Figure 2.91 Extensive myofiber necrosis in a bighorn sheep with **capture myopathy**. (Courtesy of T Spraker.)

Gross and histologic lesions are often similar to those occurring due to other causes of severe exertional myopathy. They may also resemble those of hyperthermia in pigs, with *prominent muscle edema* in animals dying acutely. Muscles may contain *indistinct pale streaks* (Fig. 2.90), and *hemorrhagic streaking* is not uncommon. Degenerative lesions in skeletal muscle are typically *monophasic and polyfocal*. In most cases, death occurs during the degenerative phase and therefore acute myodegeneration, often with macrophage invasion of affected segments, is seen affecting various muscles (Fig. 2.91). Cardiac lesions, when present, are most often acute, although animals that survive capture myopathy may die acutely at a later date due to myocardial fibrosis. Myoglobinuric nephrosis may be seen.

IMMUNE-MEDIATED CONDITIONS

Immune-mediated disorders are those in which abnormal activation of the immune system results in tissue damage. *Immune-mediated muscle damage can involve circulating antibodies directed against muscle cell components, cytotoxic T lymphocytes that infiltrate and attack muscle cells, or immune-complex deposition that subsequently exposes muscles to inflammatory mediators and ischemia.*

It is important to distinguish primary immune-mediated myositis from florid degenerative myopathy in which cellular infiltrates, primarily composed of macrophages, can mimic those of true inflammatory disease. It may be necessary to employ special procedures to identify the type of infiltrating cells or to detect specific antibody binding to muscle components. *Immune-mediated disease of muscle is characterized by interstitial and perivascular infiltration of lymphocytes and/or plasma cells* (Fig. 2.92). These cells may be mixed with macrophages and with eosinophils and neutrophils, particularly in cases accompanied by severe myofiber necrosis. *The diagnosis is dependent on determining that cellular infiltrates actually cause the myofiber necrosis and are not secondary to the muscle damage.* The finding of mononuclear leukocytic invasion of otherwise intact myofibers is the hallmark of primary myositis. Infiltrating cells may be seen surrounding intact myofibers, or may be seen centrally, causing a characteristic "coring out" of myofibers with otherwise intact peripheral myofibrils (Fig. 2.93). Lymphocytic myositis must be distinguished from infiltration of skeletal muscle by malignant lymphoma.

Masticatory myositis of dogs

An immune-mediated myositis localized to the masticatory muscles occurs in dogs. The masseter, temporal, and pterygoid muscles are selectively affected. Although previously designated as two separate disorders – *eosinophilic myositis and atrophic myositis – these are now recognized to be two ends of the spectrum of a single disease known as* **masticatory myositis**. Given the thick fascia of the masticatory muscles in dogs, the swelling that can occur in masticatory myositis may be due, at least in part, to ischemic damage due to compartment syndrome initiated by increased pressure within inflamed muscle. *Atrophic myositis is the result of prominent atrophy of temporal and masseter muscles.* The masticatory muscles of dogs have a unique myosin isoform, known as *type 2M myosin*. This unique myosin isoform results in an inability to achieve muscle fiber type reversal of canine masticatory muscle sections with an acid preincubation ATPase reaction. *Antibodies in dogs with masticatory muscle myositis are directed against this unique myosin isoform*, and diagnostic testing for type 2M antibodies in canine serum is available. It has been proposed that various bacterial infections may result in antibodies that cross-react between bacterial antigens and type 2M myosin.

Affected dogs are unable to fully open the mouth (*trismus*). Muscle swelling or atrophy is most obvious in the temporal and masseter muscles and is bilateral. Pain upon opening the jaw is common, and jaw immobility persists during general anesthesia. Swelling of muscle may result in a degree of exophthalmos. Attacks, if untreated, last up to 2–3 weeks and the periods between attacks may be a few weeks, months, or 2–3 years. If left unchecked, *this inflammatory myopathy leads to progressive destruction of the muscles of mastication and permanent inability to fully open the jaw.* Muscle atrophy gradually becomes very obvious and the head appears to have a fine fox-like contour with unusual prominence of the zygomatic arches (Fig. 2.94A, B).

This disorder occurs in many breeds, although the *German Shepherd breed* appears to be predisposed. Serum activities of CK and AST may be normal, or may be mildly to moderately increased. Masticatory myositis with a strong eosinophilic inflammatory component may be accompanied by peripheral blood eosinophilia, but this is not a consistent finding. Clinical response to immunosuppressive doses of corticosteroids may be rapid, but cases may relapse once corticosteroid therapy is discontinued. *Masticatory myositis is progressive*, but now that this disorder is often recognized and treated in early stages, fewer chronic cases are presented for postmortem examination. Affected dogs may, however, develop aspiration pneumonia or complications of corticosteroid therapy leading to death or euthanasia.

Grossly visible changes in the muscle vary with the stage of disease. The acutely affected muscles are swollen, dark red, doughy or hard, and the cut surface reveals hemorrhagic streaks and irregular yellow-white patches. In the late stages, there is advanced atrophy and fibrosis. Some areas consist only of pink-gray, semitranslucent, mature, connective tissue subdivided by the whiter residual tendons (Fig. 2.95).

Histologically, this disorder most often has a *multifocal and polyphasic pattern. Inflammatory infiltrates are interstitial and often perivascular.* Necrotic and regenerating myofibers are common in acute and active stages of the disease. Previous corticosteroid therapy can reduce and alter the inflammatory component present. Eosinophils may or may not be the predominant cell type seen in affected muscle, but *eosinophils will always be admixed with lymphocytes.* Eosinophils can be seen in muscle damaged by a variety of insults. The primary inflammatory cells causing destruction of myofibers in masticatory muscle myositis of dogs are lymphocytes, presumably recruited following binding of antibody. Lymphocytes may be admixed with plasma cells, and plasma cells may predominate in some cases. Macrophages will also be prominent in cases with marked myofiber necrosis. Fiber atrophy is common, and atrophic fibers can be seen associated with inflammation (Fig. 2.96) or with dense fibrosis.

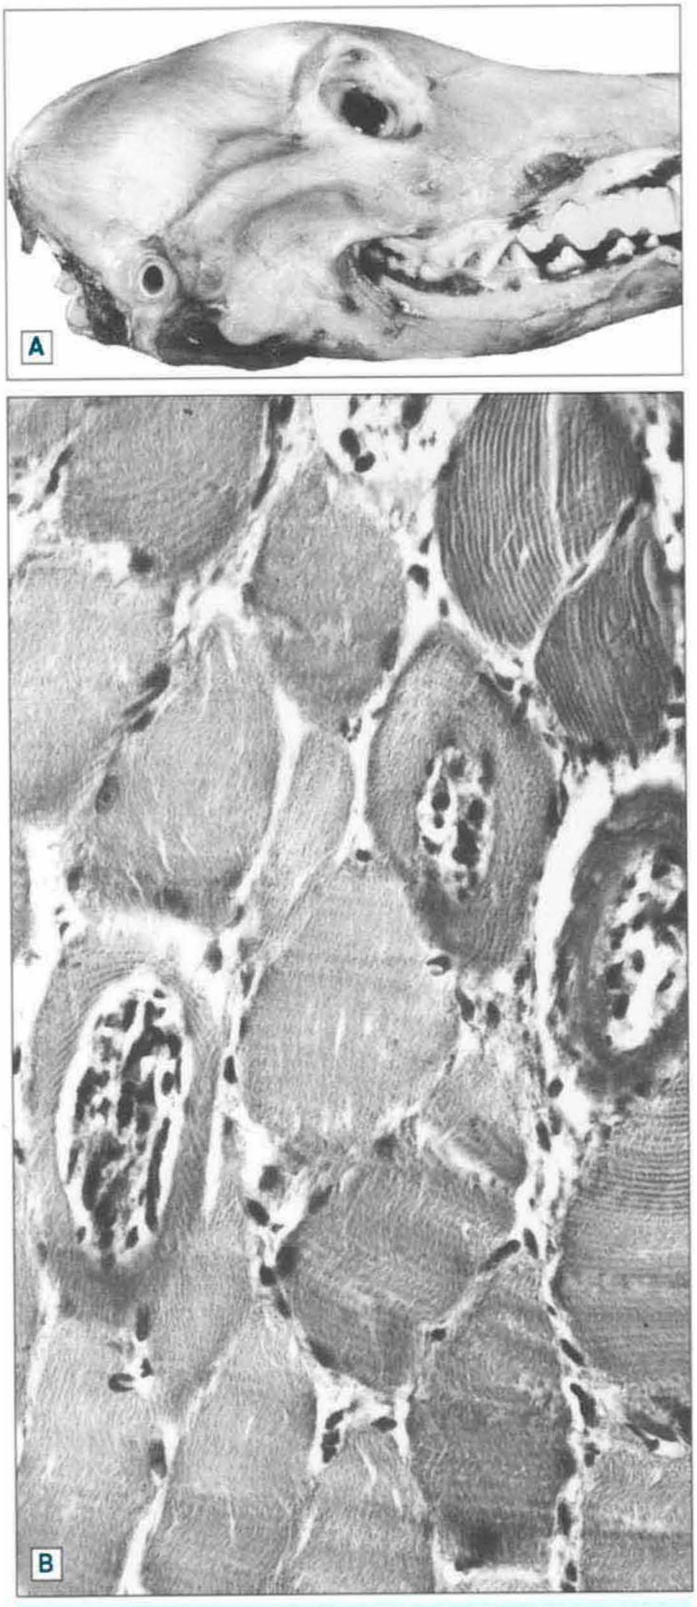

Figure 2.94 Chronic masticatory myositis in a dog. **A.** Severe atrophy of masticatory muscles. **B.** Multiple fibers being "cored out" by mononuclear inflammatory cells. (Courtesy of TJ Hulland.)

Histologic examination of muscle from suspect masticatory myositis dogs can often be frustrating. The inflammatory lesions are patchy in some cases, and biopsy may reveal only generalized fiber atrophy. *Any evidence of fiber degeneration or regeneration, even in the absence of obvious inflammation, should be considered suspicious if the clinical history is consistent with myositis.* Examination for evidence of endomysial and perimysial fibrosis is important, as severe fibrosis will negatively impact on the prognosis for return of full jaw mobility

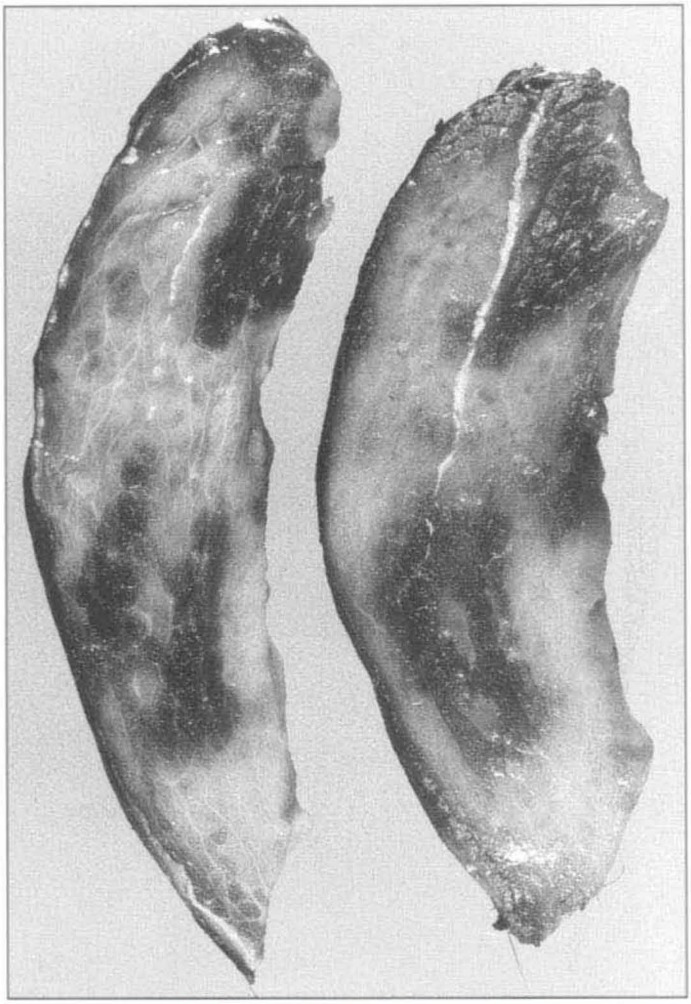

Figure 2.95 Large pale areas of fibrosis in temporal muscle from a dog with **chronic masticatory myositis**. (Courtesy of TJ Hulland.)

and muscle mass. Those cases with numerous inflammatory cells and minimal fibrosis are more likely to recover with corticosteroid therapy than cases in which inflammatory infiltrates are minimal and fibrosis is the predominant finding. An apparent increase in connective tissue may also occur due to loss of damaged myofibers and condensation of existing fibrous stroma.

The masticatory muscles of dogs, especially the temporal muscles, appear to be particularly prone to a variety of generalized myopathic and systemic disorders. Dogs with X-linked muscular dystrophy have prominent atrophy of the temporal muscle and are unable to fully open their mouths, although this condition is not painful. Labrador Retrievers with inherited myopathy also have prominent temporal muscle atrophy. Polymyositis (see below) may appear primarily as a problem with muscles of mastication, although careful evaluation will reveal abnormalities in other muscles. Dogs with any generalized illness often develop rapid atrophy of the temporal muscles that resolves with treatment for the primary problem. Persistent bilaterally symmetric atrophy of masticatory muscles not associated with pain, immobility of the jaw, or generalized disease also occurs in dogs. These latter cases of masticatory muscle atrophy appear to be idiopathic and are not associated with inflammation. If atrophy of

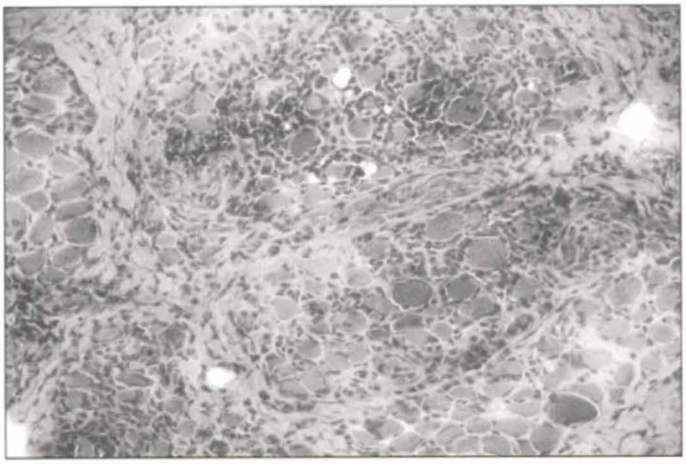

Figure 2.96 Masticatory myositis in the temporal muscle of a dog. Dense infiltrates of mononuclear inflammatory cells are admixed with atrophic and degenerating myofibers. Frozen section, modified Gomori's trichrome.

Polymyositis of dogs

Immune-mediated polymyositis occurs most commonly in dogs. Dogs with polymyositis may be presented with primary signs of masticatory muscle involvement, and both masticatory myositis and polymyositis should be considered in the differential diagnosis of such dogs. Testing for serum antibodies to type 2M myosin may be useful, as *most dogs with polymyositis do not have serum antibodies to 2M myosin.* It is possible, however, for nonspecific myosin antibodies to be found in the serum of dogs with polymyositis or other myopathies associated with myofiber necrosis. *Muscle fiber damage in polymyositis is mediated by T lymphocytes.*

Polymyositis occurs mostly commonly in *adult dogs of various breeds*, although large breeds are over-represented and German Shepherds may be predisposed. *A breed-associated polymyositis has been recognized in Newfoundlands* in which signs of muscle weakness may be apparent in dogs as young as 6 months of age. *Clinical signs of polymyositis are variable*, and include exercise intolerance, overall muscle weakness, stiff gait, and muscle atrophy. Muscle pain, elicited by deep muscle palpation, may be evident. Esophageal muscle involvement leads to regurgitation. Fever may also occur. Increase in serum activities of CK and AST is quite variable, and values may be within normal limits. Polymyositis may occur as part of the spectrum of disease in dogs with *systemic lupus erythematosus*, which is often accompanied by a positive anti-nuclear antibody (ANA) titer. Treatment with immunosuppressive doses of corticosteroids often results in resolution of signs, although if esophageal muscle fibrosis has occurred there will be persistent esophageal dysfunction.

Gross pathologic findings include mild to severe generalized muscle atrophy. In cases with esophageal involvement, *dilation of the esophagus may be evident.* Examination of multiple samples from different sites on the head and limbs may be necessary to detect inflammatory lesions. The disorder is *multifocal and polyphasic. The most common finding is of interstitial and perivascular lymphocytic infiltration in affected muscle. Invasion of otherwise intact skeletal muscle fibers by lymphocytes is*

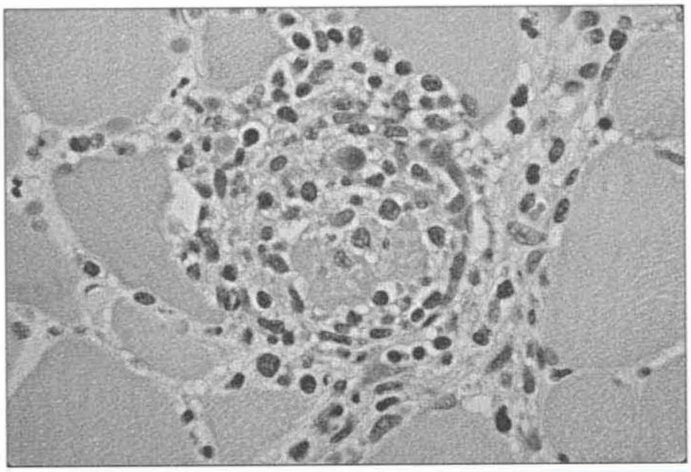

Figure 2.97 Polymyositis in a dog. Mononuclear inflammatory cells surround and invade myofibers causing necrosis. (Courtesy of BJ Cooper)

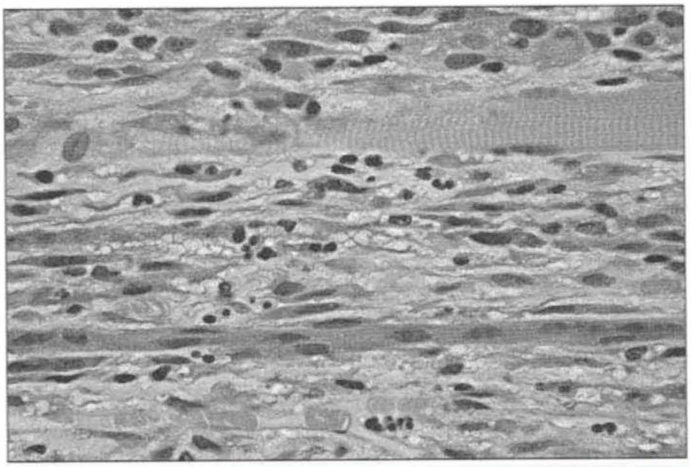

Figure 2.98 Polymyositis in a dog. There is a regenerating myotube as well as active inflammation consisting of eosinophils and mononuclear cells. (Courtesy of BJ Cooper)

characteristic (Fig. 2.97). Regenerating fibers as well as degenerating fibers are common (Fig. 2.98), and severe chronic disease may result in some degree of endomysial/perimysial fibrosis. Fibrosis may be most apparent in masticatory muscles and in the esophageal wall. Immunophenotypic studies have confirmed that, similar to polymyositis in humans, *invading lymphocytes in canine polymyositis are primarily cytotoxic (CD8+) T cells.* An admixture of inflammatory cells, however, including eosinophils and neutrophils, can be seen in particularly florid lesions.

Extraocular muscle myositis of dogs

A bilateral polymyositis involving only the **extraocular rectus and oblique muscles** *has been described in dogs.* The retractor bulbi and all other skeletal muscles are normal. Golden Retriever dogs appear to be predisposed. This disorder affects young to young-adult dogs, with age range of onset from about 6–18 months. *Clinical signs are of sudden onset of bilateral nonpainful exophthalmos.* Gross lesions of swelling and pallor can be seen within extraocular muscles. *Interstitial lymphocytic inflammatory cell infiltrates are associated with myofiber necrosis and regeneration in a multifocal polyphasic pattern.* Given the localization within extraocular muscles, an immune-mediated disorder directed at a unique epitope within these muscles is suspected. Corticosteroid therapy is usually curative, which supports an immune-mediated basis for this disorder.

Polymyositis of cats

Most reported cases of polymyositis in cats have instead proved to be degenerative polymyopathy due to hypokalemia. A lymphocytic polymyositis associated with retroviral disease has been identified in adult cats experimentally infected with *Feline immunodeficiency virus* (FIV). Clinical signs of neuromuscular dysfunction are not apparent, but serum activity of CK is moderately increased. Inflammation has the typical interstitial and perivascular pattern of immune-mediated myositis. Infiltration of muscle and myofiber necrosis of multiple muscles is mediated by cytotoxic CD8+ T lymphocytes. Other lymphocyte subsets are not found. Pelvic limb musculature is more commonly affected than thoracic limb muscles. This disorder in cats is similar to HIV-associated polymyositis in people and SIV-associated polymyositis in monkeys. A severe chronic polymyositis associated with progressive weakness and muscle atrophy has been reported in a captive Bengal tiger. Histopathologic evidence of a multifocal and polyphasic myositis characterized by interstitial infiltrates of lymphocytes and invasion of intact myofibers by mononuclear cells typical of polymyositis were seen. As this case occurred prior to the recognition of FIV infection in cats, it is tempting to speculate that this may also have been viral-associated.

Immune-mediated myositis of horses

Although exertional and postanesthetic myopathies in horses are often called "myositis," this term is not appropriate for these conditions. These disorders are degenerative myopathies and are not primary inflammatory conditions.

Hemorrhagic necrosis of muscle due to vascular injury occurs in horses with immune-complex disease due to *Streptococcus equi*-associated *purpura hemorrhagica.* In some cases, the involvement of skeletal muscle is severe enough for neuromuscular dysfunction to be the primary presenting sign. Affected horses typically have markedly increased serum activities of CK and AST associated with muscle weakness and pain. Dependent edema can also be seen. *Hemorrhagic infarcts can be found within affected muscles, and fibrinoid necrosis of vascular walls and vasculitis are seen in tissue sections* (Fig. 2.99). Inflammatory infiltrates are not seen except at the periphery of necrotic zones. Infarcts in other organs, such as lung and intestine, are common. *Streptococcus equi* can often be isolated from lymph nodes or guttural pouches. Immune complexes in purpura hemorrhagica are composed of IgA and streptococcal M protein.

Another syndrome of degenerative myopathy and rapid muscle atrophy occurs in young to young-adult Quarter Horses following exposure to *Streptococcus equi.* Skeletal muscle appears to be the only tissue affected in these horses. The cause is not yet known, although cross-reacting antibodies to streptococci affecting skeletal muscle myosin have been proposed.

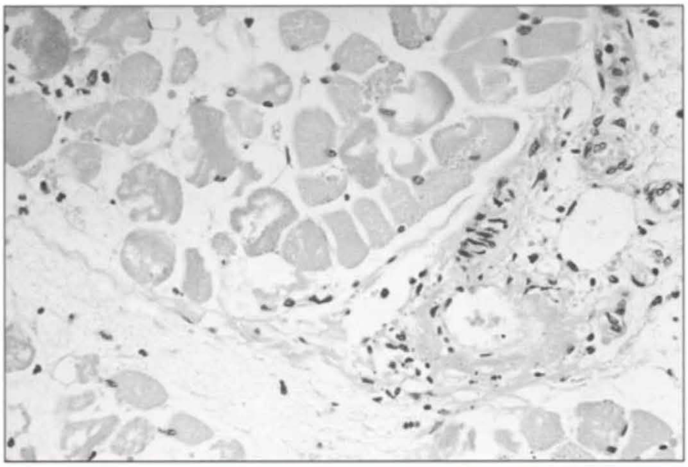

Figure 2.99 *Streptococcus equi*-associated **purpura hemorrhagica** involving skeletal muscle. Acute myofiber necrosis is associated with fibrinoid necrosis of the wall of an interstitial blood vessel. (From McGavin MD, Zachary JF. Pathologic Basis of Veterinary Disease. 2006. with permission of Elsevier Ltd.)

Acquired myasthenia gravis

Two clearly defined types of myasthenia gravis occur in dogs and cats. The *congenital disease* is due to abnormal neuromuscular junction formation and is discussed in the section on Congenital myasthenia gravis. The *acquired disease* occurs when circulating antibodies to motor end plate acetylcholine receptors bind and form immune complexes at the neuromuscular junction. The cross-linking of bound antibodies leads to increased endocytosis of acetylcholine receptors and therefore reduction in receptor density.

As in people, a link between thymic abnormalities and development of acquired myasthenia gravis occurs in dogs and cats. *Thymic follicular hyperplasia or thymoma is associated with development of myasthenia gravis in people, and thymoma is associated with myasthenia gravis in dogs and cats.* The normal thymus contains myoid cells that express muscle proteins and acetylcholine receptors. The presence of these cells is thought to be important for induction of self-recognition of these proteins. Myoid cells are readily seen by light microscopy in the thymus of neonatal or late-term aborted ruminants. Myoid cells occur in the thymic medulla and consist of large round cells with central euchromatic nuclei and abundant eosinophilic cytoplasm. These cells are scattered amongst the epithelial cells of Hassall's corpuscles, and will be found to express muscle actin and myoglobin with immunocytochemical procedures. It is thought that abnormal immune regulation occurs due to thymoma. Removal of the thymic mass often results in resolution of signs of thymoma-induced myasthenia gravis.

Acquired myasthenia gravis in dogs has also been *associated with concurrent hypothyroidism*, and sporadic cases have occurred apparently *associated with malignant neoplasia*. In most cases, myasthenia gravis occurs unassociated with an underlying neoplastic or systemic disease process.

Three clinical forms of acquired myasthenia gravis are recognized in dogs.

- The classic form is the *generalized form*, in which episodic weakness, primarily of appendicular muscles, leads to exercise-induced collapse. Signs of weakness are alleviated by rest. Generalized myasthenia may also appear as selective and persistent weakness primarily of pelvic limbs. Megaesophagus is common in generalized myasthenia gravis in dogs.
- A *localized form* with selective involvement of esophageal, facial, and pharyngeal muscle leads to megaesophagus and regurgitation without generalized weakness.
- The third form is a *fulminating form* in which rapid development of sustained generalized weakness occurs.

Only generalized myasthenia gravis has been described in the *cat*. Breeds at risk for development of acquired myasthenia gravis include German Shepherds, Golden Retrievers, Akitas, terrier breeds, German Shorthaired Pointers and Chihuahuas. An inherited predisposition to myasthenia gravis has been described in Newfoundland dogs. A bimodal age distribution occurs in dogs, with peak incidences of acquired myasthenia gravis occurring at about 3 years of age and at about 10 years of age. There does not appear to be a sex predisposition in dogs. A generalized form of myasthenia gravis occurs in cats, and Abyssinian cats may be predisposed.

Diagnosis of myasthenia gravis can be made in many cases with *electrodiagnostic testing* of repetitive nerve stimulation response, in which a decremental response in the compound motor action potential is demonstrated. A positive response to anticholinesterase therapy (edrophonium) is also considered diagnostic. *Detection of circulating anti-acetylcholine receptor antibodies is considered the most definitive test.*

Abnormalities are not seen in muscle or peripheral nerves by light microscopy, but immune complexes can be detected at neuromuscular junctions using immunocytochemical procedures. Reduction in acetylcholine receptor density due to increased internalization of receptors can be demonstrated with specialized techniques such as bungarotoxin binding assay. Alteration in morphology of synaptic clefts is seen on ultrastructural examination. Dogs with associated megaesophagus often have concurrent aspiration pneumonia.

To date, thymic follicular hyperplasia has not been described as a cause of myasthenia gravis in animals. Thymoma can be associated with either the generalized form or the fulminant form of myasthenia gravis in dogs, and with generalized myasthenia gravis in cats.

MYOSITIS

Myositis means inflammation of muscle, but it is often difficult to determine whether the process is part of a classical inflammatory response that happens to be active in muscle or whether some components of inflammation are activated by a process that is primarily degenerative. The cause of myositis is often not evident except in the obvious cases in which the inflammatory nature of the reaction is signaled by a suppurative or granulomatous response or where it is a component of a systemic infectious disease, such as *Bluetongue virus* infection in sheep, foot and mouth disease, and toxoplasmosis (see Vol. 2, Alimentary system).

Infectious agents and parasites are frequently the cause of mild myopathy (as distinct from myositis) in animals, in which case, the degenerative muscle changes are an almost incidental and often unnoticed part of systemic infection or toxemia. There are, however, some systemic and local infections that cause myositis rather than myopathy, and they will be considered here. *Living muscle is an inhospitable site for almost all bacteria*, and consequently myositis is rarely a complication of bacterial infections even when they are overwhelmingly septicemic or repeatedly bacteremic. Pyogenic organisms sometimes give rise to solitary muscle abscesses, particularly in pigs and goats, but *bacterial polymyositis is a feature of only a few infections*, such as *Histophilus somni* in lambs and cattle, and *Actinobacillus equuli* in foals. *Clostridium* spp., on the other hand, are very well adapted to growing in muscle once damage to muscle fibers provides them with an opportunity.

Other diseases of muscle with an inflammatory response are presented under immune-mediated conditions and include several canine conditions (masticatory myositis, extraocular muscle myositis, polymyositis) and an equine disease (purpura hemorrhagica).

Suppurative myositis

Abscesses in muscle may sometimes be hematogenous in origin, but more often they result from *inoculation* (penetrating wound, contaminated injection, contamination of surgical site or laceration), or by *extension from a suppurative focus* in adjacent structures, such as joints, tendon sheaths, or lymph nodes. The most common causes of abscesses in muscle are *Arcanobacterium* (*Actinomyces, Corynebacterium*) *pyogenes* in cattle and swine, *Corynebacterium pseudotuberculosis* in sheep, goats, and horses, and *Streptococcus equi* in horses. A variety of streptococci and staphylococci are retrieved from such lesions in many species.

The natural development of suppurative myositis is comparable to abscessation elsewhere. The early stage consists of *local, ill-defined, cellulitis*. Healing may take place after this with a minimum of scarring, or it may proceed to the formation of a *typical abscess with a liquefied center, a pyogenic membrane, and an outer fibrous sheath* (Fig. 2.100). The lesion may slowly organize if it is effectively sterilized, expand if it is not or, alternatively, fistulate to the surface, collapse, and heal. In the healing process, damaged muscle fibers will participate in fiber regeneration to only a very limited extent.

In cats and horses particularly, the early stage of local cellulitis may give rise to a rapidly expanding cellulitis of muscle and adjacent fibrous and fat tissue. This phlegmonous inflammation leads to extensive destruction of muscle fibers that are subsequently mostly replaced by scar tissue. The organisms involved may vary, but *Pasteurella multocida* has been incriminated in cats, while staphylococci appear to be the most common in other domestic species. Acute cellulitis and myositis may occur in *Haemophilus parasuis* infection (Glasser's disease) in swine.

Malignant edema (gas gangrene)

The muscles, especially if devitalized in some manner, are highly susceptible to bacteria of the genus Clostridium, and these organisms, when they proliferate, are highly toxigenic and cause extensive necrosis of muscle, with blood-stained edema and the formation of gas. Once the bacteria become established, the toxins they elaborate provide a suitable and expanding environment for further bacterial growth. Death occurs as a result of *systemic intoxication*.

These bacteria are gram-positive bacilli, to a greater or lesser degree anaerobic, and they exist in the environment as resistant spores. Germination of the spores and vegetative growth requires

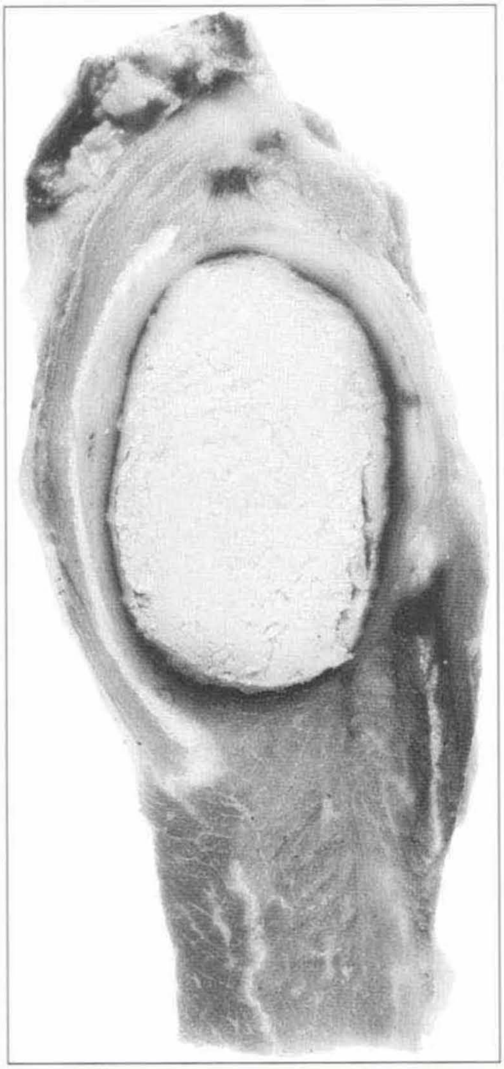

Figure 2.100 Abscess in the gluteal muscles of a goat. (Courtesy of W Hadlow.)

fairly precise local conditions, chiefly a low oxidation-reduction potential and an alkaline pH. These conditions are best produced by deep penetrating wounds and the lesions that result from the activity of the anaerobes are called "*malignant edema*," "*gas gangrene*," and "*anaerobic cellulitis*." Since the pathogenic clostridia are frequently found in soil and feces, *any contamination of an open wound is likely to introduce those potential pathogens*. Although their presence in a wound always carries a threat of gas gangrene, the very great majority of wounds thus infected heal without ill effect; in these, the local conditions in the wound must be regarded as unsuitable for germination, vegetation, or the production of toxins.

The species of the genus *Clostridium* that are of most importance as the agents of gas gangrene are *C. septicum*, *C. perfringens*, *C. novyi*, and *C. chauvoei*. These organisms not only cause gas gangrene, which is usually a mixed infection, but in animals they are, as pure infections, responsible for a number of specific diseases that are not associated with surface wounding and, with one exception, not associated with primary lesions in muscle. The exception is *C. chauvoei, which* causes bacterial myositis – *blackleg* – in ruminants. The other specific diseases include *black disease* caused by *C. novyi* (see Vol. 2, Liver and biliary system), *braxy* caused by *C. septicum*, and the *clostridial enterotoxemias* caused by *C. perfringens* (see Vol. 2, Alimentary system).

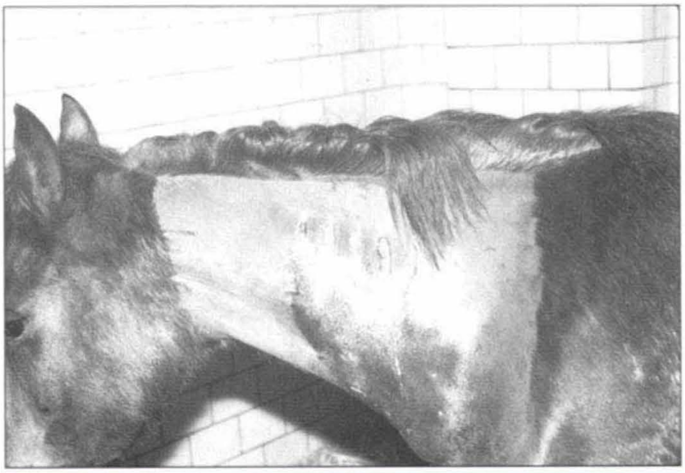

Figure 2.101 Subcutaneous swelling over neck due to **clostridial myositis** in a horse. (Courtesy of W Rebhun.)

Gas gangrene and malignant edema are essentially wound infections in which *C. septicum*, *C. perfringens*, *C. novyi*, *C. sordelli*, and *C. chauvoei* are the principal pathogens acting alone, or in combination with each other or with a variety of other aerobes and anaerobes, the latter being saprophytes with proteolytic and putrefactive properties. *Ruminants, horses, and swine are highly susceptible to these infections*, whereas carnivores are rarely affected with gas gangrene. Since deep wounds are the ones most suitable to the development of gas gangrene, the common causes of such susceptible wounds in animals are castration, shearing, penetrating stake wounds, injuries to the female genitalia during parturition and, especially in swine, inoculation sites. The distinctive characteristics of these local infections are *severe edema* (Fig. 2.101), the formation of *gas bubbles* that give crepitation, *discoloration* of the overlying skin, *coldness* of the affected part, and, in particular, the constitutional signs of *profound toxemia* with prostration, circulatory collapse, and sudden death.

Malignant edema is included in this title to distinguish certain cases of clostridial myositis of which gas gangrene is not a part; indeed, in animals, the non-gangrenous form of clostridial myositis is much more common than is the gangrenous form. *Malignant edema is more typically a cellulitis than a myositis*, and the muscles may escape significant injury even in fulminating, highly toxigenic infections of the sort that are fatal in 48 h. All of the factors that determine whether gangrene develops in these infections are not known. Even when the primary pathogens present are the same, the relative potencies and the amounts of the toxins produced may vary, and it is expected that accompanying nonprimary organisms will, to some extent, influence the local course of the infection. One factor that is probably of much importance in determining whether the inflammation will be confined to the connective tissues (malignant edema) or will directly involve muscle (myositis) is the adequacy of the blood supply to the muscle. If the muscle is devitalized by the initial trauma, or subsequently as a result of toxic injury to the blood vessels, the development of true gangrene is in order; in this manner, *malignant edema or anaerobic cellulitis may develop into gangrene.*

The pathogenesis of clostridial myositis and cellulitis is obviously not simple and is not initiated merely by the presence of spores or vegetative forms in the wound; it may begin only when the organisms have produced enough toxin to immobilize and destroy any adjacent leukocytes and enough toxin to cause death of tissue. Once the bacteria are established and producing toxins, they are capable of creating spreading conditions suitable for their advance. The progression is longitudinal, up and down fascial planes; transverse progression is very limited. The spread is facilitated by increased capillary permeability, the edema fluid separating the muscle fibers and fascia, assisted in this by gas bubbles (Fig. 2.102). This fluid also allows for further diffusion of the toxins and spread of the bacteria. Venous and capillary thrombosis result in local circulatory disturbances and these, in turn, result in further devitalization of tissue. *Once the process is started, it may progress with extraordinary rapidity*. If clostridial myositis is to develop in a wound, there is usually evidence of it within 24 hours.

In gas gangrene, there is extensive disintegration of muscle and saturation of the tissues with exudate that is in part serous and in part profusely sanguineous. When lysis of exuded red cells occurs, the tissues become stained darkly with hemoglobin. The tissues have a rancid odor in the beginning and an exceedingly foul odor in the end.

Histologically, *edema fluid*, poor in protein, separates the muscle fibers from each other and the endomysium. The *degenerating muscle fibers* stain intensely with eosin, the sarcolemma and its nuclei degenerate, but the striations are unduly persistent. Such a histologic picture is always seen at the advancing margin of the lesion. *Neutrophils are never numerous*; a few are loosely scattered at the advancing margin of the lesion and slightly greater numbers in the dermis, but they are rapidly and effectively immobilized and destroyed by the toxins. Deeper within the lesions, muscle fibers are fragmented, but this is probably an indication of physical forces having been applied to necrotic fiber segments at a stage in which the animal is still mobile. Fragmentation is by no means a constant feature of gas gangrene and the absence of it at the periphery of lesions indicates only that, in the later stages of the disease, muscle activity is drastically reduced in a recumbent animal. *Bacteria are seldom numerous in the lesions*, but collections of them may be seen either in muscle fibers or in connective tissue. Involvement of adjacent adipose tissue by the necrotizing process liberates fat droplets that may become embolic.

It is not uncommon for animals to die within 24 h of the onset of local signs of gas gangrene. Invasion, sometimes massive, of the bloodstream occurs shortly before death, or shortly after, and the offending organisms can then be obtained from most tissues. As well as the local lesion, there is at postmortem *severe pulmonary congestion* and evidence of *profound toxic degeneration of the parenchymatous organs*. By very few hours postmortem, there is extensive gas formation in all organs and they crepitate. The liver, especially, may be honey-combed with bubbles, and cut blood vessels continuously release gas bubbles.

There are some variations in the gross appearance of the lesion depending on the species of the principal pathogen. *Putrefaction is the property of contaminating saprophytes* since the primary pathogens are poorly endowed in this regard; the latter are, however, saccharolytic and that is the origin of the *gas bubbles* in the lesions. The exotoxin of *C. novyi* has a rather specific action on vascular endothelium and serous membranes, and relatively pure infections with this organism produce very extensive edematous infiltration of connective tissues. There is no putrefaction, only slight or no discoloration of muscle, and the gelatinous edema fluid is quite clear or at most pink. The toxic potency of this organism is shown by the fact that in fatal infections the organisms are so few as to be difficult to locate even in the primary focus, from which site they show little inclination to move.

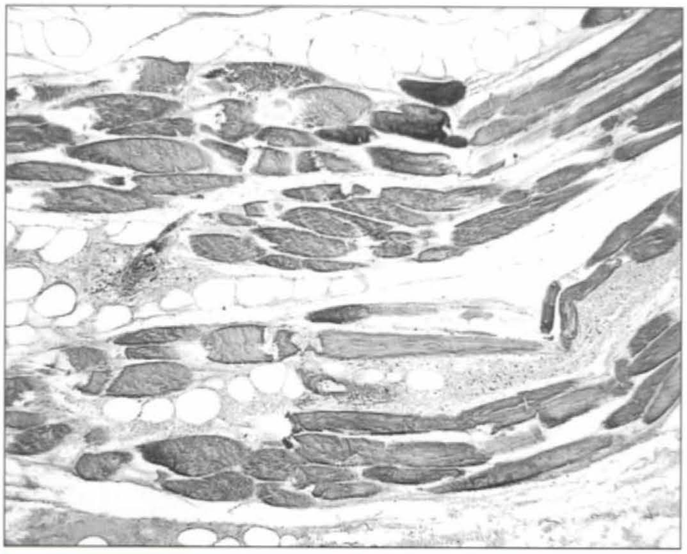

Figure 2.102 Lysed red blood cells and gas bubbles in sublingual muscle in **malignant edema** in a cow. (Courtesy of W Hadlow.)

A typical wound infection by *C. novyi* is that known as "**swelled head**" in rams, the wounds being acquired on the top of the head during fighting. This is a quickly fatal condition, death usually occurring within 48 h. There is extensive infiltration with clear, gelatinous fluid in the tissues of the head, throat, neck, and cranial thorax and sometimes also in the pleural and pericardial sacs. There is no discoloration of muscle and no, or scant, extravasation of erythrocytes. The bacilli are very few in number and cultivable only from the primary focus of infection. *Clostridium novyi* may also predominate in wound infections of horses and, when it does, these lesions too are a nonhemorrhagic variety of malignant edema. *Clostridium chauvoei* as a wound infection always produces heavily sanguineous edema fluid and much gas. *Clostridium septicum* produces large quantities of gelatinous exudate, which is, however, intensely stained with blood. The muscular tissue may be discolored dark red-to-black and, although gas is present, the bubbles are very small. Dark blood exudes freely from veins in the perimysium, and hemoglobin stains narrow collars of surrounding tissue at the margin of the lesions. *Clostridium perfringens* is the usual cause of gas gangrene in man and produces similar lesions in animals. It shows much less tendency than *C. chauvoei* and *C. septicum* to invade the bloodstream terminally or after death. The most frequent cause of malignant edema is *C. septicum*.

Blackleg

Blackleg, also known as black quarter and emphysematous gangrene, is a gangrenous myositis of ruminants caused by C. chauvoei and characterized by the activation of latent spores in muscle. This definition of blackleg separates it from gas gangrene in which, if *C. chauvoei* is involved, it is as a wound contaminant.

Blackleg can sometimes be mimicked closely by the syndrome known as "stable blackleg" or "pseudo-blackleg" caused similarly by germination of latent spores of *C. septicum* in cattle. For diagnostic, prognostic, and epidemiologic reasons, it is important to make a distinction between disease of the blackleg pattern of pathogenesis and disease of the much less complex pathogenesis of gas gangrene and malignant edema. The latter diseases occur sporadically wherever cattle and sheep are raised but appear as a confined outbreak only when groups of animals have been subjected to similar traumatic procedures such as shearing wounds or intramuscular injections. *Blackleg on the other hand is, in spite of a worldwide distribution, peculiarly localized to regions, and within regions to farms.* Within these locales, it is persistently but irregularly enzootic, but rather selective of its hosts, and controllable only by vaccination. *The muscle lesion produced is not distinctive for the blackleg pathogenesis*, nor is the presence of *C. chauvoei* in a typical gangrenous lesion, because *C. chauvoei* can also be a wound contaminant. Identification of the blackleg syndrome should be made on a freshly dead cadaver or preferably on more than one in an outbreak. In the confirmation of blackleg and of pseudo-blackleg particularly, attempts at distinguishing syndromes must be tempered by the knowledge that *C. septicum proliferates rapidly after death while C. chauvoei does not.* The probability of overgrowth is great when a few hours have elapsed between death and bacteriological examination.

Blackleg occurs most often in cattle and sheep and rarely in other domestic animals. Blackleg in **cattle** primarily affects animals 9 months to 2 years of age with a reduced incidence at 6–9 months and 2–3 years, and an even lower incidence in animals over 3 years of age. It affects animals in good condition, and often selectively causes death in the best-grown or best-fattened animals in a group. *Blackleg is chiefly a disease of pastured animals with a tendency to be seasonal in summer.* It is often associated with moist pastures and rapid growth of both forage and cattle, but it is also a problem on some arid ranges. Because the source of *C. chauvoei* organisms appears to be persistent on certain fields, *it has been assumed that the organism is soilborne*, but it is unlikely that it grows in soil. Growth does take place readily in the intestinal tract of cattle, and it is now thought that soil contamination persists by a process of constant replenishment by fecal contamination.

The detailed pathogenesis of blackleg is still somewhat uncertain, but many of the critical points in the following proposed sequence of events have been confirmed in the natural disease and in experimental infections in cattle. *The infection is acquired by the ingestion of spores*, and either these spores, or spores produced following one or more germinative cycles in the gut, are taken across the intestinal mucosa in some way. Macrophages may be responsible for this passage, but it may be possible for the spores to enter natural or transient apertures at tips of villi or in lymphoid crypts or be taken in by lymphoepithelial cells of the ileal domes by endocytosis. *Spores are distributed to tissues where they may be stored for long periods in phagocytic cells.* There may be a certain dynamic turnover, for example in and out of Kupffer cells in the liver, but spores can be found in many tissues of normal animals, including muscle. *The latent spores in muscle are stimulated to germinate when a local event creates muscle damage or low oxygen tension.* This last step is difficult to produce experimentally, but circumstantial evidence seems to confirm its inclusion in the sequence. Parallels exist in other clostridial diseases about which there is much less doubt. It may be that all that is required to establish a medium for the organisms to multiply is a small intramuscular hemorrhage or a degenerative focus initiated by traumatic damage to muscle as part of forced exercise.

The clinical manifestations of blackleg are often not observed and because of the rapid clinical course, *animals are often found dead.* When animals are seen ill, signs consist of lameness, swelling, and crepitation of the skin over a thigh or shoulder if the lesion is superficial, and fever. It is typical for swellings to increase rapidly in size and to be hot initially and cold later. Affected animals subsequently show depression and circulatory collapse. *Death rapidly ensues and seldom does an animal survive more than 24–36 h after the onset of any signs of lameness.* If the muscle lesions are deep within a muscle mass or in the diaphragm, no localizing signs may be evident and no palpable changes detectable. Similarly, lesions in the tongue, heart or sublumbar muscles may escape clinical detection.

An animal that has died of blackleg swells and bloats rapidly, but on incision it is often not as putrid as its external appearance would suggest. Blood-stained froth flows from the nose but not usually from other orifices. Blotchy hemorrhages may be present on the conjunctivae. A poorly circumscribed swelling may be visible on superficial inspection and crepitation detectable on palpation. The skin overlying crepitant swellings is taut and resonant, but normal or dark in color and of normal strength. The subcutaneous tissues and fascia around the lesion are thick with yellow gelatinous fluid that is copiously blood-stained close to the lesion. Gas bubbles may be apparent in the fluid. The affected muscles present slightly different appearances at different distances from the center of the lesion. *Towards the periphery of the lesion, the muscle is dark red, and moist with edema fluid* (Fig. 2.103). *Towards the center, it is red-black, occasionally with putty-colored islands, and the tissue is dry, friable, and porous where gas bubbles separate the primary bundles of fibers* (Fig. 2.104A, B). If this tissue is squeezed, it crepitates and a small amount of thin red fluid oozes out. When the tissue is exposed to air, it takes on a light red

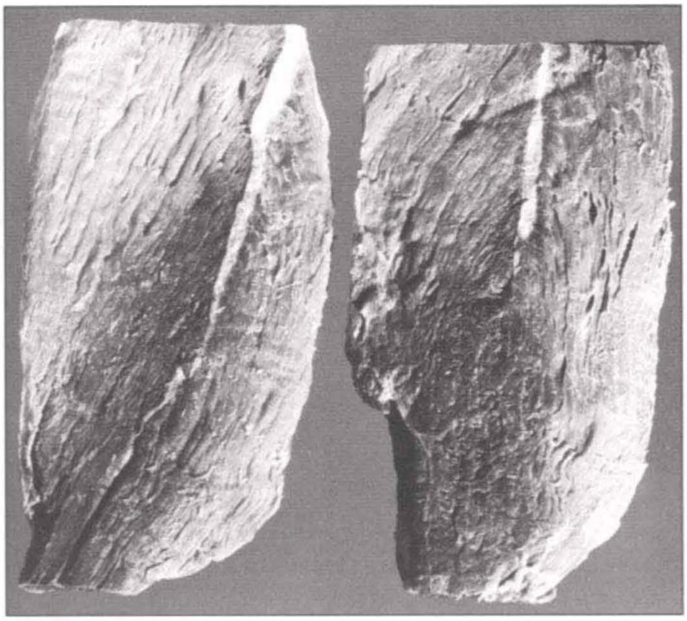

Figure 2.103 Dark areas of hemorrhage on cut surface of muscles in **blackleg** in a calf. (Courtesy of W Hadlow.)

color and watery exudate drips from cut surfaces. *The odor which emanates from the muscle is sweet and butyric, like rancid butter.*

The initial bacterial lesion in blackleg is cellulitis with copious edema and hemorrhage. Degeneration of the muscle fibers is caused by both diffusing toxin and injury to blood vessels; the extent of ischemic muscle fiber death probably determines how quickly and how extensively tissue gangrene extends through the muscle. Gangrenous lesions expand longitudinally with the long axis of muscles more readily than in a lateral direction, but "skip" areas may create necrotic zones that are highly irregular in contour. The expansion is enhanced by the edema fluid between fibers. At the time of death, animals with a single muscle lesion may have relatively small or very large areas of gangrene. Gas is not produced until muscle fibers die and are penetrated by bacteria and toxins. *The exudate and gas bubbles separate bundles of fibers and individual fibers and these undergo necrosis with preservation of striations in the center of the focus, and fatty and granular degeneration towards the periphery* (Figs 2.105, 2.106). Leukocytes are sparse, being destroyed by diffusing toxins, and only a scattering of debris is found at the periphery of the lesion.

The lesions of blackleg are usually found in the large muscles of the pectoral and pelvic girdles, but they may be found in any striated muscle including

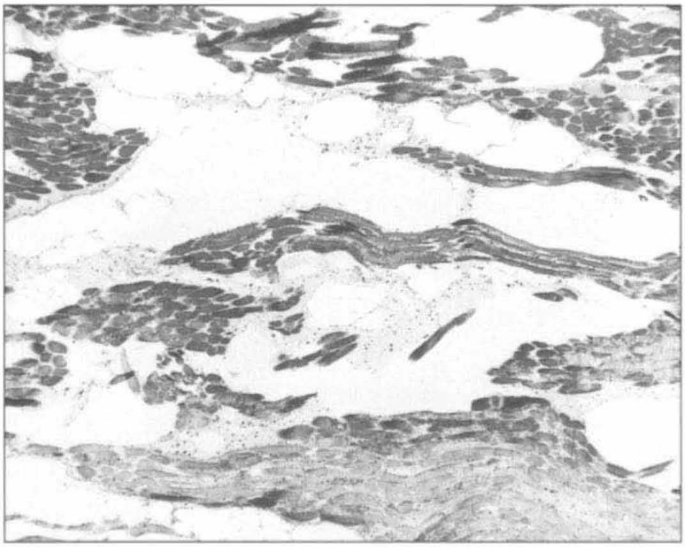

Figure 2.105 Gas bubbles in muscle in **blackleg** in a cow. (Courtesy of W Hadlow.)

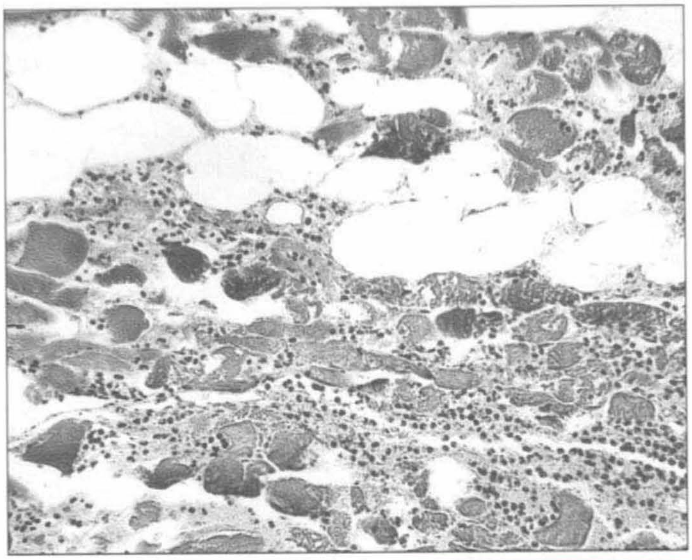

Figure 2.106 Necrosis of myofibers, neutrophilic infiltrate, and gas bubbles in **blackleg** in a cow. (Courtesy of W Hadlow.)

the myocardium. Lesions in the crura of the diaphragm and in the tongue are quite common, and if lesions are present in two or three sites simultaneously, they may be lethal before any of them is very large. This makes their clinical detection more difficult, and their detection at postmortem dependent on detailed examination of many muscles. Even with small widely separated lesions, however, the rancid butter odor may be pervasive.

In addition to the specific muscle lesions of blackleg, changes are present in the rest of the carcass. *There is severe parenchymatous degeneration of liver, kidney, and endocrine glands*, and while this is like conventional postmortem change, the rapidity of its development can suggest blackleg-related toxemia or bacteremia. There is often *fibrinohemorrhagic pleuritis* and, as a generality, when this lesion is present without severe pneumonia, blackleg should be suspected. The parietal pleura is hemorrhagic, and large or delicate blood-stained clots of fibrin overlie the ventral mediastinum and epicardium. Pneumonia is not part of the intrathoracic lesion, but the lungs are congested, and they may be quite edematous. The myocardium may be pale and friable, or dark red; some of the latter areas contain foci of *emphysematous myocarditis and necrosis*. It is these areas that give rise to fibrinohemorrhagic pericarditis; they may be primary or metastatic blackleg lesions. Endocardial lesions sometimes occur, particularly in young animals. The endocardium is hemorrhagic and may be ulcerated or contain built-up fixed, endocardial thrombi in the atrium or on the outer wall of the right ventricle. If there is atrioventricular valve involvement, it is usually on the right side. The peritoneum is intact and normal unless an underlying myositis has extended to it. The spleen may be normal, or enlarged with congested, mushy, pulp. Pale round foci of early putrefactive necrosis may be found in the liver and kidney without reaction; these enlarge with the postmortem interval and become porous. Organisms can often be recovered from many organs and from the blood shortly after death.

Blackleg in **sheep** closely resembles the disease in cattle and the causative organism is the same. *The disease in sheep, however, is much less common than in cattle*, and, although there is some overlap in enzootic distribution, *the disease in sheep usually occurs in locales quite apart from those where it occurs in cattle*. The clinical signs are similar to those in cattle except that crepitation may not be palpable during life, and there is usually dark discoloration of the overlying skin. The lesions resemble those in cattle, but there are usually fewer gas bubbles, and the muscle remains more moist.

Pseudo-blackleg

Pseudo-blackleg mimics blackleg very closely. This disease of cattle produces lesions, which are deep, like those of blackleg. A *diagnosis* of pseudo-blackleg can only be made when there is no detectable wound, the lesion is deeply located, and *C. septicum* is demonstrated in the lesions of a carcass examined immediately after death. This latter precaution is necessary to avoid, as far as possible, misdiagnosis based on the postmortem invasion of *C. septicum* and other organisms from the alimentary tract.

The lesions of pseudo-blackleg differ quantitatively and somewhat qualitatively, from those of blackleg. They tend to be multiple in widely separated muscles. There is very extensive blood-stained gelatinous exudate in the connective tissues, and this exudate contains only occasional small gas bubbles. The lesions may become confluent as very large patches throughout the connective tissues. By contrast, *the muscle lesions, although always present, are less extensive than in blackleg*. The muscles are dark red and moist, and only after examination by multiple incisions is the lack of a distinct primary focus evident. When bubbles of gas are present in necrotic muscle, they are smaller and not as numerous as they are in blackleg.

Pseudo-blackleg is reported in *pigs* in which the muscle lesions are part of a generalized body invasion by *C. septicum* organisms following entry via a primary gastric focus.

Specific infectious diseases with muscle alterations

Muscle lesions are specific findings in *foot-and-mouth disease* of calves (see Vol. 2, Alimentary system), *bluetongue* of sheep (see Vol. 2, Alimentary system), *Teschen disease* of swine, *Coxsackie virus infections* in suckling mice, and leptospirosis (*Leptospira icterohaemorrhagiae*) of dogs. In 5–10% of calves affected with foot-and-mouth disease, pale areas with or without white streaks of mineralization are present (Fig. 2.107) and represent areas of hyaline degeneration histologically. Myocarditis may also be found in calves. Sheep with bluetongue may have scattered small hemorrhagic lesions in skeletal muscle. Microscopic findings are hyaline degeneration, vasculitis, and hemorrhage.

Granulomatous lesions

Various diseases discussed elsewhere may also display granulomatous lesions in skeletal muscle. *Actinobacillosis* ("wooden tongue" in cattle) (see Vol. 2, Alimentary system), *actinomycosis* ("lumpy jaw in cattle") (see Vol. 1, Bones and joints), and *tuberculosis* (see Vol. 3, Hematopoietic system) are examples.

Beef cattle given injections of oil-adjuvant bacterins into paravertebral muscles may develop pyogranulomatous myositis with extension into the vertebral canal. Affected cattle showed lameness and paraparesis.

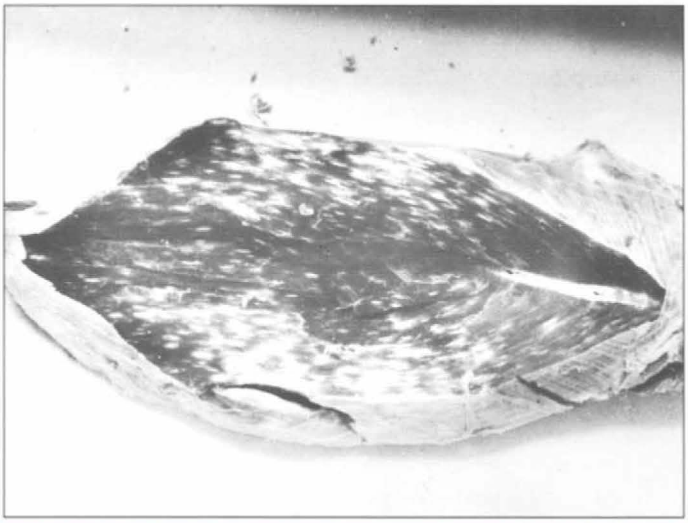

Figure 2.107 Disseminated pale areas of myonecrosis in **foot-and-mouth disease** in a calf. (Courtesy of W Hadlow.)

Other diseases with granulomatous lesions in skeletal muscle are *botryomycosis* and *Roeckl's granuloma* described in detail below.

Staphylococcal granuloma

Chronic granulomas of muscle or connective tissue caused by staphylococci, and referred to as **botryomycosis** in early literature, are much less common than they once were, but they still occur, particularly in the *horse and pig*. They represent a persistent, low-grade infection by *Staphylococcus aureus,* but it is not clear why the same organism at other times produces a conventional abscess or a gangrenous phlegmon. In horses, lesions are most frequent on the neck and pectoral region ("breast boils"), while in the pig, castration wounds and the mammary glands are the most common sites.

The lesion begins as a microabscess around a small colony of organisms and progresses rapidly, sometimes to a very large size. The *fully formed granuloma* is a hard, nodular, gray-white mass of dense, fibrous tissue, irregularly cavitated by small abscesses. The abscesses may be joined by tracts or they may fistulate to the surface. They contain a small quantity of thick, orange-yellow pus, which in turn contains minute granules. The granules consist of a central colony of the organisms while the bulk of the granule mass is made up of "clubs" of reactive protein material; hence the *typical club colony of botryomycosis*. Histologically, the organisms are readily visible in tissues since they stain with hematoxylin and are relatively large. Variable numbers of neutrophils, lymphocytes, and plasma cells are present in the loose fibrous tissue outside of the club colony. Muscle is involved at the periphery of the expanding granulomatous lesion where fibrous septa surround fibers causing atrophy and segmental degeneration.

Roeckl's granuloma of cattle

This nodular lesion of skeletal muscle is apparently specific for cattle, and it may be associated with similar lesions in liver, lungs, lymph nodes, and testes. The lesion is sometimes referred to as "*nodular necrosis*," and it is well known in Europe but rare elsewhere. Included in the list of suggested causes are tuberculosis, pseudotuberculosis, sarcocystosis, blastomycosis, and larvae of *Hypoderma bovis*, but none has been regularly found in typical lesions. Acid-fast organisms are usually not present, and although *Arcanobacterium pyogenes* is sometimes recovered, it is not considered to be the cause of the multiple granulomas.

The lesions occur in cattle of all ages. In any single animal, nodules are all of the same size but the size varies from one animal to the next, from 0.5–5.0 cm in diameter, in or under the skin. *Sites of predilection are the skin around the base of the tail, the limbs, the withers, and the abdominal wall* but lesions are seldom seen deep in muscle masses.

When nodules are cut, surfaces tend to bulge and consist of three zones. The *central zone* is dry, dull, necrotic-looking, and often distinctly yellow. The *reactive zone* is gray-pink, semitranslucent and elastic. The *outer layer* is thin, white fibrous tissue that radiates out along trabecular divisions in adjacent muscle. Larger nodules may be laminated, indicating periodic growth, and small nodules may be reduced to a hard scar with or without mineralization.

Histologically, the early stages of Roeckl's granuloma are small abscesses surrounded by granulation tissue that may contain abundant eosinophils. In other animals, the predominant inflammatory cell may be the lymphocyte. Epithelioid cells and a few giant cells may be present in the reactive zone. The capsule is made up of mature collagen. *These lesions seem to be the modified or exaggerated response of a sensitized animal to a persistent or repetitively introduced antigen.*

Changes in muscle secondary to systemic infections

Lesions in muscle caused by the specific presence of an infectious agent are described elsewhere. More common than these lesions of muscle are the degenerative changes of muscle fibers that occur in acute systemic infections such as pneumonic pasteurellosis of cattle ("shipping fever"); these may be the result of endotoxemia. The lesions, although widespread, cannot be appreciated grossly and consist of *segmental degeneration of a few or many fibers with retraction of fiber segments.* The extent of the degeneration of contractile substance may be very slight, and for this reason floccular or mineralizing changes may be sparse. Some fibers show the distinct hyaline change of Zenker's degeneration with retraction cups visible but not frequent. The fiber breaks lead to *minimal reactive cellularity* since there is little call for extensive clean-up by macrophages or for regenerative proliferation by satellite cells. The changes may be easily overlooked, but a clue to their presence is corrugation of only some fibers or groups of fibers in a longitudinal section of muscle. Although the corrugated fibers may appear otherwise normal, the recoil can be traced to proximal or distal transverse separations. Endomysium and blood vessels are intact, although occasionally there are petechial or larger hemorrhages, and infiltrating lymphocytes or neutrophils are few or absent. *Since the degeneration is almost exclusive to sarcoplasm, survival of the animal should allow complete restoration.*

PARASITIC DISEASES

Sarcocystosis

***Sarcocystis* spp.** *are protozoal parasites of animal muscle that in many respects resemble coccidia, the main difference being their obligatory development in two hosts.* The sexual stages develop in a predator host, while the asexual phases develop in the prey animal. Some animals, such as the opossum and man, are vehicles for both parts of the *Sarcocystis* spp. cycle but not for the same species, there being considerable specificity on the part of both the intermediate and definitive hosts. There is, however, some latitude. For example, several individual parasites develop in dogs, or coyotes, or foxes, or wolves as a definitive host, and a number of intermediate host species of the same general type may be "accidentally" infected at low level. Currently over 90 *Sarcocystis* species are recognized in mammals, birds, and reptiles, and 14 of these are regularly found in muscles of domestic animals as part of the intermediate host infection. The prevalence of infection in cattle, sheep, and horses approaches 100%. Where it was once thought that the muscle phase of infection was asymptomatic and safe for the intermediate host, it is now known that particularly *the schizogonous phase may cause severe clinical disease and death* under both natural and experimental conditions. The production of enteric disease by the sexual phase in the predator host is considered elsewhere (see Vol. 2, Alimentary system). Fetal infection with abortion and neonatal mortality is described in Vol. 3, Female genital system.

The very substantial differences between *Sarcocystis* species in respect of the intermediate host response appears to be a parasite characteristic, not a difference in host immunologic response, although clinical disease may be modified by immunity.

Consideration here is primarily given to those *Sarcocystis* spp. infections affecting the muscles of domestic animals as intermediate hosts. *Sporocysts* are ingested when herbage contaminated by carnivore or human fecal material is consumed. *Sporozoites* are released and these invade many tissues. One or two generations of *schizogony* take place within endothelial cells, the first in small arterioles, the second (if there is one) in capillaries. The second or third generation of *schizonts* develops within striated muscle fibers as thin-walled cysts initially containing round *metrocytes*, which repeatedly divide to produce numerous banana-shaped *bradyzoites*. The much-enlarged mature cyst persists in muscle for long periods and the cycle is completed when muscle is consumed by the predator host and the *sexual cycle* of the parasite is developed in the intestinal epithelial cells.

Clinical disease in an intermediate host may occur at either of two stages of the developmental cycle. It may take the form of fever, petechiation of mucous membranes, edema, icterus, and macrocytic hypochromic anemia 3–5 weeks after initial infection and lasting for 6–8 weeks during the *schizogonous (parasitemic) stage*. These signs seem to be related to many small episodes of intravascular coagulation, although endothelial schizonts are not the site of thrombus formation. The parasites are also present in perivascular macrophages. The second stage in which clinical signs and death may occur comes as the *schizonts enter muscle at about 40 days*, sometimes with extensive fiber degeneration and marked enzyme release which attracts macrophages and plasma cells. Another wave of muscle disease may be associated with enlargement of the cysts in a massive infestation and this can cause lameness. Maturation of cysts may take 60–100 days, by which time any tissue reaction has subsided; this may account for the earlier impression that the parasite was an innocuous passenger in muscle.

Two species of *Sarcocystis* have been recognized in the muscles of the **horse;** *S. bertrami* (*S. equicanis*) and *S. fayeri*. Both species complete their cycle in the dog. *S. bertrami* seems to cause the greatest tissue response but neither seems to cause clinical disease and both are therefore, judged "non-pathogenic." Cysts in horse muscle are microscopic in size and rarely numerous, but occasionally there is massive involvement of skeletal muscles.

Sarcocystis species in **cattle** are presently considered to be: *S. cruzi* with a cycle completed in domestic and wild Canidae; *S. hirsuta* with a cycle completed in the domestic cat; and *S. hominis* with a cycle completed in man. Two additional species are found in the water buffalo; *S. fusiformis* with a cat–buffalo cycle, and *S. levinei* with a dog–buffalo cycle. Only *S. cruzi* seems to be capable of causing significant clinical disease in cattle. Clinical signs exhibited during the schizogonous stage may include evidence of hemolysis as described above as well as progressive debility, abortion, drooling, lymphadenitis, sloughing of the tip of the tail and, in some outbreaks, death in a high proportion of affected animals. See also Eosinophilic myositis of cattle and sheep.

Four species of *Sarcocystis* regularly affect **sheep,** namely *S. tenella* (*S. ovicanis*) and *S. arieticanis,* which have a sheep–dog cycle, and *S. gigantea* and *S. medusiformis,* which have a sheep–cat cycle. *Sarcocystis tenella* is quite virulent in lambs if infective doses are large, and naturally occurring encephalomyelitis in mature sheep with neurological disease has been blamed on this organism. Chronically debilitated sheep often have an enormous number of cysts in their muscles. This ought to have some effect on muscle performance, but lameness is not apparent. *Sarcocystis gigantea* cysts are very large (1–3 mm) and distend segments of esophageal striated muscle fibers well above the adventitial surface of the esophagus (Fig. 2.108A, B). It is the only *Sarcocystis* of domestic animals that is visible with the naked eye.

Two species (*S. capricanis* and *S. hericanis*) have a goat–dog cycle, and another (*S. moulei*) has a goat–cat cycle. None appears to be pathogenic for **goats** as natural infections but, experimentally, even moderate levels of infectious sporocysts led to death of some animals.

Three species of *Sarcocystis* are found in **swine;** *S. miescheriana* with a pig–dog and pig–wild Canidae cycle, *S. porcifelis* with a pig–cat cycle, and *S. suihominis,* which completes its cycle in humans. Of the three, only *S. miescheriana* is known to produce clinical signs of diarrhea, myositis, and lameness.

Sarcocystis organisms have been observed in the muscles of **dogs** and **cats** from time to time. It was thought that these represented erratically traveling parasites in an abnormal site, but it now appears that such cysts are morphologically unlike the species that originate in the cat or dog and complete their cycle in the sheep, horse, or cow. A new identity has not yet been given to these sarcocysts.

Sarcocystosis occurs in many wild species; for example, deer have at least five distinct species all of which complete their cycle in the dog or in wild Canidae.

Histologically, *Sarcocystis* organisms are rarely accompanied by an acute inflammatory reaction, and *schizonts in endothelial cells cause little or no evidence of endothelial cell destruction.* As the organisms enter muscle, a wide range of change may be encountered. Usually there is no muscle fiber degeneration but there may be thin, linear collections of lymphocytes between fibers in the region. Sometimes the muscle fiber undergoes segmental hyaline change in the region of the invading parasite and rarely, extensive floccular degeneration of muscle fibers occurs. The extent of muscle change bears little relationship to the numbers of developing cysts, but generally, very low numbers of *Sarcocystis* produce no reaction.

As cysts mature, and the contained bradyzoites become more distinct, the cyst capsule within the enlarged muscle fiber becomes

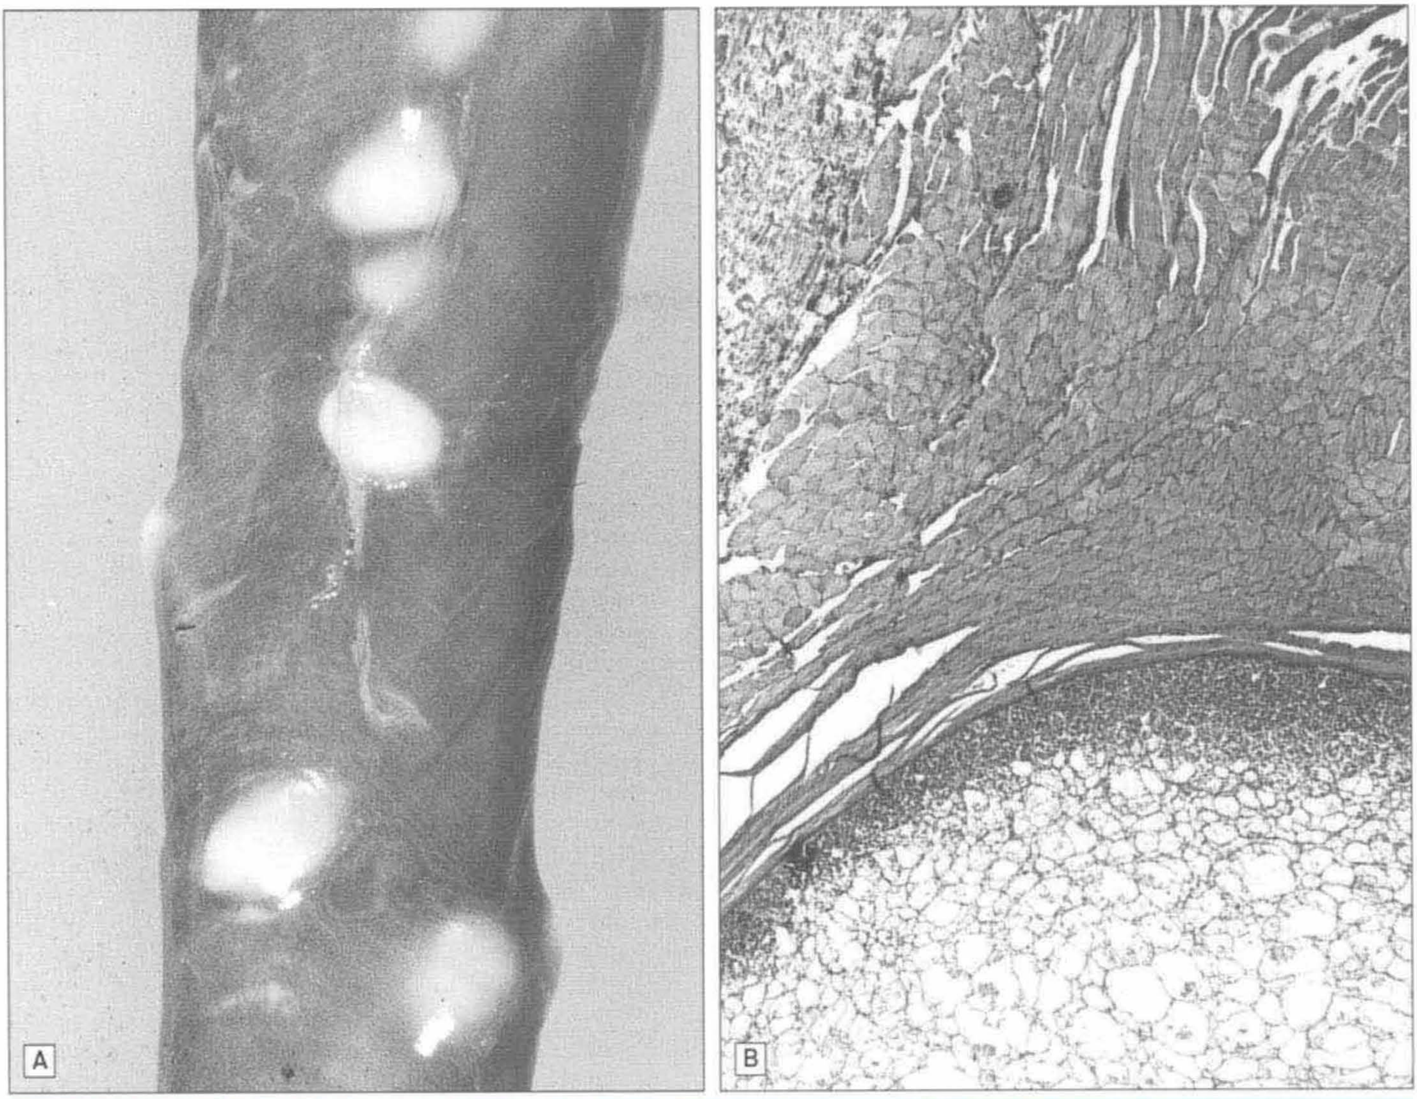

Figure 2.108 **A.** ***Sarcocystis gigantea*** **A.** In the esophagus of a sheep. **B.** Cyst margin in muscle section. (Courtesy of TJ Hulland.)

thicker and more clearly differentiated from the muscle sarcoplasm. Muscle sarcoplasm and muscle nuclei gather around the parasite in the early stages. In some parasitic species, the outer capsular zone develops distinct radial striations, which, on electron microscopy, prove to be complex convolutions of the cyst wall. Small pores allow communication between cyst contents and muscle cell content, but apart from the obvious nutritional dependence of the parasite on muscle fiber, little is known of the biochemical interplay which must take place.

Microscopic inspection of *Sarcocystis*-infected muscle often reveals occasional degenerate parasitic cysts surrounded by variable numbers of inflammatory cells (very few of which are eosinophils), or, at a later state, macrophages and granulation tissue. It is not known whether these represent "over-age" cysts or simply random changes in an easily modified host–parasite relationship. Such reactions in muscle increase with host age.

Eosinophilic myositis of cattle and sheep

Eosinophilic myositis *is a relatively rare condition in cattle and sheep of all ages* that has some significance for meat inspection because the lesions are usually discovered in skeletal muscle and myocardium of animals slaughtered for human consumption. *Sudden deaths in cattle and sheep have been ascribed to the myocarditis.* The disease is included here because *there is good evidence that eosinophilic myositis in sheep and cattle may be caused by degeneration of* Sarcocystis *spp. The converse is not true and, in some cases of eosinophilic myositis, no degenerating parasites can be found. Sarcocystis* spp. remnants are often found in the center of the myositis lesions, and IgE specific for the parasite is associated with degranulated eosinophils. Animals with parasites but not myositis have serum levels of IgE comparable to those in animals with lesions, suggesting that the inflammatory reaction in eosinophilic myositis is stimulated by independent parasite tube rupture or by trauma to muscle fibers. There are reports of traumatic muscle rupture in cattle initiating an eosinophilic response. A heat-stable, eosinophil-chemotactic substance has been isolated from affected bovine muscle in which eosinophilic myositis lesions were present. The substance has a molecular size less than bovine albumin, and its activity seems to correlate with lesion size and severity.

The gross lesions of eosinophilic myositis in cattle are characteristic, being well-demarcated, green, focal stripes or patches that fade to off-white when exposed to air. Some lesions have a brown-green or gray-green color. Single muscles or groups of muscles may be involved or the lesions may be widespread through all muscles, including the heart. Individual lesions may be 2–3 mm to 5–6 cm in diameter in both heart and skeletal muscle, and no part of the muscle mass seems to be exempt.

Histologically, both acute and more chronic fibrous reactions may exist side by side. *The reaction is characterized by large numbers of eosinophils, and it is these that impart the green color to the lesion.* Dense masses of mature eosinophils separate adjacent endomysial sheaths and perimysial trabeculae. Muscle fiber degeneration is not an obvious feature of the disease, but *occasional segments of fibers do undergo hypercontraction and degeneration.* These may be later evident only as endomysial sheaths stuffed with eosinophils rather than muscle fibers because muscle fiber regeneration seems to be impaired or modified.

With time, fibroplasia is evident. In the chronic lesion, dense collagenous tissue is prominent and the inflammatory cell population changes from eosinophils to a smaller population of lymphocytes, plasma cells, and histiocytes.

In some cases, individual lesions may take on some of the characteristics of a *granuloma* in which central muscle fibers along with adjacent eosinophils undergo degeneration. This central necrotic mass acquires a fringe of epithelioid cells and giant cells, and fibrous tissue becomes circumferentially oriented. The central eosinophilic mass may gather calcium salts while the edge of the lesion consists of infiltrating eosinophils and fibroblasts that radiate into adjacent muscle. Granulomatous lesions will leave a small scar, but it is likely that the more diffuse lesions of eosinophilic myositis in cattle can disappear in time with very little residual lesion.

Eosinophilic myositis in *sheep* tends to occur in young animals under 2 years of age. Lesions are comparable in distribution and type to those in cattle although the frequency of the granulomatous type of change may be higher.

Toxoplasma and *Neospora* myositis

In addition to *Sarcocystis,* two apicomplexan parasites, *Toxoplasma* and *Neospora*, produce myopathy in several species. Both infections are dealt with more fully elsewhere (see Vol. 2, Alimentary system; and Vol. 1, Nervous system, respectively).

Toxoplasma gondii infections, particularly in puppies and kittens, or in any species of farm animal naturally immunosuppressed, or in animals on immunosuppressive therapy, may massively involve skeletal muscle fibers. *Myositis with mononuclear leukocytic infiltration, myofiber necrosis, and myofiber atrophy is accompanied by polyradiculoneuritis.* In the majority of toxoplasma infections, however, muscle lesions are rare. In muscle fibers, both tachyzoites and thin-walled cysts (bradyzoites) may be present but the former are generally transient, spherical, and nonreactive.

Neospora caninum infections occur worldwide mainly in dogs, but the organisms are also found in cats, and the disease may have originated in the latter species. *The disease is associated with abortion and perinatal mortality in cattle with nonsuppurative encephalitis, myocarditis, and periportal hepatitis in affected animals.* Neosporosis appears to have been present in the US for over 30 years and many of the organisms originally identified in tissue sections as *Toxoplasma* are now recognized as *Neospora*. The two organisms can be distinguished definitively by immunoperoxidase procedures, and presumptively by microscopic appearance. *Neospora* cysts are thick-walled; *Toxoplasma* cysts are thin-walled and found in several tissues, including muscle. Serologic tests can detect antibodies to *N. caninum* and to *T. gondii.*

Neospora caninum has a much greater tendency to produce *myositis* because the tachyzoites form large fusiform packets in muscle after the second division stage of meronts. When these escape from the muscle fiber in a partially immunized host, an inflammatory reaction, abundant and predominantly histiocytic and plasmacytic, separates individual fibers. There is also segmental muscle fiber degeneration, which may be a response to direct parasite invasion, but is likely the result of a local release of free radicals from dying inflammatory cells. At this stage, clinical signs of muscle weakness may be obvious and at necropsy, muscles over the entire body may be pale, streaky, and atrophic. Inflammatory lesions often also affect nerves and nerve roots and result in denervation atrophy.

The life cycle and source of infection for neosporosis are unknown. The only known mode of natural infection is transplacental in persistently infected bitches, with affected litters having distinctive clinical features of progressive pelvic limb weakness, muscle atrophy, and joint contracture. The disease has been produced experimentally in immunocompetent cats, but the lesions are more severe in cats given corticosteroids.

Trichinellosis

Muscle is the habitat for encysted larvae of the nematode *Trichinella* spp., which may survive there for many years (Fig. 2.109). The muscle belongs to the animal that earlier harbored the adult worm in its duodenum, and *since animal-to-animal transmission of infection is accomplished by the consumption of infected muscle, most of the species regularly involved are carnivores or scavenger species.* Man, dogs, and a variety of wild Canidae, cats and wild Felidae, pigs, rats, mustelids, bears, polar bears, raccoons, and mice become hosts to the adult and their persistent larvae. Other species including horse and birds may become infected when muscle tissue is included in their feed; horsemeat has been a natural source of trichinellosis in man. *Trichinellosis is a zoonotic disease sometimes occurring in spectacular outbreaks in man and animals.* Humans become infected when they consume uncooked or incompletely cooked meat of pigs, bears, or aquatic mammals. In those regions of the world where inspection of meat is routine, the incidence of infection is very low, but even in countries such as Canada and the USA, the incidence in wild carnivores is 1–10%.

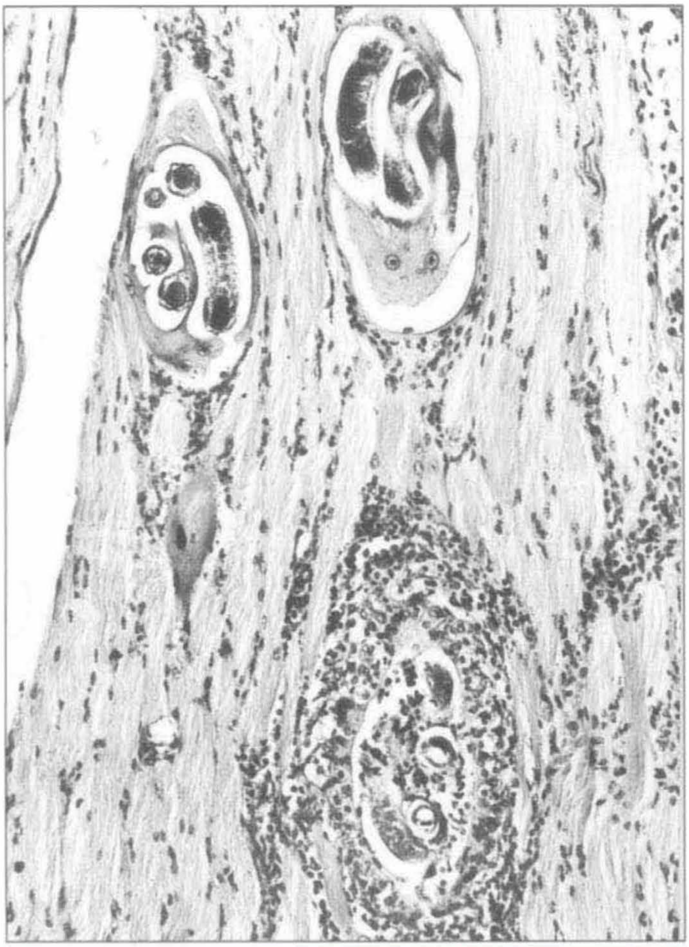

Figure 2.109 ***Trichinella spiralis*** larvae encysted in muscle of a pig.

The parasitic cycle for *T. spiralis* begins with ingestion of infected meat fibers. Gastric juices liberate the encysted larvae, which then molt twice, grow to a length of 1–4 mm as threadlike fourth-stage worms, and molt again. Maturity is reached in about 4 days following ingestion, the adults copulate and the male dies. The ovoviviparous females penetrate via the crypts of Lieberkuhn to the submucosal lymphatics where they deposit 0.1 mm long larvae into lymph vessels. The persistence of females in the duodenum is dependent on the state of surface immunity (probably IgA antibody produced locally in the gut wall) and varies from days to 5–6 weeks. Some larvae may be passed in feces as the female moves out of the duodenal crypts. The remaining larvae migrate with the lymph, then the blood, to reach the pulmonary and systemic circulations. Those that find their way to muscle may achieve a safe haven away from developing immunity by entering a muscle fiber; those that arrive elsewhere may survive for a brief period but are soon destroyed. In a previously sensitized host, few of the approximately 500 larvae produced by each female are able to enter a muscle fiber in time to ensure survival.

Within the muscle fiber, the larva grows, coils and enlarges a segment of the host muscle fiber, which is induced to develop some unusual changes as the "nurse cell." Nuclei enlarge, myofibrils are greatly reduced, the basal lamina is very greatly increased in its thickness and number of folds around the affected segment of muscle fiber, and the sarcoplasmic reticulum, which is in intimate contact with the worm, proliferates. Mitochondria in the immediate vicinity increase in number as they are reduced in size. After a month, the larvae are up to 100 μm long and coiled in a figure of eight. There is usually one per fiber. *Larvae are not normally visible by naked eye inspection of muscles unless they are old and mineralized.* On routine microscopic examination of muscle, larvae lie in bulging glassy segments of muscle fiber that may be loosely encircled by eosinophils, and in due course, by a scattering of lymphocytes, plasma cells, and macrophages. If the parasitized muscle segment degenerates, the larva is exposed and soon dies to become the center of a more acute inflammatory, but still predominantly eosinophilic, reaction. Segments of muscle fiber adjacent to the encysted larva may show evidence of degeneration or subsequent regenerative repair with basophilia and centrally located nuclei. In a heavy infestation, a large proportion of the muscle fibers in predilective muscle sites may be taken up with either the parasite or adjacent reactive zones. Purely physical replacement of functional muscle accounts for most of the clinical signs of infestation when they are present, though usually they are absent.

In 2–3 months, the cellular reaction subsides and the muscle fibers enclosing larvae become further modified to give the impression, on light microscopy, of a fibrous capsule. Since parasite survival can only be assured by intracellular seclusion, the "capsule" is, in reality, modified muscle cell components or, perhaps more correctly, modified satellite cells and basal lamina. Once the larvae are encysted in this way, further change, apart from muscle fiber degeneration, is usually confined to deposition of mineral in the encapsulating muscle structure, but this does not seem to affect parasite viability. *The larvae may survive more than 20 years* although the average life span is probably a good deal less depending on host longevity and the occurrence of fiber degeneration.

Several features of this parasitism are unexplained, including the distribution of larvae within the host. Certain muscles such as the respiratory and masticatory muscles are preferentially and heavily infected while other muscles contain a reduced burden. Activity alone is not responsible because a paralyzed diaphragm is still preferentially susceptible. Concentration of larvae in preferred sites may be influenced by blood distribution, increased larval survival, the presence of some needed nutrient, or preferential shielding from normal body defense mechanisms. Heart muscle is sometimes involved, but not heavily; *the muscles most involved are tongue, masseter and laryngeal muscles, diaphragm, intercostal muscles, and muscles of the eye*, but no striated muscle is exempt. Since some of the selectively involved muscles are small, heavy infestation may have a significant clinical effect in the form of muscle weakness, paralysis, or reduced responsiveness. Usually parasitic infestations of muscle are asymptomatic, and this feature enhances the transfer of infection from animals to man.

Five species of *Trichinella*, with eight genotypes identified by DNA analysis, are parasites of muscle:

- *Trichinella spiralis* is the parasite of pigs, rodents, and man in temperate and tropical climates, and is the most prevalent strain. It is moderately resistant to short-term freezing, and its infectivity is not reduced by freezing and thawing.
- *Trichinella nativa* is found in colder climates and is the species most often encountered in polar bears, bears, aquatic mammals, and the Inuit. Its cycle is similar in most respects to that of *T. spiralis* but the larval form is much more resistant to freezing for long periods.
- *Trichinella nelsoni* is found in carnivores in eastern and southern Africa and also in central and eastern Europe.
- *Trichinella britovi* has been reported in southern Europe.
- *Trichinella pseudospiralis* is found in northeastern Europe and differs from the other species in its failure to encyst in muscle. The species migrates through muscle more or less continuously under experimental conditions, but appears otherwise to have a cycle similar to that of *T. spiralis.*

Cysticercosis

Many of the larval forms of tapeworms of carnivores develop and are temporarily stored in the viscera or other tissues of prey species. A few have a special predilection for skeletal muscles and myocardium, and this much smaller group is dealt with here. The pathological effects of adult tapeworms in the intestinal tract of the carnivorous host are described in Vol. 2, Alimentary system.

Taenia solium is a large tapeworm (up to 8 m long) common in many parts of the world and resident in the intestinal tract of humans and sometimes other primates. The larvae (or metacestode form) usually develop in the pig or wild pig, but for this species of tapeworm humans can sometimes be host to both the tapeworm and the larval cysticercus. Gravid tapeworm segments are passed in feces, and because they are nonmotile, the 40 000 eggs in each segment tend to be concentrated over a small area. Susceptible pigs having access to infected human feces are easily infected. Eggs resist destruction for relatively long periods in soil, moist ground surfaces or sewage sludge, and survive in flowing water for a while. Following ingestion, the outer shell is digested in the stomach releasing and activating the tiny *oncosphere*, which penetrates the intestinal blood vessels and reaches the general circulation. *Most of the larvae in the pig find their way to heart, masseter, tongue, or shoulder muscles.* When they migrate in humans, they are distributed to connective tissues, brain, and viscera. The larvae become *cysticerci* (*Cysticercus cellulosae*), enlarge to a cyst with a single inverted scolex, which, when mature, measure 1–2 cm and are easily visible between muscle fibers. Cysticerci are rapidly ensheathed at first in a loose, and then a more dense, connective tissue capsule derived from endomysium. A few lymphocytes and a few or many eosinophils lie in the outer regions of the capsule. The cysticercus seems to avoid effective immune-mediated destruction for some time by converting elements of the complement system to inactive products, although in a strongly immunized animal the larvae are eventually destroyed, mineralized, and removed (Fig. 2.110A). In order to allow themselves growing room within developing inelastic collagenous capsules, the cysticerci create a crescentic zone of degenerative lysis (presumed to be induced enzymatically); this can often be seen in histologic sections of encysted metacestodes, as can parts of the scolices and hooks in those species which have them. *Cysticercus cellulosae* has rostellar hooks. The survival time in muscle for *C. cellulosae* is not known, but the question is usually not relevant since *pigs are normally slaughtered at a young age when virtually all cysticerci in muscle are viable.* Humans complete the cycle and become infected when they consume raw or incompletely cooked pork.

Taenia saginata is probably the *most common tapeworm in humans; its larvae are in cattle,* and are found in most regions of the world. Transfer of the very resistant eggs from the fecund proglottids to calves or cattle is often enhanced by contamination of open water by sewage, or by use of sewage as fertilizer on fields. It also occurs directly by contamination of animal feeds with human feces or from soiled human hands. The life cycle is similar to that described above for *T. solium* and *the larval form (Cysticercus bovis) similarly preferentially infests heart and masticatory muscles*, although cysts are often widespread throughout the muscles. Histologically the reaction to the parasite involves few eosinophils. *Cysticercus bovis* does not have rostellar hooks. Following a period of growth and development of about 10 weeks the larvae become infective. After about another 30 days the cysticerci begin to die, but some larvae may be viable 9 months after infection. Death of the larvae is probably the result of development of an immune reaction. Cattle that have acquired resistance to the invasion of oncospheres across the gut apparently do not have an enhanced capability to cause degeneration of preexisting muscle cysticerci. Humans acquire infection when they consume inadequately cooked beef or veal.

Taenia ovis is a tapeworm commonly found in dogs and wild carnivores throughout the world that, in its larval form, has a cysticercus (*Cysticercus ovis*) that develops in the heart and skeletal muscles of sheep and goats (Fig. 2.110B). The cycle is similar to that for *T. saginata* but the larvae do have rostellar hooks, which may sometimes be an aid to histologic identification in lesions even after the cysticercus has begun to disintegrate.

Taenia krabbei is a tapeworm in *wild carnivores* in temperate and arctic climates whose larval form (*Cysticercus tarandi*) is found in reindeer, gazelle, moose, and other wild ruminants. Lesions produced in the intermediate host are similar to those seen in cattle with *C. bovis,* and a similar cycle is assumed.

Hepatozoonosis

Myositis caused by *Hepatozoon americanum* (initially classified as *H. canis*) was a consistent feature of 15 natural cases of infection in

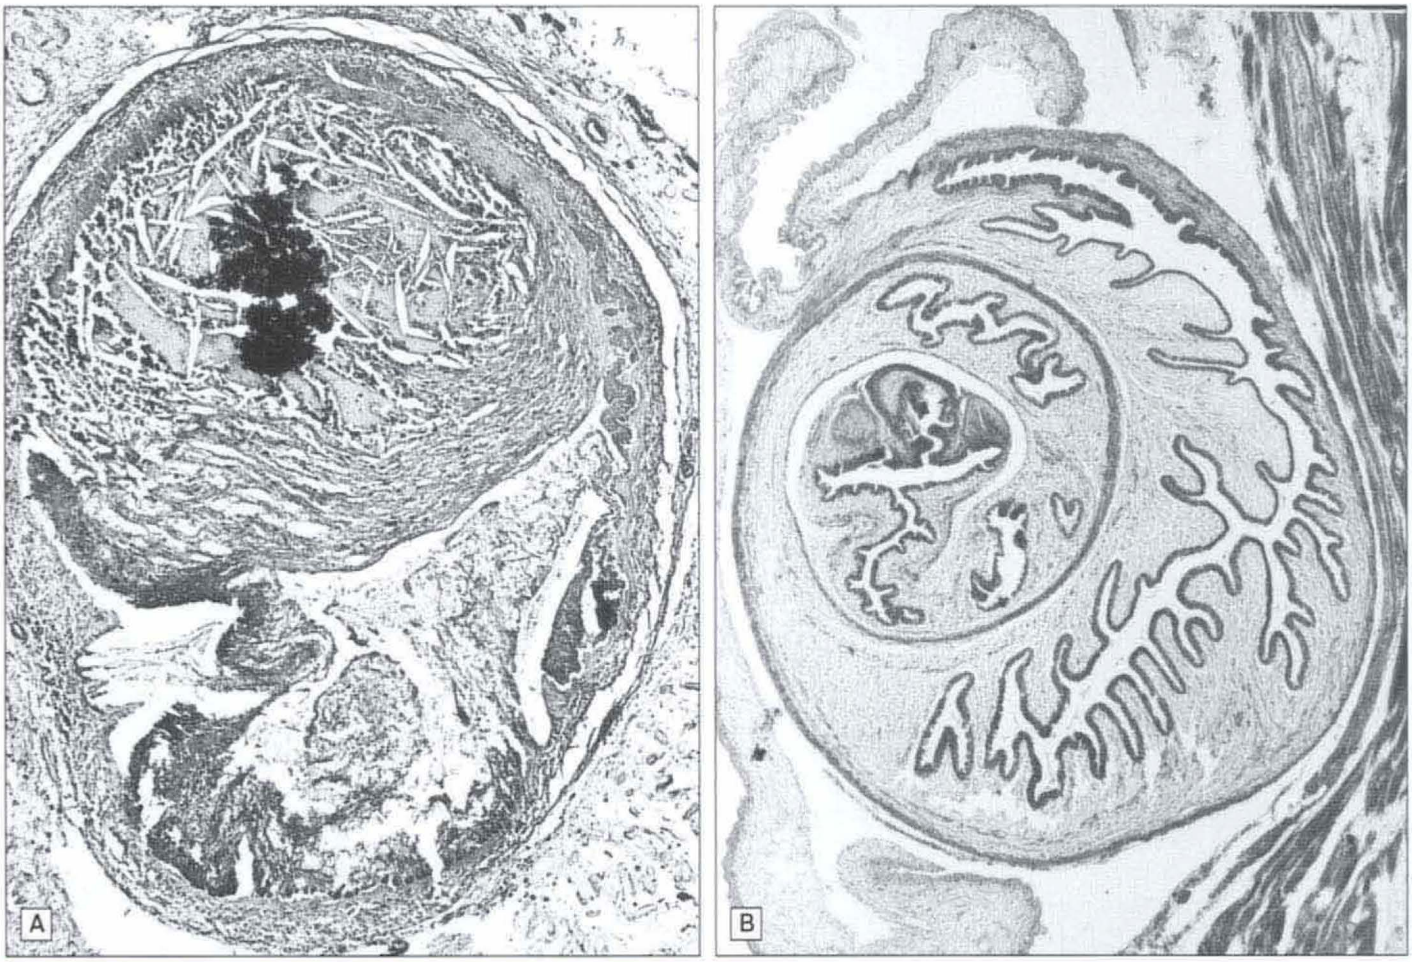

Figure 2.110 A. Degenerating and mineralizing ***Cysticercus cellulosae*** in the brain of a dog. **B.** ***Cysticercus ovis*** in the diaphragm of a sheep.

dogs in the southern USA. Cases have been limited mainly to the Gulf Coast area of Louisiana and Texas and from Oklahoma. The disease occurs in a variety of Canidae and Felidae in South Africa and the Middle East, and has become established in the dog and brown tick (*Rhipicephalus sanguineus*) populations in North America. Animals become infected by ingesting an infected tick or possibly another infected arthropod; sporozoites are released, invade the gut wall, and *undergo schizogony in many tissues of the host, including skeletal muscle*. Rupture of schizonts in time leads to an inflammatory reaction, but the subsequent stage, a large 250 µm, thick-walled, single-celled cyst does not stimulate a body response.

Affected dogs (generally less than 6 months old) show fever, anorexia, weight loss, general body pain, and gait abnormalities, and many show respiratory signs. Concurrent disease may be needed to facilitate infection. The clinical disease is often prolonged by spontaneous remissions. Radiographs may show irregular periosteal proliferations. Most dogs have marked leukocytosis and a slight increase in serum creatine kinase activity. The organism in gametocyte form may be present in neutrophils, and muscle biopsy may demonstrate the cysts, or the typical pyogranulomatous reaction in response to the release of merozoites, or the schizonts themselves.

At postmortem, muscle lesions consist of *multiple acute granulomas* interspersed with rows of neutrophils between muscle fibers. Developing stages of the parasite are usually abundant. Dogs may die with *secondary amyloidosis and glomerulonephritis*.

Chagas' disease (American trypanosomiasis)

The disease in dogs has prominent lesions of myocarditis but may also have skeletal muscle involvement. Affected muscle has *myofiber necrosis with infiltrates of lymphocytes and macrophages*. See Vol. 3, Hematopoietic system for further information.

NEOPLASTIC DISEASES OF MUSCLE

Primary tumors of striated muscle are uncommon in domestic animals and include tumors of cardiac as well as of skeletal muscle. Myogenic tumors do not arise from fully differentiated muscle fibers and rarely arise from satellite cells. *In most cases, myogenic tumors are thought to originate from uncommitted pluripotential mesenchymal stem cells,* which can also give rise to mixed tumors containing myogenic elements as well as neurogenic, epithelial, or other mesenchymal elements. Such mixed tumors are quite rare in animals.

The cell types encountered in tumors of skeletal muscle reflect the developmental stages of embryonic and regenerating muscle. That is, *tumor cell morphology varies from a round cell resembling a satellite cell or myoblast, to spindle cell, to multinucleate cell.* Historically, the *diagnosis of skeletal muscle tumors has relied heavily on the identification of cross striations within tumor cells.* Cross striations may be identified in elongate multinucleate cells with central chains of nuclei, the so-called "strap cells," or in ovoid cells such as the so-called "racquet cells." Cross striations may be more readily identified following staining with phosphotungstic acid hematoxylin (*PTAH*). Cells with such cross striations are often rare or nonexistent within skeletal muscle tumors, and this approach is time consuming and often frustrating. Identification of primitive sarcomeric structures such as filaments arranged in parallel with associated electron dense Z bands by *electron microscopy* has been somewhat more rewarding. More recently, given the specificity of myogenic markers and relative ease of immunohistochemical identification of muscle tumors, *immunohistochemistry has largely replaced electron microscopy and PTAH staining. Desmin and muscle actin* are proteins expressed early in skeletal muscle differentiation and are expressed by many or most skeletal muscle tumor cells. Desmin will often highlight cross striations in skeletal muscle tumors far better than PTAH stain. These markers will not, however, differentiate tumors of skeletal and cardiac muscle origin from tumors of smooth muscle origin. *Myoglobin and sarcomeric actin* are specific markers of striated muscle differentiation that are expressed later in myocyte differentiation. Typically, fewer tumor cells will express these proteins, and often only the most differentiated skeletal muscle tumor cells will express myoglobin.

When evaluating tumors involving skeletal muscle, *be aware that nonmyogenic tumors infiltrating or metastatic to skeletal muscle can cause extensive damage and bizarre regenerative fibers that often mimic neoplastic cells.* This is especially true of tumors with extensive sclerosis. These bizarre cells should not be mistaken for tumor cells. Entrapped skeletal muscle fibers within a nonmyogenic tumor will also stain with immunohistochemical markers for skeletal muscle and can cause confusion.

Both benign (rhabdomyoma) and malignant (rhabdomyosarcoma) skeletal muscle tumors occur in domestic animals. As in people, rhabdomyoma and rhabdomyosarcoma often occur in young animals. Classification of these tumors, particularly rhabdomyosarcoma, has been difficult and often confusing. The classification presented here is based on the current scheme of classification of myogenic tumors in people.

Rhabdomyoma

Benign tumors of striated muscle origin are most common in the *heart of pigs* and involving the *larynx of dogs*. In pigs, the red wattle pig breed appears to be predisposed. Rare cases of cardiac rhabdomyoma have also occurred in sheep, cattle, and dogs. Females may be predisposed. **Cardiac rhabdomyomas** *are incidental findings* most often involving the left ventricular wall. Tumors can also occur in the septum, and least commonly involve the right ventricular wall. These lesions are present in young animals, and current opinion suggests that they are *most likely hamartomas or dysplastic lesions rather than true neoplasms*. These lesions occur as smooth-surfaced nodular masses up to about 3 cm diameter embedded in the myocardium. These lesions are circumscribed but nonencapsulated, and are formed by *large vacuolated myocytes with pale eosinophilic cytoplasm*. Mitoses are not seen.

Laryngeal rhabdomyomas have been reported in dogs from 2 to 10 years of age. Tumors most often occur as nodular masses protruding into the lumen of the larynx, resulting in clinical signs of dyspnea, stridor, or altered bark. One tumor occurred in the laryngeal pharynx. *Laryngeal rhabdomyoma cells are large, round, and moderately pleomorphic, and contain abundant vacuolated to granular eosinophilic cytoplasm* (Fig. 2.111). Scattered multinucleate and elongate strap cells may be seen. Intracytoplasmic glycogen may be revealed by PAS staining. Ultrastructural features include numerous mitochondria, and these tumors were initially misdiagnosed as laryngeal oncocytomas. Ultrastructural identification of *primitive myofilaments and Z band type material* (Fig. 2.112), and *positive immunostaining for skeletal muscle markers* (Fig. 2.113), has confirmed the striated muscle origin of these tumors. Although there are reports of invasive tumors classified as laryngeal rhabdomyosarcoma, *these tumors typically exhibit minimal invasion and mitotic figures, metastasis has not been seen*, and the vast majority of these tumors are thought to be benign and cured by wide surgical excision.

Rhabdomyoma is rare in other sites and other species. Rhabdomyoma of the *skin* has been reported to occur on the convex surface of the pinna in four white cats aged 6–7 years. Rarely, rhabdomyoma occurs in the skin of the trunk or legs. A cystic rhabdomyoma attached to the *diaphragm* by a stalk has been reported in the mediastinum of a 2-year-old filly.

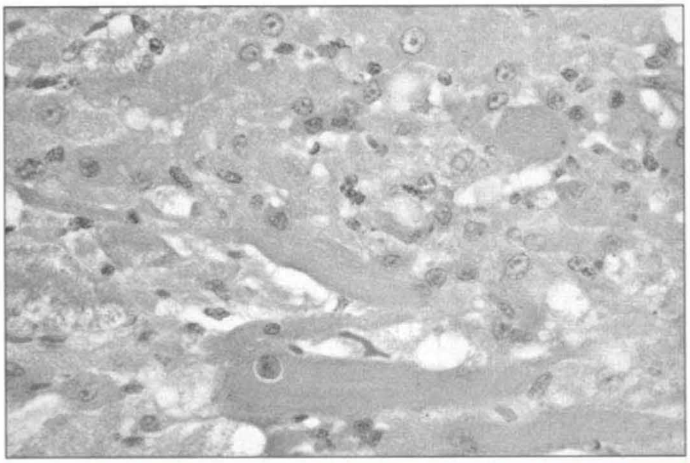

Figure 2.111 Canine **laryngeal rhabdomyoma** with characteristic moderately pleomorphic plump round-to-elongate cells with euchromatic nuclei. (Courtesy of BJ Cooper.)

Rhabdomyosarcoma

Rhabdomyosarcomas are most often fleshy growths that may form within skeletal muscle or grow into the lumen of tubular organs of the urogenital tract. Growth is often rapid, resulting in central areas of hemorrhage and necrosis.

Rhabdomyosarcoma in people has been classified histologically as *embryonal* rhabdomyosarcoma, *alveolar* rhabdomyosarcoma, and *pleomorphic* rhabdomyosarcoma. *Botryoid* rhabdomyosarcoma, a tumor most common in the urogenital tract, is considered a variant of embryonal rhabdomyosarcoma. *Embryonal rhabdomyosarcoma, and the botryoid variant, are the most common forms in people and, it would appear, in animals.* The alveolar variant is less common in both people and animals, and pleomorphic rhabdomyosarcoma, often thought to be the most classic and most common form, is actually the least common tumor. A review of the veterinary literature revealed that most tumors designated as pleomorphic variants actually had histologic features warranting designation as embryonal rhabdomyosarcoma.

Embryonal rhabdomyosarcoma is composed of primitive cells that may be either round and myoblast-like, or elongate and myotube-like ("strap cells"), and can be binucleate or multinucleate. Tumors may consist entirely of one cell type or may contain a mixture of these cell types. Embryonal rhabdomyosarcoma occurs most commonly in *young animals* and often *involves the head or neck, including the oral cavity*, although occurrence at other sites is possible. The round cell form is the most common, and embryonal rhabdomyosarcoma should be considered in the differential of any nonhistiocytic and nonlymphoid round-cell tumor of the head or neck of a young animal. The *round cell embryonal rhabdomyosarcomas* consist either of small cells with large central euchromatic nuclei, often with a single prominent nucleolus, and indistinct cytoplasm, or of larger round cells with similar nuclei and prominent eosinophilic cytoplasm (*rhabdomyoblast cells*); there is often an admixture of these two cell types (Fig. 2.114). Muscle markers are most often expressed by the larger rhabdomyoblast cells (Fig. 2.115). Scattered cells may have prominent cytoplasmic vacuolation resulting in a "spider-web" cell. The *botryoid variant* – a "grape-like" tumor – occurs most often in the trigone area of the urinary bladder in young large breed dogs. In these tumors the cells consist of elongate multinucleate myotube-like cells, often in a myxoid stroma (Fig. 2.116A, B). A similar embryonal rhabdomyosarcoma with prominent myxoid stroma can occur at subcutaneous sites and can be misdiagnosed as myxosarcoma. Although embryonal rhabdomyosarcoma is most common in dogs, this type of tumor also occurs in cats, sheep, cattle, pigs, and horses.

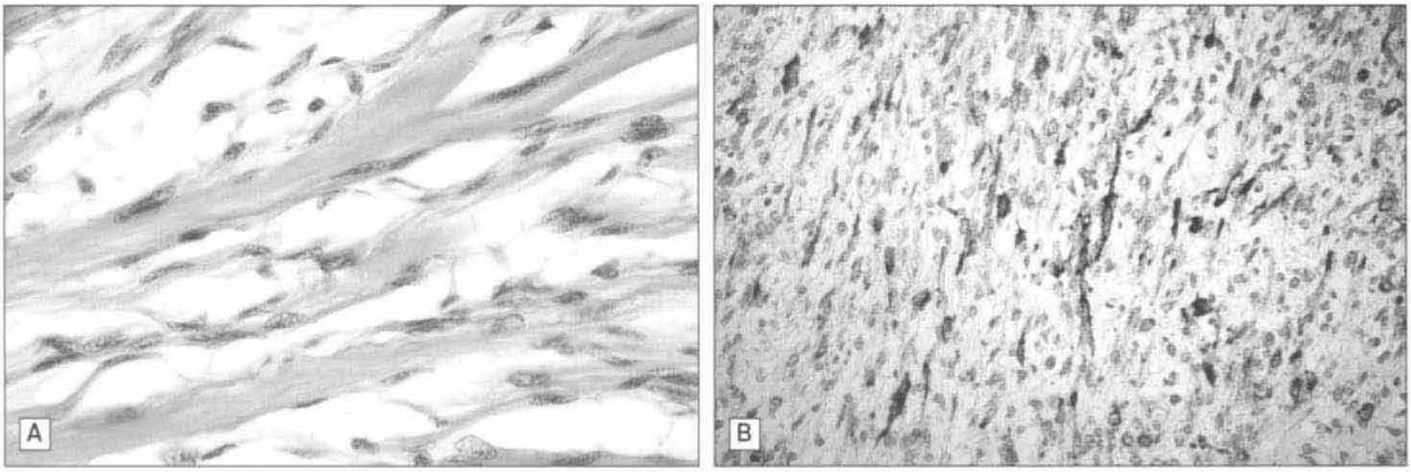

Figure 2.116 Urinary bladder embryonal rhabdomyosarcoma in the trigone of a 1-year-old large breed dog. **A.** Characteristic elongate myotubes. (From McGavin MD, Zachary JF. Pathologic Basis of Veterinary Disease. 2006, with permission of Elsevier Ltd.) **B.** Positive immunostaining for desmin. (Courtesy of BJ Cooper.)

Embryonal rhabdomyosarcoma in all species often occurs in young to young-adult individuals. There appears to be a female predominance, especially for the botryoid variant in the urogenital tract. Cytogenetic abnormalities are commonly associated with childhood rhabdomyosarcomas in people, and a similar situation has been seen in pigs in which a cluster of rhabdomyosarcomas in young pigs was found to have a *genetic basis*.

Alveolar rhabdomyosarcoma is also a tumor of adolescent and young adult people. This tumor consists of sheets of uniformly small, undifferentiated round cells in which tumor cells are supported on a fibrous framework and often *form alveolar-like structures due to loss of cohesiveness in the center of cell nests*. Multinucleate cells can be seen, but cross-striations are rare. A *solid alveolar pattern* is also possible, with sheets of small, undifferentiated round cells that resemble embryonal rhabdomyosarcoma but that lack any differentiation towards the larger eosinophilic rhabdomyoblast cells (Fig. 2.117). This form of rhabdomyosarcoma has been seen in dogs, horses, and a cow.

Virtually all rhabdomyosarcomas exhibit some degree of cellular pleomorphism. Pleomorphic rhabdomyosarcoma is often diagnosed, however *only tumors lacking any areas with features of embryonal or alveolar rhabdomyosarcoma should be designated as pleomorphic variants*. In people, pleomorphic rhabdomyosarcoma is a tumor of adults, most often occurring in major muscle groups such as the muscles of the thigh. Pleomorphic rhabdomyosarcoma has been seen arising in the neck muscle of a 3-year-old dog and in the tongue of a 5-year-old horse. Pleomorphic rhabdomyosarcoma consists of plump spindle cells in a haphazard arrangement that may be admixed with scattered multinucleate cells, strap cells, racket cells, and large, round rhabdomyoblasts (Fig. 2.118A, B).

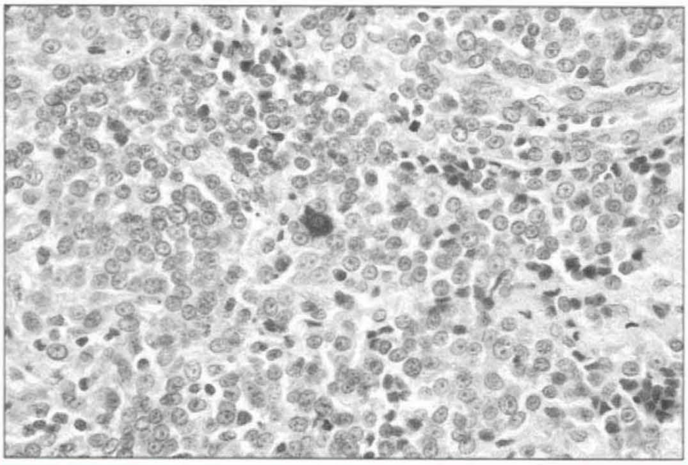

Figure 2.117 Solid sheets of undifferentiated small cells with focal intense cytoplasmic staining for myoglobin in a **solid alveolar rhabdomyosarcoma** in the hip muscle of a 7-year-old dog. (Courtesy of BJ Cooper.)

Cardiac rhabdomyosarcomas occur, but are rare, with all cases to date reported in dogs. The age range of affected dogs was 14 months to 7 years. Clinical signs of cardiac failure can occur, although one tumor was found as an incidental finding. Histologic features of poor differentiation, cellular pleomorphism, mitotic activity, and local invasion warrant the diagnosis of rhabdomyosarcoma rather than rhabdomyoma.

The behavior of rhabdomyosarcoma in animals parallels that of humans, in which aggressive local invasion and frequent metastasis are seen. Although the data regarding pattern of metastasis is scanty in animals, metastasis to atypical sites such as to other skeletal muscle sites, to cardiac muscle, and to spinal cord have been seen.

Nonmuscle primary tumors of muscle

These tumors arise from supporting mesenchymal tissues of muscle. Malignant tumors are far more common than benign tumors.

- *Poorly differentiated sarcomas* and *giant cell sarcomas* occur within muscle, especially at the site of intramuscular vaccinations in predisposed cats. These tumors may be mistaken for rhabdomyosarcoma but rarely express skeletal muscle cell markers, and are most often variants of fibrosarcoma.
- *Hemangiosarcoma* arising within skeletal muscle occurs most frequently in the dog and in the horse (Fig. 2.119). Due to the large amount of hemorrhage and scanty tumor cells, these tumors are often difficult to diagnose from biopsy specimens. Intramuscular hemangiosarcoma is often mistaken clinically for intramuscular hematoma. Intramuscular hemangiosarcoma is an aggressive tumor, exhibiting both local invasion and distant metastasis, such as to lung.

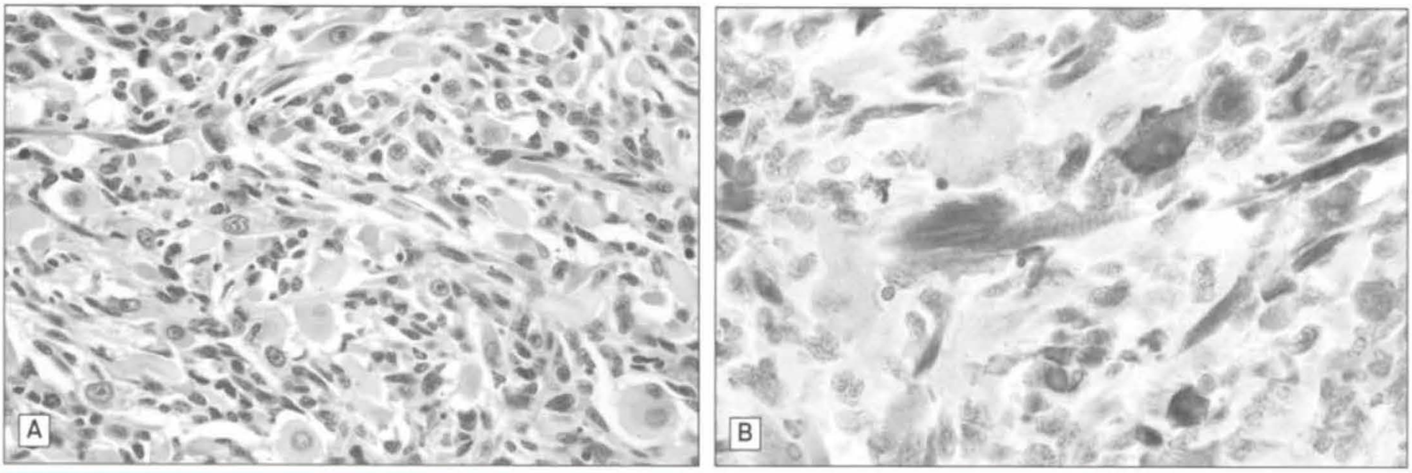

Figure 2.118 Pleomorphic rhabdomyosarcoma in the neck muscle of a 3-year-old dog. **A.** Characteristic mixed plump and pleomorphic spindle cells and round-to-ovoid cells. **B.** Positive immunostaining for desmin that highlights cross striations in spindle cells and in round-to-ovoid cells. Figure 2.122 Invasion of skeletal muscle by mature adipose tissue typical of **infiltrative lipoma** in an adult dog. (Courtesy of BJ Cooper.)

- *Nerve sheath neoplasms* can arise from major nerve trunks within skeletal muscle but are typically localized to intramuscular nerves without infiltration of adjacent muscle.
- *Granular cell tumor* ("myoblastoma") is a tumor that can occur in the musculature of the tongue of dogs and cats and, rarely, within cardiac muscle. Granular cell tumor consists of closely packed round cells with prominent intracytoplasmic PAS-positive, amylase-resistant granules. Ultrastructurally, these granules consist of secondary lysosomes. Although previously thought to be of skeletal muscle origin, more recent studies have refuted this theory, and granular cell tumor appears to be most often a tumor of Schwann cell origin.
- *Malignant lymphoma* may occur within skeletal muscle, but whether this represents primary intramuscular tumor or local or metastatic spread is not always certain. Infiltration of skeletal muscle by neoplastic lymphocytes must be distinguished from lymphocytic infiltration due to immune-mediated myositis. Lymphoma cells are typically relatively homogeneous and often atypical, and surround myofibers and efface skeletal muscle architecture without obvious myofiber necrosis or "coring out" of myofibers (Fig. 2.120).

Secondary tumors of skeletal muscle

The *infiltrative variant of lipoma* arising within the subcutis is characterized by prominent intramuscular invasion (Figs 2.121, 2.122). This tumor, although locally invasive, does not metastasize, and wide surgical excision is generally curative. Infiltrative lipoma occurs most often in dogs and horses. Although uncommon, *subcutaneous mast cell tumors* can invade underlying skeletal muscle. *Other soft tissue sarcomas* arising in the subcutis, such as fibrosarcoma and hemangiopericytoma, can also extend into adjacent skeletal muscle. *Carcinomas,* such as squamous cell carcinoma, are often seen invading and destroying adjacent skeletal muscle.

In general, tumor metastasis to skeletal muscle is less common than metastasis to other organs. There is evidence to suggest that tumor cells in skeletal muscle microvasculature are destroyed at a higher rate than tumor cells within other organs, such as liver. Dermal melanoma of older gray horses often metastasizes to the muscle fascia, but less commonly involves the muscle itself. Skeletal muscle metastasis of canine prostatic carcinoma can result in foci of intramuscular fibroplasia, sometimes with associated chondroid differentiation, that can mimic focal or multifocal myositis ossificans (see Physical injuries

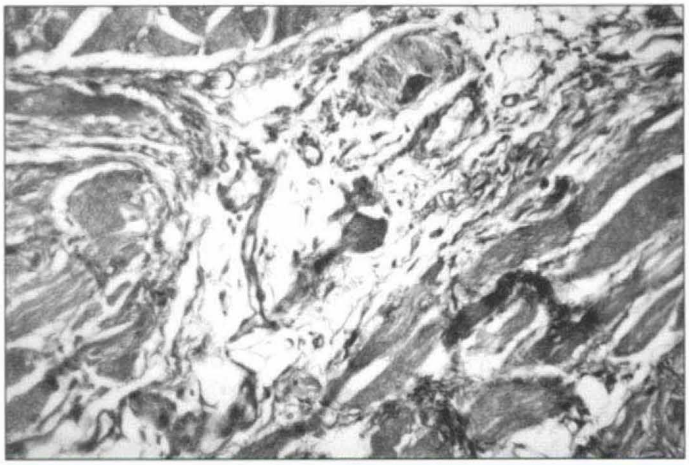

Figure 2.123 Irregular myofiber orientation with associated endomysial fibrosis in a **muscle pseudotumor** from a Great Dane dog. Masson trichrome stain.

of muscle). Diaphragmatic muscle is often a site of intraabdominal or intrathoracic tumor spread by "seeding."

Muscle pseudotumors

Muscle pseudotumors include a group of reactive lesions that can mimic neoplasia. *Localized myositis ossificans* and *musculoaponeurotic fibromatosis* qualify as muscle pseudotumors but are discussed in the sections Physical injuries of muscle and Tendons and aponeuroses, respectively. An *unusual muscle pseudotumor* has been seen in two dogs, both Great Danes, in which a localized swelling in the dorsal scapular area was found to be associated with skeletal muscle. These lesions were composed of irregularly arranged mature skeletal muscle fibers with marked cytoarchitectural alterations and associated endomysial fibrosis (Fig. 2.123). Muscle pseudotumors in man are most often thought to be *associated with muscle trauma*, and a similar etiology seems logical for animals.

Tendons and aponeuroses

GENERAL CONSIDERATIONS

Tendons are derived from the same pool of embryonic mesenchymal cells as muscle fibers and it is very likely that although commitment occurs early, the differentiation of myoblastic and tenoblastic cells occurs relatively late. In some tendons, notably the suspensory ligaments of the limbs of the foal, the first wave of differentiation is as a muscle and only subsequently does further development produce a tendon. As might be suspected, the two end products have many structural similarities. *The basic structural units of tendons are bundles of collagen that cluster around a central elongated collection of tendon fibroblasts or tenocytes and capillaries.* Multiples of these units combine to form *fascicles* somewhat like primary muscle bundles, and fascicles in turn combine in clusters to form the *complete tendon*, which is ensheathed by a looser fibrous tissue called the *peritenon*.

Tendons are quite completely, though sparsely, supplied with blood vessels but in keeping with low nutritional requirements once the tendon is formed, relatively wide distances may separate adjacent parallel vascular channels in mature animals. Segments of long tendons may appear to be almost avascular at times, if flow volume is used as an indicator of vascularity.

At birth, tendons are cellular and vascular, as tenoblasts or tenocytes elaborate the orderly, synchronously kinked, parallel collagen bundles. The kinking provides a mechanism for absorbing stretch impact and provides an interlocking adhesive strength for adjacent fibers, which is enhanced by the presence of an amorphous, noncollagen ground substance that acts as a "glue." The physical properties of tendons are largely dependent on cross-linking of collagen molecules.

TENDON AGING AND INJURY

As tendons age, they change color from pearly white to yellow-tan and may acquire an even darker brown or red-gray center. Some of these color changes are related to repeated minor episodes of capillary hemorrhage that occur even in normal, unworked horses or cattle. The distinction between normal and abnormal is often a difficult one to make, but *it is normal (in the sense of usual and harmless) for tendons to undergo focal cartilaginous metaplasia.* Osseous metaplasia in tendons, however, is distinctly pathologic.

An important issue in the process of tendon aging and injury relates to predisposing lesions. Cartilaginous metaplasia, ischemia, and local fibroblastic proliferations have been regarded as predisposing changes, but they are frequently found in normal animals. It now seems that preparatory events need not be postulated to explain most of the lesions seen. *The predilection sites for tendon damage are predictably those with anatomic weakness or that receive disproportionate stretch forces.* The subsequent changes relate to stretching of tendon collagen and vessels.

When a tendon is stretched beyond load capacity, fibrils are very likely to be pulled out of kink register and even if no fibrils break, the tendon will be subsequently weaker at that point. Such *stretch lesions* are usually accompanied by ruptured collagen as well, although it may be only microscopically detectable. The sequence of events that follows involves the rupture of capillaries, release of fibrin, stimulation of tenocytes and/or peritenon cells to form myofibroblasts, and the formation of scar collagen that in many ways resembles the original tendon. In the acute stages, this process makes the tendon swollen, warm, and painful; in the chronic stage, the tendon is larger and longer than normal. Original tendon is uniquely constructed entirely of type I collagen. *When tendon repairs, the mature scar will no longer consist only of type I collagen since 20–30% of the replacement tissue will be type III collagen, a form of fiber less able to withstand stretch forces than type I.* It is likely that alterations in the proportions of the component glycosaminoglycans (e.g., hyaluronic acid, dermatan sulfate, chondroitin sulfate) occur following injury and during repair. The differences between a minor sprain and incomplete or even complete tendon rupture are differences in quantity not form. In larger lesions, there is a greater chance for tendon necrosis and sequestration, and a greater chance for the formation of a fibrin clot that is not longitudinally oriented by tension. This may lead to misalignment of the scar fibrils, adhesions to adjacent sheaths, and irregular contours of the tendon. Since myofibroblastic scar tissue is capable of contracting as it matures, the result of tendon repair is not necessarily a longer tendon but, inevitably, a weaker tendon.

PARASITIC DISEASES OF TENDONS AND APONEUROSES

Nematodes of the family Onchocercidae make connective tissue, vessel walls, or tendons of cattle and horses their preferred habitat. Most of these, and especially those that live in tendons, belong to the genus *Onchocerca*, although not all *Onchocerca* parasites have an affinity for tendons. Three different parasites infect domesticated cattle, *Onchocerca gibsoni, O. gutturosa,* and *O. lienalis,* but full investigation may eventually increase the number. Three different parasites, *O. gutturosa, O. reticulata,* and *O. cervicalis* infect horses. *Onchocerca gibsoni* infects cattle in Africa, Asia, and Australia. *Onchocerca gutturosa* occurs in cattle and horses in North America, Africa, Australia, and Europe. *Onchocerca lienalis* is considered to be a separate species by some and synonymous with *O. gutturosa* by others; it is not as widespread as is *O. gutturosa,* but is seen in cattle in Australia and North America. *Onchocerca reticulata* infects horses in Europe and Asia, and *O. cervicalis* infects horses worldwide. The prevalence of onchocerciasis can be very high, ranging from 20–100% of the population in endemic areas, but *infection by these connective tissue parasites has been greatly reduced by widespread use of ivermectin as an anthelmintic.*

The adult worms, less than 1.0 mm thick and 50–80 cm long for the female, much shorter for the male, live in tendons, tendon sheaths, or connective tissues of the brisket or abdominal wall from which site they liberate *microfilariae* over long periods. The larvae make their way to skin where they are picked up by a blood-sucking parasite in which the next phase of development takes place.

Onchocerca gibsoni characteristically provokes and inhabits a "worm nodule" or "worm nest" on the *brisket or external surfaces of the hindlimbs* that may reach 3 cm in diameter. These fibrous lesions are important in the meat industry because the worms must be manually removed and this is time consuming if several dozen are present. The nodules may be palpable or moveable in the skin or they may be fixed to the dermis or ribs. Those in the flank are usually beneath the fascia lata and are not externally palpable. The adult worms inhabit fine tunnels in the discrete nodules of dense fibrous tissue where they form a tangled mass in a milky fluid. Female worms are just grossly visible but the smaller males are not. Sometimes old hemorrhages, or mineralized remnants of worms, are contained in the larger nodules, and microscopically many larvae may also be seen in the capsule as they exit, perhaps via lymphatic vessels. Microfilariae are rarely seen in lymph nodes or blood vessels, but these routes may be used to reach the skin where they collect in large numbers without stimulating a reaction. The intermediate blood-sucking host is probably a simulid or a culicoid insect.

Onchocerca gutturosa is most frequently located on the surface of the *ligamentum nuchae* of cattle adjacent to the thoracic vertebral spines and less frequently on the scapula, humerus, or femur. It is sometimes found in the horse. The adult worms, which are found in pairs, do not stimulate the formation of a nodule as is the case for *O. gibsoni*, but lie in loose connective tissue. They apparently cause no disease or reaction and in spite of their wide distribution around the world they are rarely dissected out or even detected. The intermediate hosts are not all known, but simulids can transfer the infestation.

Onchocerca lienalis lies in delicate tunnels in the gastrosplenic ligament and in the splenic capsule of cattle.

Adult worms of *Onchocerca cervicalis* live between the fibers of the ligamentum nuchae over the shoulder or neck of the horse or in loose connective tissues nearby. A second very similar parasite, *O. reticulata*, resides at a much lower level of frequency in the tissue around tendon sheaths adjacent to the carpus or suspensory ligaments or at the fetlock where a low-grade tissue reaction is initiated by the presence of adult worms. When the worms die, they mineralize and are engulfed by a poorly defined, dense, fibrous reaction. The infestation usually goes undetected and most horses are apparently asymptomatic. The long threadlike female worm is less than 1 mm thick but 50–70 cm long. Larvae are hatched from eggs prior to their release from the uterus, and they make their way through connective tissue to the skin where they presumably travel in the dermal lymph vessels. Larvae (microfilariae), which are about 4 μm wide and 200–250 μm long, tend to aggregate in certain skin regions, particularly the skin of the ventral abdominal midline, the inner thighs, and the eyelids. Living microfilariae seem to stimulate no reaction whatever, but dead larvae are capable of stimulating a response that involves lymphocytes and eosinophils. These local nodular responses may be seen in skin accompanied by pruritus, alopecia, and scaliness, and they may be seen histologically in areas where larvae are particularly numerous. Living larvae can be quite readily detected as loosely curled structures just under the epidermis and adjacent to adnexal skin structures in histological sections. Microfilariae of *O. cervicalis* and *O. reticularis* are transported to another horse by blood-sucking insects in which an obligatory stage of development occurs. Several different insects may be suitable hosts, but only *Culicoides* midges and mosquitoes of the *Anopheles* species have been confirmed in the role.

FIBROMATOUS DISORDERS OF TENDONS AND APONEUROSES

A number of degenerative disorders resulting in proliferation of fibrous, cartilaginous, and osseous tissue within tendons and aponeuroses are described in man and animals. Some such disorders are inherited, whereas others are acquired. For the most part, little is known regarding the pathogenesis of these processes.

Fibromatoses *are defined as progressive, infiltrative, nonmetastasizing fibroblastic lesions.* A variety of such disorders are recognized in humans, and a similar disorder occurs in the horse. These lesions, although considered nonneoplastic by most investigators, can exhibit marked local infiltration and distortion of affected muscle.

Musculoaponeurotic fibromatosis (desmoid tumor) of the horse

A peculiar progressive fibrosing disorder, **musculoaponeurotic fibromatosis (desmoid tumor)**, occurs in the horse. Although most cases involve the *pectoral region*, other sites are possible. Affected horses develop progressive distortion and induration of affected musculature due to proliferation of fibroblasts, myofibroblasts, and subsequent fibrosis dissecting between muscle fibers and fascicles that is often accompanied by foci of lymphocytic infiltration (Fig. 2.124). Although wide surgical excision may be curative, in most cases the extent of the lesion at diagnosis precludes effective surgical intervention. Studies of a small number of horses have revealed fluid-filled pockets of apparently sterile inflammation deep within the lesion, suggesting that this disorder in horses may be a peculiar response to trauma such as from an injection or ruptured bursa.

Fibrodysplasia ossificans progressiva (FOP)

Fibrodysplasia ossificans progressiva *(FOP) is a progressive fibrosing and ossifying lesion of tendons and muscle-associated aponeuroses that occurs in humans and cats.* This disorder was previously referred to as myositis ossificans progressiva, which is incorrect, as the disorder involves muscle-associated connective tissue and is not a primary myopathy (see Physical injuries of muscle). Fibrodysplasia ossificans progressiva in man is a devastating disease of children and young adults. Progressive fibrosis and ossification of muscle-associated connective tissue, including tendons and fascia, result in eventual incapacitation. This disorder is inherited as a dominant trait.

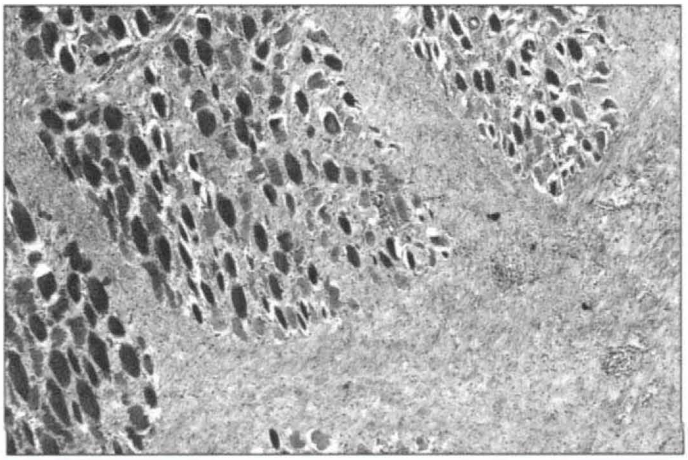

Figure 2.124 Perimysial and endomysial connective tissue dissecting between muscle bundles and myofibers in a horse with **musculoaponeurotic fibromatosis**. Foci of lymphocytes are also visible within the perimysial connective tissue. Masson trichrome stain. (Courtesy of BJ Cooper.)

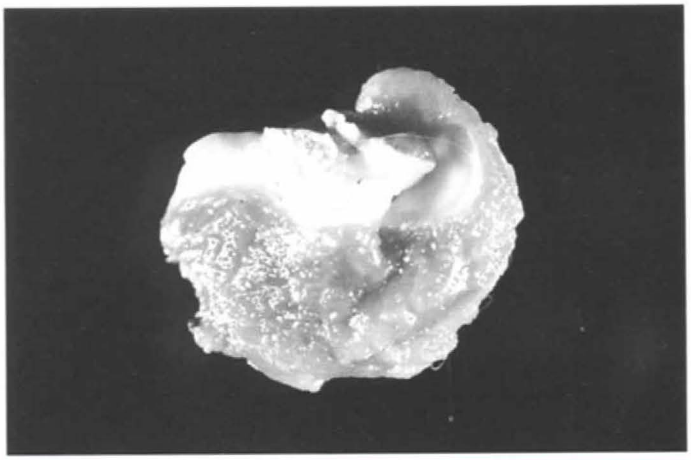

Figure 2.125 Marked thickening of the gastrocnemius muscle fascia of a young adult cat with fibrodysplasia ossificans progressiva. (Courtesy of L. Fuhrer.)

A similar disorder occurs sporadically in young to young-adult *cats*. Age at diagnosis in the cat has ranged from 10 months to 6 years. To date, inheritance of FOP has not been confirmed in the cat. Clinical signs include progressive stiffness of gait, decreased joint mobility, increased bulk and firmness of muscle, and pain upon handling. Radiography and gross pathology reveal *characteristic thickening with mineralization and ossification of muscle fascia* (Fig. 2.125). The histopathologic features are of fibroblastic proliferation within fascia with subsequent cartilage and bone formation. Early lesions may have an associated mild lymphoid infiltrate.

An inherited form of what was described as generalized myositis ossificans has been described in young *pigs*. The lesion in these pigs, however, was a proliferation of periosteal bone involving vertebrae, ribs, and tarsal bones, suggesting that this may be a primary bone disorder.

CYTOPATHOLOGY OF NERVOUS TISSUE

Nervous tissue is highly specialized and structurally complex, and neuropathology has always tended to be set apart as an arcane specialist area, to be entered only by a select few. However, the veterinary pathologist cannot escape having to deal with it frequently, and we attempt in this section to provide a contemporary basis for understanding veterinary neuropathology.

The principal cells of the central nervous system (CNS) are *neurons* and *glia*, plus cells of the meninges and blood vessels. *Macroglia* (astrocytes, oligodendrocytes, ependymal cells) are of neuroectodermal origin; *microglia* are derived from bone marrow.

Neuron

The **neuron** *is the fundamental cell of the nervous system, and ultimately all neurologic disease must involve functional disturbances in neurons.* In conventional histopathology, the term "neuron" refers to the cell body of the nerve cell that often is only a small part of the total cell volume. For the purposes of comprehending pathogenetic mechanisms, it is important to remember always that the neuron comprises both the *cell body* ("soma" or "perikaryon") and the cell processes, in particular the *axon*. The whole cell constitutes a structure concerned with the generation, conduction, and transmission of impulses, and in some cases a single cell performs this task over a very long distance. For example, in a lumbar dorsal root ganglion of a horse, the cell body of a sensory neuron may project a process distally to the extremity of the hind foot and centrally to the caudal brain stem, making it without doubt the largest cell in the body. If the soma were enlarged to the size of an orange, the processes would have the dimensions of a garden hose and would be over 20 km in length. Pathologic reactions within one cell may therefore be separated by considerable distance. Also, neurons function in hierarchical chains organized into anatomic systems.

The soma is the metabolic factory for the whole cell and the great bulk of synthetic and degradative operations take place there. The axons are serviced throughout their length by a bidirectional transport system that moves components both away from and towards the soma (anterograde and retrograde transport respectively). The transport mechanisms are fuelled by the consumption of energy along the course of the axon. Many components are moved in the anterograde direction within 25 nm vesicles by a "fast" transport system at a rate of 20–30 mm/h. The motor for this system, intimately associated with the neurotubules, is an ATPase called *kinesin*. Larger vesicles of about 500 nm are transported retrograde by this fast pathway, and the translocator is an isoform of dynein, the ATPase which powers cilia and flagella in other types of cell. Mitochondria are also moved by fast transport, but at a somewhat slower rate. Neurofilaments, neurotubules, and some soluble proteins move by slow transport in the anterograde direction only, at a rate of about 1–3 mm/day, and are degraded when they reach the terminus. Should the operations of the soma or the transport systems be impaired, the health of the axon will suffer and, appropriately, in most instances the largest and longest axons are most vulnerable. Equally, *when a neuron is fatally damaged the whole cell dies*, and the consequent changes will spread over the whole extent of its domain. However, long lengths of the axon may degenerate without compromising the viability of the remainder of the cell and without inducing dramatic morphologic change in the soma, and there is often scope for adequate regeneration of the lost axonal extremity. These issues will be addressed more fully below, under *axonopathy*.

The vitality of individual neurons is sustained by their active relationship with other neurons, or other types of cells with which they interact. If a neuron dies, surviving neurons with which it has synaptic connections may regress due to lack of activation, undergo atrophy, and eventually die. This process is called *transynaptic degeneration* and it will progress along specific anatomic pathways. It is useful also to realize that neurons are extremely diverse pharmacologically and biochemically; this is well illustrated by the highly selective and regionalized effects of different toxins and metabolic disturbances. The selective effects of tetanus and botulinum toxins are good examples.

During organogenesis, vast numbers of neuroblasts proliferate and immature neurons migrate to their final destinations. As large numbers of developing neurons are superfluous, there is a need to select amongst them and eliminate the excess by apoptosis. Discrimination between those that will survive and those that are effete will depend on the transfer of trophic factors between cells including from glia to neurons. Around the time of birth, and for variable periods afterwards, the latter stages of the process may still be extant, particularly in the cerebellar cortex and paravertebral ganglia. It is probable that the signals between cells during growth and physiological activity are the same as those which if overloaded may lead to neuronal injury. The margin of safety between proper levels of transmitter and too little or too much is very narrow.

The mature neuron is a postmitotic cell and there is a net loss throughout adult life, especially during senescence. Thus in a thorough scan of a histologic section from a senile animal, it might be expected that a few degenerate neurons will be found, even when fixation artifacts are minimal. There is however continuous postnatal generation of neurons in some parts of the brain and in at least some species. In species so far examined, neuroblasts generated in the dentate gyrus of the hippocampus and from the progenitor cells of the subependymal zone between the lateral ventricle and the caudate continue to migrate postnatally to the olfactory bulb. These migrations do not depend on guidance from radial glia as in the embryonic brain. Rather the postnatal neuroblasts migrate in a chain designated as the "rostral migratory stream" strictly delineated by rows of astrocytes. There is evidence that new neurons are generated in the olfactory bulb. Axonotomy procedures that sever the pituitary stalk in the rat and some other mammalian species are known to be followed by re-establishment of functional hypothalamic–hypophyseal connections within a few weeks. Cells with neuron-like characters appear to migrate through the neuropil of the median eminence to congregate on its surface. The functional significance of these migrations and the dynamics of these populations are obscure. It is assumed that the olfactory migrants and their proliferation in situ in the bulb may have a bearing on the development of olfactory neuroblastomas.

Degenerative changes of the nerve cell body

Nuclear margination – the neuronal nucleus is usually single and centrally located (Fig. 3.1), and its *margination can be taken to indicate*

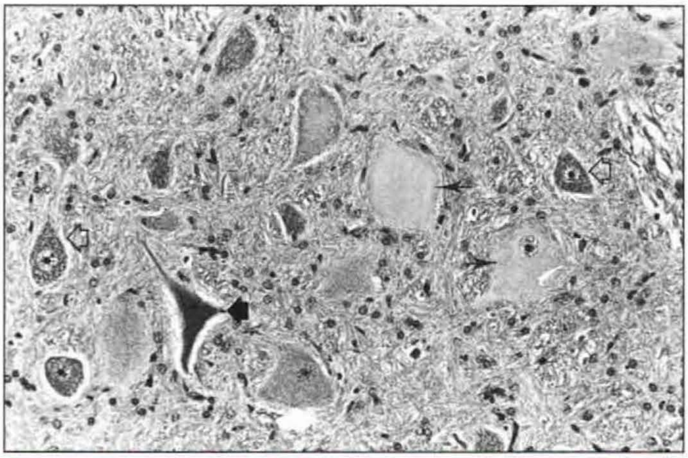

Figure 3.1 Red nucleus in swayback in a goat. Normal neurons (open arrows); **central chromatolysis** (arrows); shrunken, necrotic neuron (closed arrow).

nonspecific degeneration, especially when combined with loss of staining affinity. However, an eccentric nucleus can be normal in some groups of smaller neurons, and is often present in the large cells of the periventricular gray matter such as the mesencephalic nucleus of the trigeminal nerve and the olives. These cells also tend to have a "chromatolytic" appearance.

Chromatolysis is a change in appearance of the soma brought about by the *dispersal of the rough endoplasmic reticulum* (Nissl granules), and is subclassified as *central* or *peripheral* according to its locus within the cell body. Its assessment depends upon an appreciation of the prominence and distribution of Nissl granules seen normally at the particular location. There are no artifactual changes that mimic chromatolysis and, provided it is accurately identified, it can always be regarded as a lesion. A number of special stains, such as cresyl violet, will demonstrate it better than routine hematoxylin and eosin.

Central chromatolysis is best appreciated in large neurons of some of the brain stem nuclei, in the spinal motor neurons, and peripheral ganglia. The chromatolytic cells are swollen and rounded, rather than having the normal angulated appearance, and the nucleus becomes eccentric. Nissl granules clear from the central region of the cell body, leaving this zone with a smooth ground-glass appearance (Fig. 3.1). Central chromatolysis occurs in a number of pathologic situations. It is often seen in bulbo-spinal motor neurons and sensory neurons whose peripherally projecting axons are injured, and especially when the injury occurs close to the cell body. The reaction follows such injury quickly, beginning within 24 hours, and becoming maximal in 1–3 weeks. When the dynamics of axonal flow are remembered, it can be appreciated that such an event will have a major feedback on the soma. In effect, the cell must rearrange its metabolism to adapt to its changed circumstances, and organize for a regenerative effort, involving the reconstruction of an axonal segment greater in volume perhaps than its surviving volume. In this context, *central chromatolysis has been termed the* **axon reaction**, *and represents an anabolic adaptive response*. In this reaction, the nucleus becomes extremely eccentric, and develops a prominent nucleolus and a basophilic cap of RNA on its cytoplasmic aspect. The Nissl substance disperses, and the cytoplasm becomes rich in free ribosomes, lysosomes, and mitochondria. There may also be some increase in the number of neurofilaments. All these changes reflect a shift in metabolic activity, with a switch towards increased synthesis of structural cellular proteins, and a marked decline in synthesis of transmitters. With completion of successful axonal regeneration, the chromatolytic soma returns to normal, sometimes passing through a densely basophilic phase in which it is packed with Nissl granules.

In some circumstances following axonal injury, central chromatolysis may proceed to cell death or permanent atrophy, and this is usually the case in neurons whose axons project entirely within the central nervous system (CNS). *In general, the closer to the cell body the axonal lesion, the more likely is the cell to die.* Those cells destined to die have swollen achromatic cytoplasm depleted of organelles.

Central chromatolysis is also induced in more overtly neuronopathic conditions, most notably the numerous motor neuron degenerations described in various species, and it is a feature of the pathology of perinatal copper deficiency in the sheep and goat (Fig. 3.1). Similarly, it is a striking feature in autonomic ganglia in equine and feline dysautonomias. In all such cases, the affected cells often proceed to necrosis and dissolution (Gudden's atrophy). In many of these degenerative neuronopathies, the cytoplasmic alteration is due to massive accumulation of neurofilaments in the soma (see Progressive motor neuron diseases, p. 372). Nuclear margination is not as marked as in the axon reaction, and the prominent nucleolus and nuclear cap are not evident. These differences distinguish a regressive state from a regenerative one.

Peripheral chromatolysis indicates clearing of the periphery of the soma, with Nissl granules persisting around the nucleus. This change is generally associated with slight cellular shrinkage rather than swelling. It is a nonspecific lesion and can often be regarded as an early stage en route to necrosis.

In both forms of chromatolysis, microglia and astrocytes may proliferate and cover large expanses of the cell surface, thereby separating terminal boutons from the neuronal surface.

Neuronal atrophy – loss of cytoplasmic bulk and reduction in size (Fig. 3.2A) might be expected in situations of permanent loss of synaptic connections (see transynaptic degeneration above), as when central axons undergo Wallerian degeneration but fail to regenerate.

Ischemic necrosis – in this *characteristic acute degenerative change*, the cytoplasm of the neuronal soma becomes shrunken and distinctly acidophilic (Fig. 3.2B), and the nucleus progresses through pyknosis and rhexis to lysis, leaving the coagulated cytoplasmic remnants to undergo liquefaction without undergoing phagocytosis. The remnant "ghosts" may persist for several days. *The reaction is not confined to ischemia*, and may be seen in the cerebral cortex in hypoxia, hypoglycemia, the encephalopathy of thiamine deficiency, and in some chemical intoxications, such as organomercurialism and indirect salt poisoning. Following seizures, it may frequently be found in the dentate gyrus of the hippocampus and the cerebellar Purkinje cells. There are usually obvious proplastic changes in astrocytes and capillary endothelia in the vicinity of the affected neurons.

This raises the concept of **excitotoxicity**, in which neuronal degeneration and death are considered to result from excessive stimulus by an excitatory neurotransmitter. This phenomenon is thought to operate particularly in those neuronal systems utilizing glutamate as a transmitter, such as the cells in the hippocampal areas mentioned above. Paradoxically, glutamate is potentially highly toxic to neurons, and normally is rapidly cleared by the glia following its release. Excessive release or defective clearance of glutamate from the environment of postsynaptic neurons predisposes to excitotoxicity, and

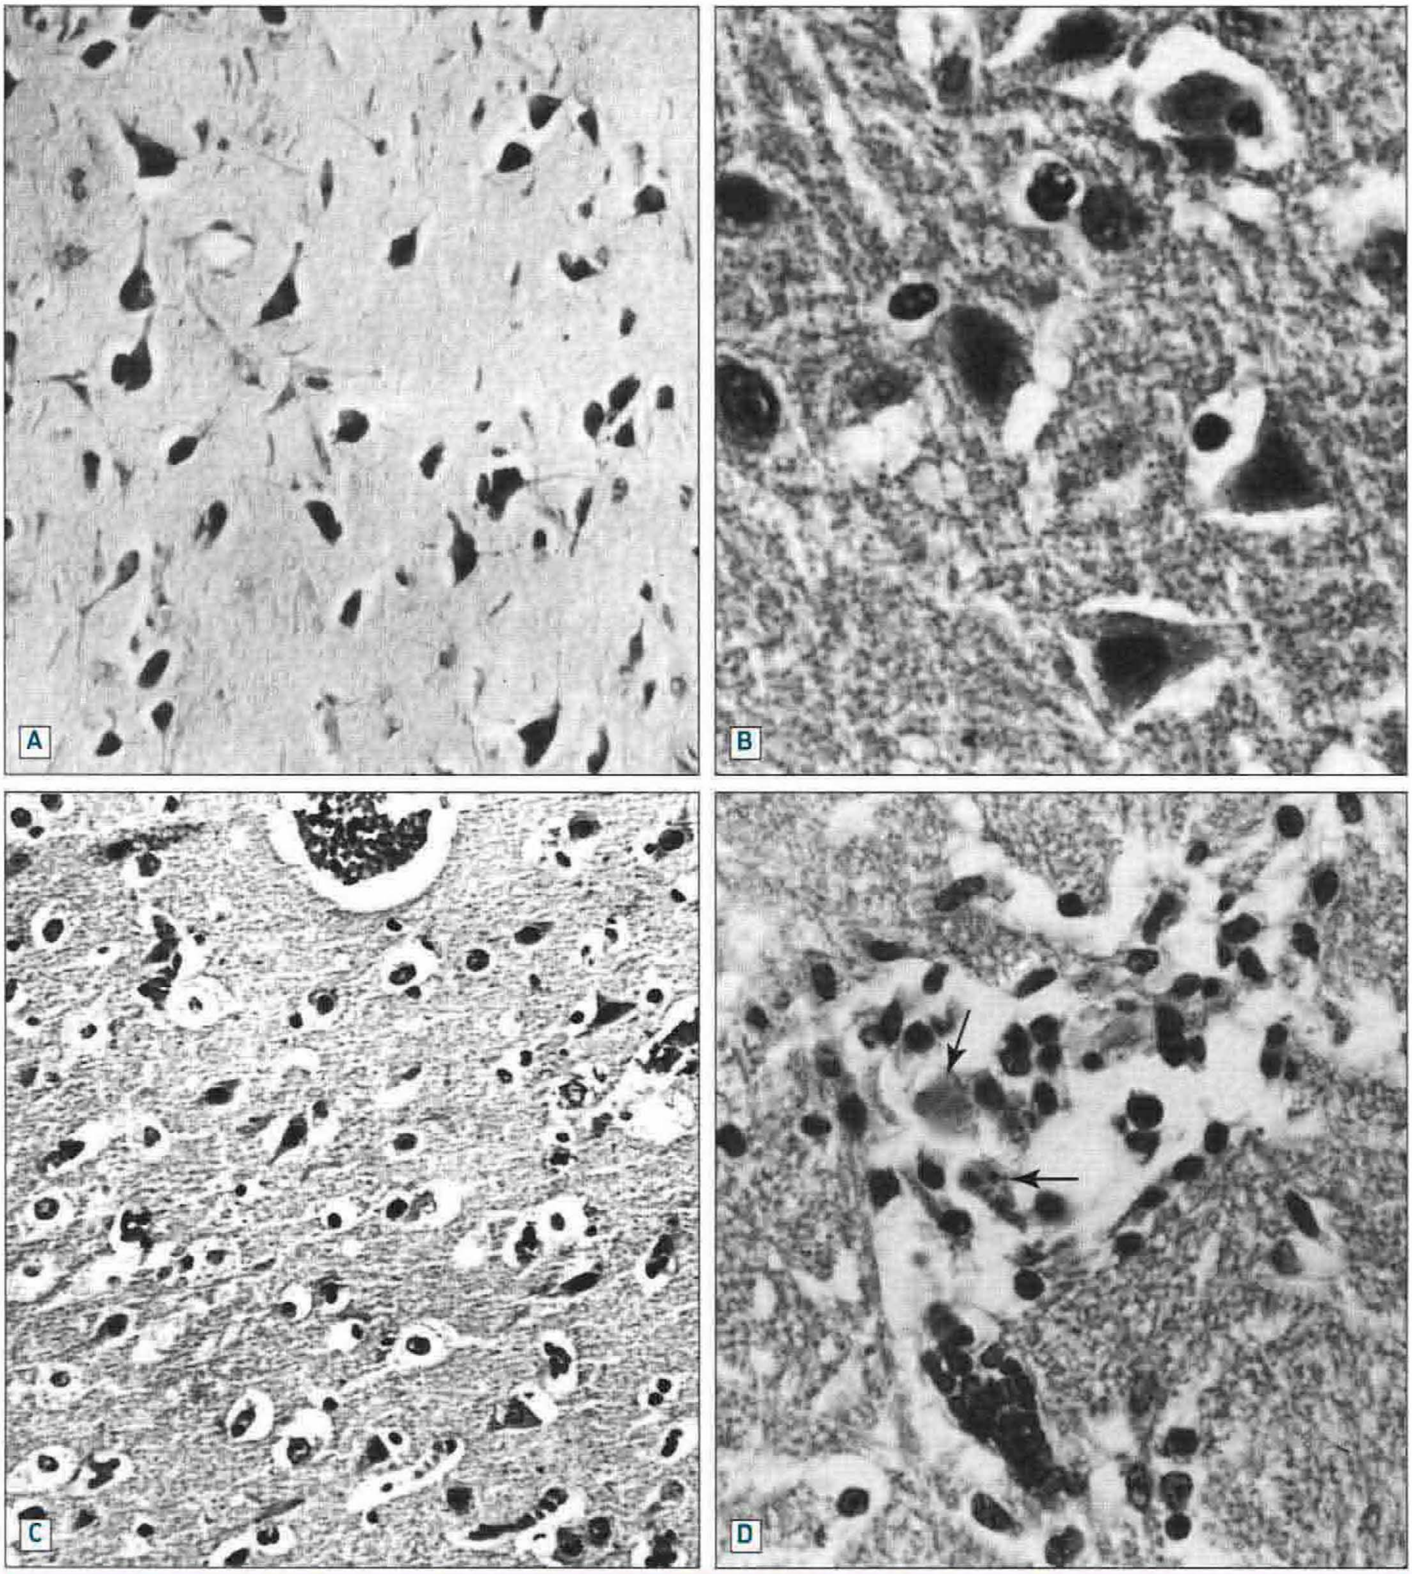

Figure 3.2 A. Chronic nerve cell degeneration. B. Early ischemic nerve cell degeneration. Note cell shrinkage with condensed cytoplasm. **C. Autolyzing cerebral cortex** easily misinterpreted as liquefactive necrosis. **D. Neuronophagic nodule** in equine encephalitis; fragmented neuron (arrows).

such circumstances are provided by hypoxia and hypoglycemia. The pathogenesis is thought to involve ionic overloading of the cell, acute swelling, and then cell death with cytoplasmic coagulation and eosinophilia.

Neuronal necrosis may occasionally be expressed as cytoplasmic shrinkage and basophilia with nuclear dissolution (Fig. 3.1). Shrunken basophilic neurons with normal nuclei ("*dark neurons*") are generally taken to be artifactual, and are often numerous.

Liquefactive necrosis is often at risk of being misinterpreted as autolytic change and fixation artifact, particularly shrinkage artifact (Fig. 3.2C). A lesion can sometimes be distinguished from an artifact by the presence or absence of significant alterations in other tissue cells, for instance the swelling of capillary endothelium or indications of glial proliferation.

Necrosis with neuronophagia – in many viral infections, the death of neurons provokes the gathering of phagocytes around the cell body (**satellitosis**), and removal by them of the debris, forming **neuronophagic nodules** (Fig. 3.2D). This is usually a response of the microglia, although satellite perineuronal oligodendrocytes may also proliferate in response to neuronal injury. Neuronophagia may also be seen in metabolic or toxigenic neuronal degenerations, but is generally not as extensive as in viral infection.

Vacuolar degeneration – neurons in the early stages of acute injury inflicted by viruses, toxins, or metabolic derangements, such as excitotoxicity, may develop numerous small cytoplasmic vacuoles, usually reflecting *mitochondrial swelling*. However, *artifactual peripheral vacuolation is very common*, giving the periphery of the cytoplasm a foamy web-like appearance. This is particularly so in the cerebellar Purkinje cells and large neurons of some of the brain stem nuclei.

Large neuronal vacuoles, few in number per cell, are occasionally observed in otherwise normal brains, and may be seen in the red and oculomotor nuclei of aged cattle and sheep. When they occur at high frequency in the neurons of the medulla and midbrain, they are virtually pathognomonic of *scrapie* in sheep and goats (Fig. 3.3). Widespread neuronal vacuolation with single or multiple large vacuoles, unexplained as to pathogenesis, is occasionally seen in dogs and cattle with progressive neurological dysfunction.

Vacuolar change is strikingly evident in those *lysosomal storage diseases* in which the stored material is extracted during processing, or is unstained by the routine methods. In these situations, the neuron can become dramatically bloated by the accumulation of myriad secondary lysosomes that displace the normal organelles and distend the soma with a foamy mass of apparently empty vacuoles. In most cases, the storage process involves other cell types inside and outside the nervous system, and is accompanied by additional neuropathological manifestations (see Storage diseases).

Storage of pigments and other materials – neurons may accumulate large quantities of **ceroid/lipofuscin** or other pigments, either as a consequence of aging, or in storage disorders involving such substances. The pathogenesis of the *ceroid/lipofuscinoses* remains unclear but, as is discussed elsewhere, there is a genetic basis in some instances, while in others unspecified environmental factors may be involved. The complex storage material accumulates as granules in a manner analogous to the other lysosomal storage diseases, although a clearly defined limiting membrane is not usually apparent ultrastructurally. When the process is intense, rusty-brown discoloration of the gray matter and ganglia may be evident grossly.

Neuromelanins may also accumulate excessively in those midbrain nuclei where they are usually present in modest amounts, and extensive neuromelanosis can occur in sheep chronically poisoned by *Phalaris* sp. In extreme cases, the gray matter and ganglia may have macroscopic green discoloration.

Siderotic pigmentation of neurons, in which the cells become encrusted with basophilic complexes of iron, calcium, and phosphorus, may be found near contusions and hemorrhages. It is not known, however, whether the iron is derived from the hemoglobin or from intracellular iron-containing respiratory enzymes. The neurons may be otherwise normal, or their degeneration may produce small lakes of basophilic deposit. The latter are common in the neonatal cerebellar cortex.

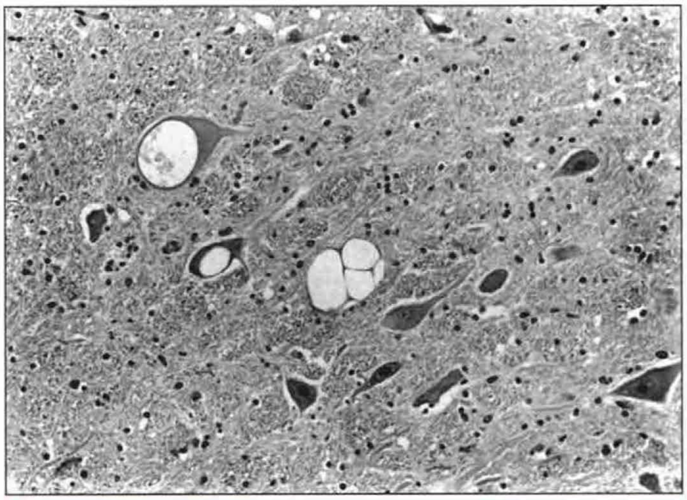

Figure 3.3 Neuronal vacuolation in scrapie in a sheep. (Courtesy of RF Slocombe.)

Viral inclusion bodies – the best known is the *Negri body* of rabies, which is eosinophilic and intracytoplasmic. Herpesvirus inclusions are characteristically intranuclear, while those of the paramyxoviruses such as *Canine distemper virus* may be intracytoplasmic or intranuclear. The use of specific immunostains has greatly facilitated the identification of viral inclusions.

Non-viral eosinophilic cytoplasmic inclusion bodies also occur. Sometimes they are an incidental finding in otherwise normal brains at sporadic locations; in cats, they can sometimes be found in the pyramidal cells of the hippocampus and lateral geniculate nuclei.

More specific inclusions have been described in people and animals in neuronal degenerative diseases. In humans, ultrastructural differences define several types of inclusion: **Hirano**, **Pick**, **Lewy**, **Lafora**, and **Bunina bodies**. *Hirano-like bodies*, appearing histologically as elongated eosinophilic inclusions and, ultrastructurally, as masses of beaded filaments, are reported in horses and dogs, together with other structures having some of the features of Bunina bodies. Further definition of these types of inclusions in animals is required, and their pathogenetic significance is not understood; they are a feature of equine motor neuron disease (Fig. 3.4). *Bunina bodies* are small eosinophilic inclusions of 2–5 μm, sometimes in small clusters or chains that characterize human *amyotrophic lateral sclerosis*; similar inclusions are occasionally observed in degenerative and inflammatory neurological disease in animals.

Lafora bodies are occasionally observed in neurological disease, but most frequently are incidental findings in aged animals. They are basophilic to amphophilic inclusions that are strongly PAS positive and metachromatic, 5–20 μm in size, intracytoplasmic or in processes or free in the neuropil (Fig. 3.5). They represent an abnormality of carbohydrate metabolism producing glucose polymers called *polyglucosans*. In the very rare *Lafora disease* (see Storage diseases), they occur in massive numbers throughout the brain within the neuronal soma, the dendrites, and less commonly the axons; they are associated with severe myoclonus epilepsy.

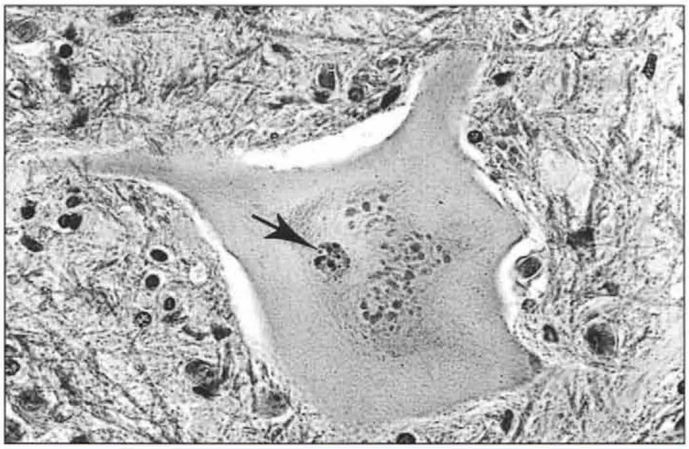

Figure 3.4 Spinal motor neuron in **motor neuron disease** in a horse. Chromatolysis, nuclear dissolution (arrow) and cytoplasmic inclusions.

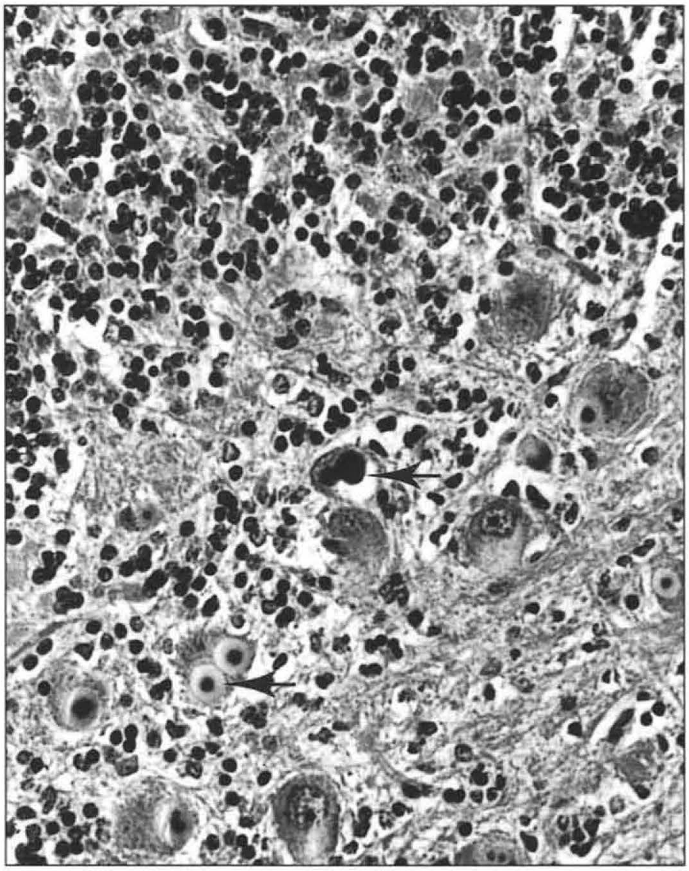

Figure 3.5 **Lafora bodies** in Purkinje cells (arrows) in a dog.

Mucocyte (Buscaino body) is the term applied to glassy, pale gray-blue bodies of variable size and shape, roughly the same size as neurons, seen on routinely processed and stained sections of brains. These are usually dispersed in the neuropil, typically in major white matter tracts and are considered by most to be an *artifact* of fixation and processing. They may be PAS positive, but are not always so, and there are rare reports of the accumulation of mucocytes associated with disease.

Axon

The axon acts as the solitary efferent extension of all neurons except those sensory neurons in the spinal ganglia whose peripherally directed myelinated axons function as dendrites, in that they conduct impulses towards the cell body. Axons may branch extensively towards their terminations.

The first part of the axon is called the *initial segment* and it has distinctive ultrastructure, related to its being the site of membrane ion channels critical for the initiation of a propagated action potential. The axoplasm contains mitochondria, endosomes, intermediate filaments (neurofilaments), microtubules (neurotubules), and secretory vesicles or granules containing neurotransmitters appropriate for the particular cell. The axoplasm will also contain soluble macromolecules such as enzymes.

Axons are sustained by their parent cell bodies and by the cells that invest them along their course. The axoplasm is devoid of ribosomes, and axoplasmic proteins are provided by the soma. Similarly, the lysosomal apparatus is limited in the axon, in terms of digestive capacity, and many obsolete materials and organelles are returned by retrograde transport to the cell body for complete degradation. The role of neurotubules in transport mechanisms has been mentioned above, and is critically important for the maintenance of the axon. Axonal diameter is distinctly reduced at the nodes of Ranvier, and these "strictures" are probably the reason that paranodal swellings filled with transported vesicles and organelles are a feature of many axonopathies in which transport has been disturbed.

Neurofilaments are responsible for the maintenance of axonal size and geometry, and are part of the generic cytoskeletal intermediate filament family. The proteolytic destruction of neurofilaments, triggered by the influx of calcium ions, is a common pathway for the collapse and disintegration of damaged axons. Larger axons are invested in a segmental manner by a *myelin sheath*, interrupted at the *nodes of Ranvier,* and penetrated at intervals by incisures.

All this sophistication is not resolved in routine light microscopic examination of paraffin-embedded tissues. The course of axons can be highlighted by the use of silver staining techniques, which emphasize the shrinkage artifact and distortion produced by routine tissue preparation. Nonetheless, with experience, many lesions in paraffin-embedded tissue can be interpreted but, particularly for peripheral nerves, plastic embedding of specimens is far preferable.

Types of **axonopathy** have been grouped according to whether they begin in the *proximal* or the *distal* portion of the axon, and whether they involve central or peripheral axons or both. Thus, for example, one may distinguish central and peripheral distal axonopathy, or central proximal axonopathy. The principal categories of axonopathy can now be discussed in broad terms.

Wallerian degeneration *denotes the changes that follow acute focal injury to a myelinated axon*, such that distal to the injury it becomes nonviable. When the soma is uninjured, there is potential for regeneration and, in peripheral nerves, this may be complete. Should the acute injury involve death of the cell body, then Wallerian degeneration of the axon will proceed as part of the dissolution of the entire neuron. The classical scenario for Wallerian degeneration is *acute focal mechanical injury in a peripheral nerve*, which effectively transects axoplasmic flow. Within 24 hours, the distal segment begins to degenerate fairly evenly along its length. Focal eosinophilic swellings occur, often containing accumulations of degenerate organelles, and

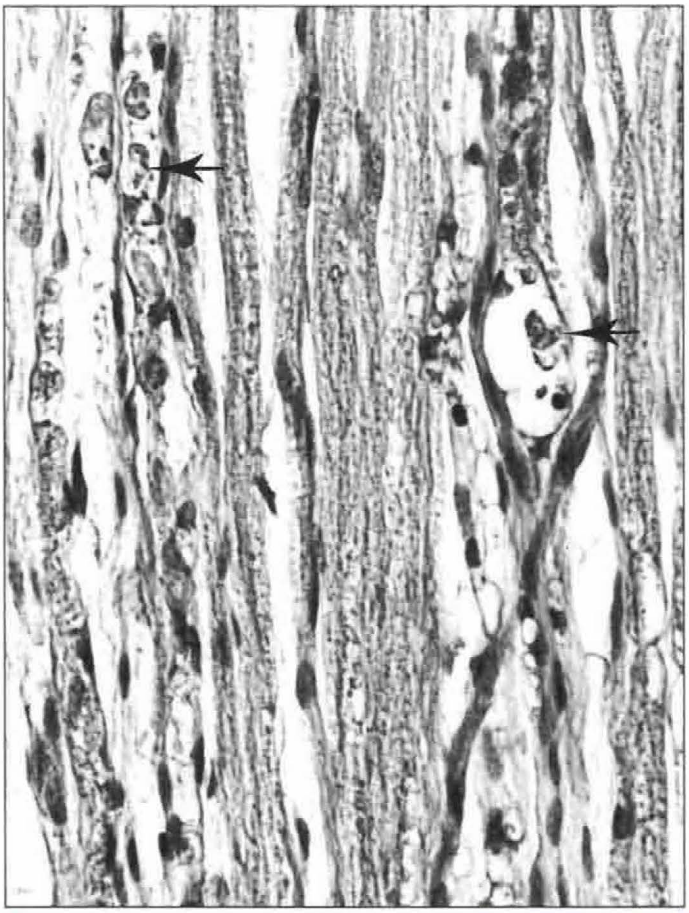

Figure 3.6 Wallerian degeneration in peripheral nerve (arrows) in copper deficiency in a goat.

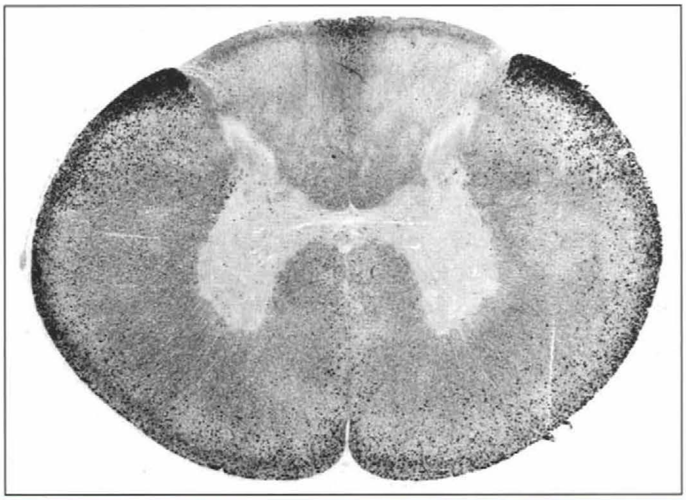

Figure 3.7 Degeneration of myelin in spinal cord in a pig with copper deficiency. Stained with Marchi. Note selective involvement of tracts, namely the fasciculus gracilis and dorsal and ventral spinocerebellar tracts. (Courtesy of MD McGavin.)

then fragmentation becomes evident by 48 hours or so. Schwann cells respond rapidly as myelin sheaths are made redundant by disintegration of the axon. Initially, myelin retracts from the nodes and then forms into *ellipsoids*, regarded originally as "*digestion chambers*" for the enzymic lysis of the axonal fragments (Fig. 3.6). The myelin itself condenses into aggregates and fragments and, together with remaining axonal debris, becomes the target of invading macrophages. Prior to this, the complex myelin lipids are progressively transformed into simpler neutral lipids over a period of 10–20 days, and this is reflected in the reaction to specific lipophilic stains. Macrophages enter the sheath and soon become filled with sudanophilic droplets. These lipid-laden cells may persist in the interstitium for many weeks. Some of the myelin debris is phagocytosed by Schwann cells themselves, and they begin to proliferate. As the debris is cleared away, proliferating Schwann cells form bands along the former course of the myelinated axons (*Bungner's bands*). Similar Wallerian changes occur proximal to the site of injury over several internodes. If conditions are favorable at the site of injury, sprouts from the axonal stump will find their way along the Schwann cell bands and be directed to their correct destinations. In most instances, the *growing axonal sprouts* advance at a rate of 2–4 mm/day, and the new axon will be invested by Schwann cell cytoplasm. Sprouting from individual axons is initially multiple and, by an unknown mechanism, one sprout is selected for the completion of regeneration. Thus a new axon may arise from a different soma than did the original. *The regenerated axon is remyelinated by Schwann cells*, although the new sheath is thinner than the original and nodal length variable and shorter. Should axonal regeneration be prevented, Schwann cell bands persist, and endoneurial fibrosis usually develops. *Abortive regeneration can lead to a tangled clump of neurites, Schwann cells, and fibrocytes at the injury site.* This will happen after transection if too great a distance separates the severed ends of the nerve fibers.

The effectiveness of regeneration in peripheral nerves is related to the comparatively simple axon/Schwann cell relationship, the presence of a basal lamina tube around each myelinated axon, and the replicative ability and metabolic resilience of the Schwann cells.

These conditions do not apply in the **CNS**, where the oligodendrocyte/axon relationship is far more complex – the oligodendrocyte is a relatively poorly regenerative cell type, there is no basal lamina scaffold, and the debris from central myelin is thought to inhibit axonal sprouting. The initial regressive changes of Wallerian degeneration are similar to those described for the peripheral nerves, although they proceed over a longer time-course. This is because the involvement of hematogenous macrophages is slower and less intense in the CNS, and activated microglial cells undertake most of the work. Axonal sprouting and some remyelination can occur. However, the poverty of the regenerative response results mostly in the *permanent disappearance of the axons, myelin, and oligodendrocyte cell bodies*. Some of the myelin debris may be phagocytosed by reactive astrocytes, and their processes extend to fill the vacancy, creating a ramifying network of astroglial scar tissue. Wallerian degeneration in the CNS is most commonly seen in the spinal cord, the optic tract, and the brain stem. Probably the best-known association is with the focal compressive myelopathies in the horse and dog (the wobbler syndromes).

During the active degenerative phase, recently phagocytosed and partially digested myelin debris may be distinguished in paraffin sections by the use of the Luxol fast blue/periodic acid Schiff stain. Degenerate myelin is well visualized by the Marchi technique (Fig. 3.7), or by immunostaining of myelin basic protein (MBP). End-stage plaques of astrogliosis may be demonstrated by traditional gliophilic stains or by the use of immunostaining for glial fibrillary acidic protein (GFAP – intermediate filament protein).

The destruction of myelin in Wallerian degeneration is known as **secondary demyelination** and is to be distinguished from **primary demyelination** in which the axon is initially undamaged (see below).

Distal axonopathy is seen in a number of chronic intoxications and genetically determined entities. It begins with degenerative changes in the distal reaches of the affected fibers and fairly characteristically involves the largest and longest, such as the proprioceptive and motor tracts of the spinal cord, the optic tract, and the recurrent laryngeal and other long peripheral nerves. Implicit in this pattern is a disturbance of anterograde axonal transport, upon which the maintenance of axonal wellbeing depends. In general, the process begins with the formation of focal axonal swellings containing degenerate organelles. These swellings are ovoid or circular eosinophilic structures commonly referred to as **spheroids**. This may progress to axonal fragmentation and attempted regeneration that may be abortive and is succeeded by further degeneration. These changes may develop focally in the distal regions of the axon and may extend more proximally with time. Diagnostically, the key is the recognition of the pattern of degenerative changes towards the terminations of long tracts (see Cycad poisoning, p. 364). The lesion is a feature of intoxication with certain of the organophosphates for example.

Proximal axonopathy is the contrasting situation in which focal swellings and degeneration begin in the proximal axonal regions. It is a pattern less likely to be encountered in natural animal disease than the distal variety. It is perhaps best exemplified by the large fusiform swellings, **torpedoes**, seen on the proximal axonal segments of cerebellar Purkinje cells in the mycotoxicosis of perennial rye grass poisoning and some storage diseases (Fig. 3.8). Such lesions may develop in central or peripheral axons and be associated with genetically determined or acquired disease. Proximal axonal swellings caused by the accumulation of neurofilaments are a feature of several neurodegenerative diseases described elsewhere in this chapter. A defect in the transport of phosphorylated neurofilaments results in the accumulation of masses of them, where they cause large, amphophilic axonal swellings. The fundamental pathogenesis remains undefined.

Axonal dystrophy is a term used to describe an axonopathic process characterized by the occurrence of *large focal swellings, often concentrated in the terminals and preterminals of long axons.* They are therefore frequently seen in and around relay nuclei in the brain, and in peripheral endings. The spheroids in axonal dystrophy can become extremely large, over 100 μm in diameter, and are filled with accumulations of normal organelles, degenerate organelles, and abnormal membranous and tubular structures. In hematoxylin and eosin sections, their appearance can be variable (Fig. 3.9A, B); some are densely eosinophilic, and either smooth or granular or vacuolated; others may be pale with central denser-staining cores; some may have a basophilic hue and evidence of focal mineralization. However, the swellings are not usually associated with any marked reaction on the part of surrounding elements and only rarely are seen to be undergoing fragmentation and dissolution. They are long-lasting, in contrast to the spheroids of acute axonal degeneration. Thinning of the myelin sheath around spheroids will occur as lamellae slip to accommodate the focal axonal enlargement (Fig. 3.10). The pathogenesis is unclear, but evidence points to a *disturbance of retrograde axonal transport.* The lesion is a common finding in the relay nuclei of the caudal brain stem in old age, and is a frequent accompaniment to neuronal storage diseases. It is the principal feature of diseases known as **neuroaxonal dystrophies**, of which several are recorded in the veterinary literature. In several such diseases, the topography of the axonal dystrophy seems to fit the clinical deficits but there is evidence that, in many situations, even intense development of the lesion has no functional significance. This seems generally so in regard to axonal dystrophy in the gracilis and cuneate nuclei.

Oligodendrocytes, Schwann cells, and the myelin sheath

The **oligodendrocyte** is one of the close companion cells of the neuron in the CNS. One population of these cells occurs as satellites to nerve cell bodies and may proliferate in the event of injury to the neurons, but the role of the satellites is essentially unknown. *The role of oligodendrocytes is to provide and maintain the myelin sheaths around those axons with a diameter greater than about 1 μm.* They are accordingly located in the myelinated tracts amongst the fascicles of axons and are referred to as *interfascicular oligodendrocytes.* Particularly in neonates and in cases of hypo- or delayed myelinogenesis, distinction histologically between astrocytes and oligodendrocytes can be uncertain. Oligodendrocytes are smaller than astrocytes, nuclear density is greater, and the cells are arranged in rows between fascicles. In immature animals, nuclei of oligodendrocytes are morphologically

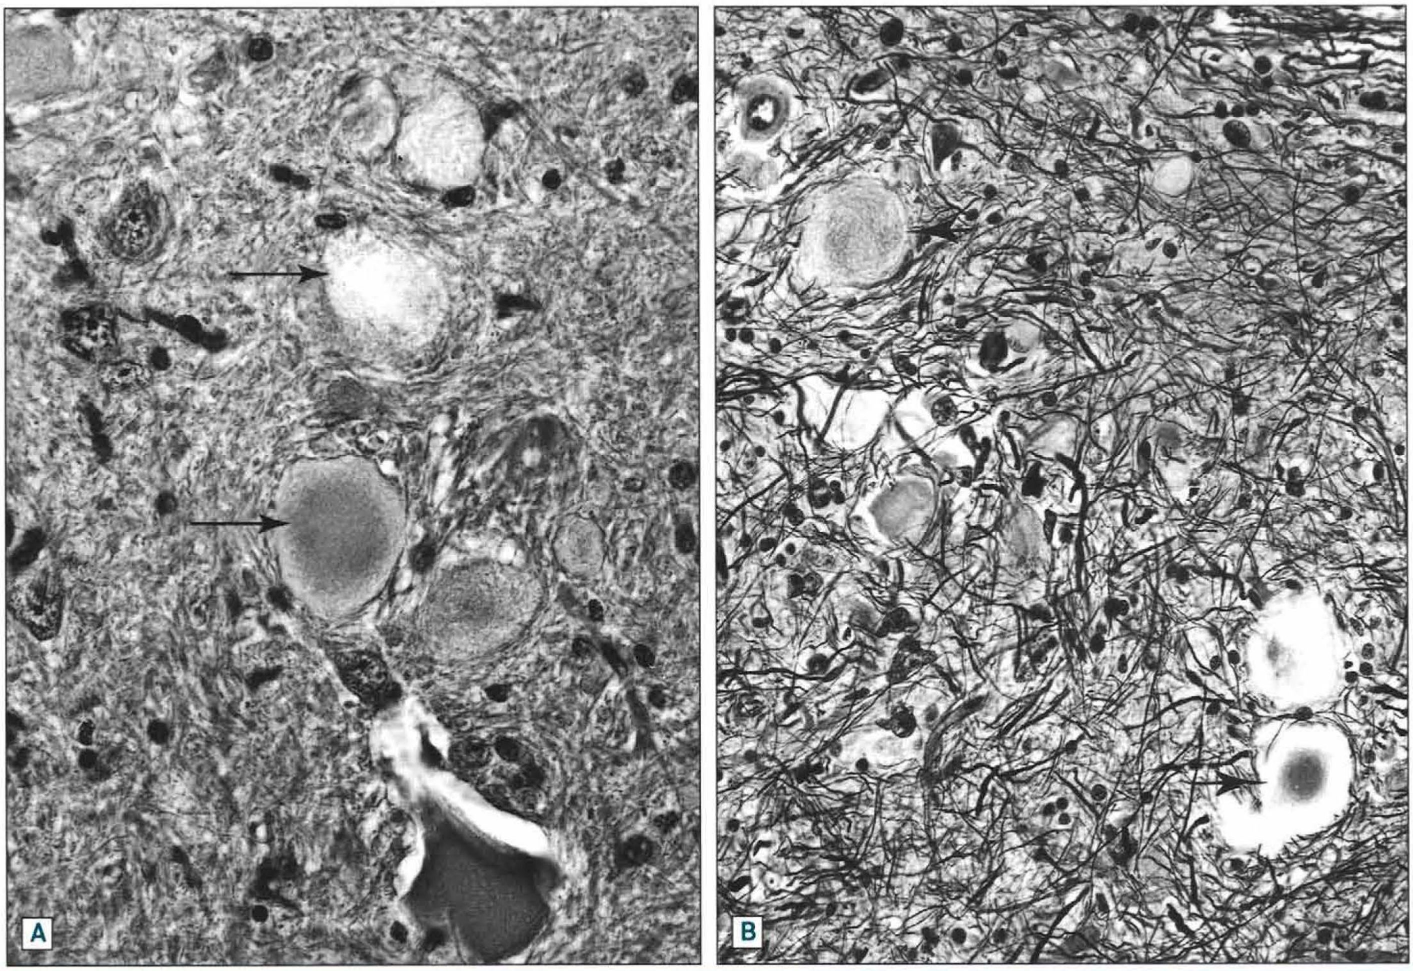

Figure 3.9 Axonal dystrophy in a Rottweiler. **A.** Focal axonal swellings (arrows); H&E stain. **B.** Silver stain reveals varying content of neurofilaments in swellings. (Courtesy of LC Cork.)

heterogeneous and those with large nuclei and clear nucleoplasm and not readily distinguished from astrocytes are probably immature and capable of division or synthesis of membrane myelin.

Oligodendrocytes arise from precursor cells in the subventricular zone of the developing forebrain and from the floor plate of the neural tube in brain stem and spinal cord. These progenitors migrate extensively to settle along fiber tracts of the developing white matter where they go through a series of maturation changes to produce myelin.

Each mature oligodendrocyte has a compact cell body of characteristic ultrastructural appearance, and a dozen or so thin processes each of which connects the perikaryon to a segment of myelin some distance away. Each segment of myelin covers one axonal internode, and is an extended and compacted sheet of specialized oligodendroglial plasma membrane bilayers, wound concentrically and spirally around the axon, like a rolled-up newspaper. In the formation of this compacted membrane, both the intracellular and extracellular spaces are obliterated, creating the major and minor dense lines of myelin lamellae as seen with the electron microscope. In some axons, a sheath of 100 or so bilayers may be formed. A portion of intact cytoplasm remains at the innermost and outermost lamellae, known as the "inner" and "outer" tongues respectively. Tracts of uncompacted cytoplasm course through the sheath to form the "incisures," and also occur where the myelin lamellae terminate at the paranodal region, as the "terminal loops." The lamellated myelin sheath is a relatively stable but plastic structure, whose lipid and protein components are supplied and turned over by the oligodendrocyte.

For light microscopy, myelin is well demonstrated by several special stains, with osmium tetroxide being particularly effective. Biochemically, central myelin is largely composed of cholesterol, galactocerebroside, and phospholipids, together with a number of distinctive protein constituents. The most abundant of these is the proteolipid protein (PLP), with lesser amounts of myelin basic protein (MBP), and myelin-associated glycoprotein (MAG). PLP is concentrated at the intraperiod line, MBP on the cytoplasmic face of the major dense line, and MAG at the axoplasmic/myelin interface. They probably play an important role in maintaining the stability of the sheath.

It is thus apparent that one oligodendrocyte myelinates several axonal internodes, that the myelin sheath is part of the oligodendrocyte, and that death of the oligodendrocyte will result in the demise of all the myelin sheath segments supplied by that cell. However, destruction of one or more myelin sheath segments does not necessarily result in death of the parent oligodendrocyte, but may stimulate it to withdraw its remaining myelin. The dynamics of the oligodendrocyte population are still not absolutely clear, but it is becoming accepted that there is a system of undifferentiated reserve cells able to take on to some extent regenerative and reparative tasks. These cells may originate from the perineuronal satellite oligodendroglia.

Myelination occurs relatively late in the development of the CNS, and maturing oligodendrocytes invest axons with myelin by replacing an initial ensheathment of astrocytic processes. Once this is completed, most of the cells assume the characteristics of maturity, while some do appear to remain in a less mature state. The ability of oligodendrocytes to synthesize myelin at specific times and in specific tracts that are specific for the animal species must require signaling mechanisms that wait to be clarified.

Oligodendrocytes do not exhibit a range of reactions for the light microscopist, generally undergoing rapid lysis when injured. Acute injury may be manifested by hydropic swelling of the perikaryon. On occasion, mitotic activity and an increase in numbers may be observed when a primary demyelinating process is operating, but this seems to be very rare in veterinary pathology. Their numbers may be increased by condensation in linear rows in interfascicular gliosis. Inclusion bodies may be present in the nuclei in some viral diseases such as canine distemper. Excepting oligodendroglial tumors, damage to the cells is expressed in disordered myelin.

The process of myelination is dependent on close interaction between the axon and the myelinating cell. The two act as a unit, and signals are exchanged between them for all aspects of the process. While the axon may survive for a long period without its myelin sheath, loss of the axon provokes immediate disintegration and removal of the myelin sheath. *This situation of axonal degeneration with secondary myelin loss is termed Wallerian degeneration*, and has been discussed above under axonopathy.

Myelination in peripheral nerves is the responsibility of **Schwann cells**, and they have a distinctly different relationship with axons to that of oligodendrocytes. Each peripheral internode is myelinated by a single cell, and the myelinated axon is invested by a basal lamina tube of Schwann cell origin, and by endoneurial collagen. Signals from Schwann cells influence the development of all components of the nerve and endo- and epineural connective tissue and the Schwann cells themselves. Schwann cells develop from the neural crest as two different cell types, *myelinating* and *nonmyelinating*. This differentiation is reversible, which is consistent with the absence of precursors in mature nerves regenerating after injury. If mature Schwann cells lose contact with axons, as occurs in nerve injury, the cells undergo regression and the myelin disintegrates. The dedifferentiated cells multiply and provide growth factors that support the regrowth of axons.

The cell body of the Schwann cell directly apposes the axon. Peripheral myelin is also chemically distinct from central myelin and this can be appreciated by the tinctorial difference between the two in appropriately stained sections of the spinal cord/spinal nerve interface. This chemical difference is reflected in antigenic differences; the major protein is termed Po and is distinct from PLP, as is the basic protein P1 from MBP. *Schwann cells are able to replicate prolifically, to phagocytose damaged myelin, and to remyelinate newly regenerated or previously demyelinated axons.* This replicative ability means that the loss of a proportion of the cells may be compensated. The peripheral myelinated axon is therefore a much more resilient structure than its central counterpart. The general principles of the axon/myelin relationship, as outlined for CNS, still apply however. *Destruction of Schwann cells will result in the disintegration of the dependent myelin.* Destruction of axons will cause myelin degradation, Schwann cell proliferation and, in time, endoneurial fibrosis.

In paraffin sections of normal nerve, Schwann cells appear as ovoid nuclei closely apposed to the axon. Proliferating Schwann cells in longitudinal section often appear as bands (*Bungner's bands*) of spindle-shaped cells resembling fibroblasts. In cross-section, they form concentric whorls called "*onion bulbs.*" Nodular proliferations of Schwann cells are referred to as *Reynaud bodies*. Large Reynaud bodies are a common incidental finding in nerves of horses.

A number of diseases primarily involve the myelin sheath, and may frequently leave the myelinating cell body intact. These diseases usually require ultrastructural evaluation for adequate investigation.

In **demyelinating diseases**, the sheath is removed from the axons, leaving them naked over variable lengths and providing potential for serious slowing of impulse conduction. In peripheral nerves, the removal of myelin from randomly scattered internodes gives rise to segmental demyelination, which is best appreciated in teased fiber preparations. Demyelination is frequently carried out by macrophages that insinuate cytoplasmic processes into the intraperiod lines and strip the sheath from the axonal internode, ingesting and digesting myelin debris. In other situations, myelin appears first to be disrupted by humoral factors and undergoes splitting and vesiculation prior to phagocytosis. Myelinophagy can be identified by the use of stains such as the Luxol fast blue/periodic acid Schiff technique. Degenerate myelin can be visualized by the Marchi technique (see Fig. 3.7).

In the CNS, there is some scope for remyelination, but the complex arrangement and limited replicative capacity of the oligodendrocytes limits the reparative potential. Regenerated myelin sheaths are thinner than the originals, appearing to the experienced eye as being too narrow for the diameter of the axon they ensheath. Remyelinated internodes are also shorter. In the peripheral nervous system, the potential for remyelination is much more favorable. Repeated bouts of demyelination may result in "onion bulb" and

Reynaud body formations, and in the production of thin and irregular myelin segments.

In **hypomyelinating diseases**, myelinating cells fail, for various reasons, to provide adequate myelination during the development phase, and the affected individual suffers transient or permanent myelin deficiency, varying in extent and severity according to the particular disease (Fig. 3.11A, B, C, D). The majority of these conditions involve the CNS only (see Myelinopathies). Myelin sheaths are thin or absent, but myelinophagy is generally minimal or nonexistent. Oligodendrocytes may be few, or present in normal numbers, and may exhibit features of immaturity.

In **dysmyelinating diseases**, there is a qualitative defect in the myelin produced, and the quantity may also be reduced. A large variety of these disorders has been produced for research purposes in inbred strains of laboratory mice.

Myelinic edema *is disruption of the lamellar structure by reopening of the extracellular space along the intraperiod line.* It may occur in both central and peripheral myelin. It is caused by a number of chemical agents, e.g., hexachlorophene, and leads to a spectacular state of spongy degeneration of white matter, one form of status spongiosus. With some causal agents, there are associated degenerative and reactive changes, but with other causes there is, remarkably, no apparent response on the part of other tissue elements including the oligodendrocytes themselves. The lesion does not necessarily cause functional disturbances even when well developed; it seems that this may depend on the number of intact lamellae left in place. It may resolve over a period of weeks with no evidence of breakdown of the affected myelin (see Spongiform myelinopathies).

Astrocytes

Astrocytes may be regarded as the interstitial cells of the CNS, as their processes occupy most of the space between and around the neuronal and oligodendroglial elements, and the perivascular and subpial zones. Astrocytes are of two types: the **protoplasmic** (type 1), located mainly within the cerebral gray matter, and the **fibrous** (type 2), located mainly within white matter tracts. Evidence suggests a common progenitor cell, the 011A cell, for the type 2 astrocyte and the oligodendrocyte. Indeed, there is evidence for several different functional types of astrocyte, the functional diversity reflecting diverse locational needs. Radial glial cells, which are the precursors of astrocytes, guide the migration of neurons from the subependymal generative zones to their final positions; astrocytes guide axons into their proper fiber tracts; astrocytes are important in the regulation of ionic exchanges between cells of the nervous system; astrocytes form functional connections by production of molecules that are tropic for other specialized cells of the nervous system.

The intercellular space of CNS tissue is a 20-nm cleft between astrocytes and the other elements, and is interrupted by loose junctions and zonulae adherentia between the former. The astrocytic perikaryon is sparse and barely evident in routine paraffin sections, and the numerous and ramifying processes are invisible. The nuclei appear, therefore, as naked and spherical, and about the size of those of small to medium-sized neurons; they usually lack a nucleolus, but sometimes have a chromatic dot, the centrosome. Immunochemical demonstration of *vimentin* is used to confirm the identity of immature astrocytes, and *glial fibrillary acidic protein* (GFAP) to confirm identity of mature astrocytes including neoplastic astrocytes. However, GFAP is not entirely specific for astrocytes. Ultrastructurally, the astrocytic cytoplasm throughout is relatively devoid of organelles and appears largely empty and watery. The chief features are bundles of intermediate filaments, clusters of glycogen granules, and a few mitochondria and lysosomes.

All capillary blood vessels in the CNS are closely invested by the expanded ends of astrocytic processes, the *end feet*. There is also a dense network of processes at the surface beneath the pia mater, the *glia limitans*. A specialized population of astrocytes occurs in the Purkinje cell layer of the cerebellum and is known as *Bergmann's glia*. These cells have long straight processes that extend out through the molecular layer to the surface.

Astrocytes and their processes are well visualized by the application of special stains, such as the Cajal method (Fig. 3.12A, B), or immunostaining for the intermediate filament glial fibrillary acidic protein (GFAP) (Fig. 3.13A, B). Astrocytes are considered to play an important role in the movement of cations and water, to be much involved in maintenance of conditions favorable for the electrical activity of neurons, and to be a source of cytokines and growth factors that support neurons and neuronal activity. Type 2 cells have a major role in this regard at the nodes of Ranvier where they form a close relationship with both the axon and the terminal myelin loops. They are also involved in the detoxification of ammonia, and perhaps other metabolites.

When lethal astrocytic injury occurs, the cytoplasm swells and becomes visible, albeit faintly, and the nucleus becomes eccentric and pyknotic. Disintegration of cytoplasm and nucleus follows rapidly. Astrocytes, however, are capable of a number of reactive responses when they, or cells around them, are damaged. *A frequent response is swelling and eosinophilia of the cytoplasm, with some cells acquiring two or more nuclei. These plump reactive astrocytes are called* **gemistocytes** (Fig. 3.14). In a mild response, cytoplasmic swelling may be minimal but some proliferation of both cells and processes generally occurs (*astrogliosis*). With cessation of injury, cytoplasmic swelling regresses but there may be a permanent residuum of extra cells and processes. Around the borders of severe lesions, such as malacic foci, the proliferation of processes may become extremely dense (Fig. 3.15). Astrocytic proplasia is limited to surviving tissue however, and post-malacic cavities cannot be filled by astrocytic processes.

Reactive astrogliosis is expected in Wallerian degeneration, following neuronal loss, and in sustained cerebral or spinal edema, and is a feature of many viral encephalitides in which viral infection of astrocytes is probably a prime stimulus. This is certainly the case in canine distemper, in which inclusion bodies are common in reactive astrocytes. Astrocytes are the cells primarily responsible for repair and scar formation in the brain.

In acute cerebral or spinal vasogenic edema, swollen astrocytes and their processes undergo a type of hydropic degeneration. This can only be resolved satisfactorily with the electron microscope, when the clear distension can be seen, particularly in the perivascular end-feet.

An acute astrocytic reaction known as the formation of **Alzheimer type II cells** is best exemplified by the metabolic disturbance in *hepatic encephalopathy* resulting from liver failure (Fig. 3.16). The nucleus becomes distinctly enlarged and vesicular but remains rounded; the cytoplasm swells and may become visible. This change does not involve the generation of large masses of cytoplasmic intermediate filaments, and there is a weak reaction to GFAP

immunostains. It is caused by the accumulation of ammonia and other endogenous toxins, and would therefore also be expected in cases of exogenous ammonia intoxication. In some circumstances, cells suggested to be astrocytes are capable of *phagocytosis of tissue debris*, particularly myelin. This can be seen in Wallerian degeneration in the optic nerves when the bulk of myelinophagy may be performed by astrocytes. It has also been observed in other regions of the brain and cord.

A bizarre and rare astrocytic response is the formation of **Rosenthal fibers**; these are irregularly shaped, hyaline eosinophilic structures of undetermined composition, formed within the cell bodies and processes. The massive production of Rosenthal fibers is a feature of *Alexander disease*, an idiopathic entity described in humans and dogs, now regarded as the only primary genetic disease of astrocytes.

Microglia

Microglia are derived from the mononuclear phagocyte lineage, and function as the *fixed macrophage system* of the CNS. In the normal brain and cord, they appear by routine microscopy as *inconspicuous, small hyperchromatic nuclei, often wedge-shaped, and with no visible cytoplasm*. However, special staining techniques reveal extensive thin cytoplasmic processes and, with the electron microscope, dense perikaryal cytoplasm with elongated strands of rough endoplasmic reticulum and lipofuscin-like granules are characteristic. They are most frequent in the gray matter where they may group in the vicinity of neurons, and in both gray and white matter they are most numerous adjacent to blood vessels. During organogenesis, they are derived from blood monocytes that also give rise to the rich population of leptomeningeal and perivascular histiocytes that can migrate into the neuropil when significant vascular damage has occurred. Microglia are the primary immune effector cells of the central nervous system. Activated microglia at the site of injury express increased levels of major histocompatibility antigens and, like other macrophages, microglia release inflammatory cytokines that amplify the inflammatory response by recruiting other cells to the site of injury. They may also be important in the persistence of some viral infections.

The simplest microglial response to tissue injury is a *hypertrophic reaction* in which the nucleus becomes rounded and the cytoplasm visible as a narrow, often eccentric, eosinophilic rim. In routinely stained preparations, such cells may be difficult to distinguish from astrocytes. They may also proliferate, although their ability to do so seems limited, and many of the cells in proliferative foci are probably derived from immigrant histiocytes. Focal proliferation gives rise to nodules of 30–40 or more cells, while diffuse proliferation creates an overall impression of increased cellularity in the microscopic field (Fig. 3.17). *Microglial nodules are very commonly a feature of viral encephalitides*, occurring in both gray and white matter, but are

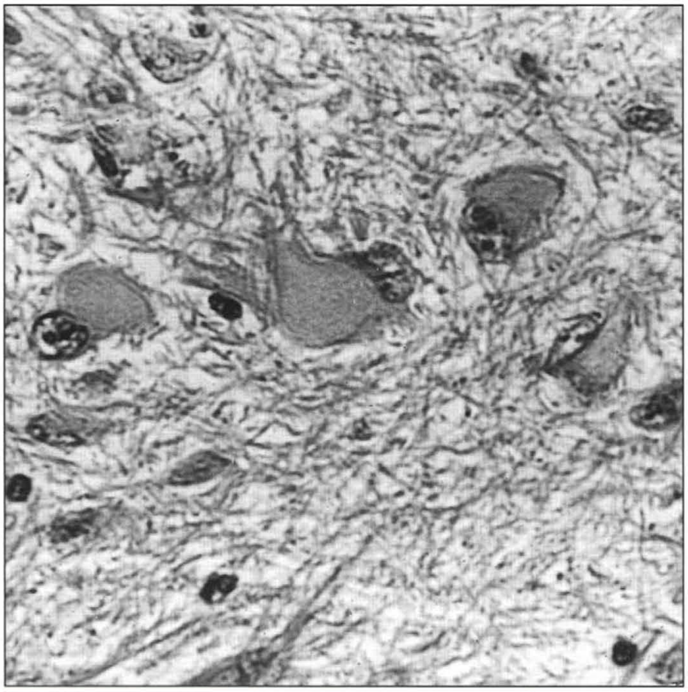

Figure 3.14 **Reactive astrocytes** (gemistocytes) near malacic focus.

not specific for viral infections. Reactive microglia may develop greatly elongated and sometimes tortuous nuclei, in which case they are called *rod cells*. These again are often seen in viral diseases. Activated microglia release cytokines and chemokines that aid in defense against CNS infections, as well as contributing to neurodegenerative conditions.

The most vigorous response of the microglia is their *transformation to macrophages*, when they assume the morphology typical of cells engaged in phagocytosis. When ingesting myelin debris, their cytoplasm becomes foamy as they load themselves with lipid vacuoles. Often the nucleus becomes pyknotic, and they are referred to as **gitter cells, compound granular corpuscles**, or **fat-granule cells** (Fig. 3.18A, B). In severe lesions, many of the gitter cells will have arisen from blood monocytes as well as from microglia. Lipid-laden cells may persist for months around focal lesions, but slow migration to the perivascular spaces and the meninges does take place. Some of the cells may be found at these locations after even longer periods, with the ingested lipid transformed to lipofuscin.

Microglial phagocytes are usually responsible for **neuronophagia**, in which phagocytic cells gather around fragmenting degenerate neuronal cell bodies (see Fig. 3.2D). This response is a feature of many viral infections in which neurons die, but is uncommon in ischemic or other forms of neuronal necrosis.

Microcirculation

There are some structural peculiarities of blood vessels in the CNS that have a bearing on the development of pathologic processes. The capillaries differ from those in other tissues by being surrounded by an investment of astrocytic end-feet. Also, the endothelial cells are sealed together by tight junctions, and the basement membrane divides to incorporate pericytes into the capillary wall. This arrangement in its totality creates the **blood–brain barrier** that selectively limits the entry of many molecules into the neuropil in most of the brain. The barrier is lacking in a few locales, such as the area postrema and certain other periventricular nuclei.

The distribution of brain capillaries varies considerably, but they are more abundant in the gray matter than the white. Their concentration is higher in some parts of the gray matter, such as the supraoptic and paraventricular nuclei and the area postrema, especially where neuroendocrine activity is concentrated. It is in these areas that the blood–brain barrier is lacking.

Regional variations in the concentrations of capillaries do not appear to influence local pathologic processes. The capillary and venular endothelium is highly labile and responds to a variety of injuries by swelling and proliferating (Fig. 3.18B). However, in spite of fairly vigorous proplasia, *cerebral capillaries seem to be almost incapable of budding, so reactive neovascularization is minimal.* The formation of new capillaries is probably limited to situations where granulation tissue is derived from the mesenchyme of the meninges.

Both arterioles and venules of the CNS are thin walled, especially the latter whose walls are composed mainly of a thin layer of fibrous tissue with very little elastica and no muscle. They are thus susceptible to injury and prone to hemorrhage and, in the cerebral white matter, leukocytes tend to sequester in them in bacterial

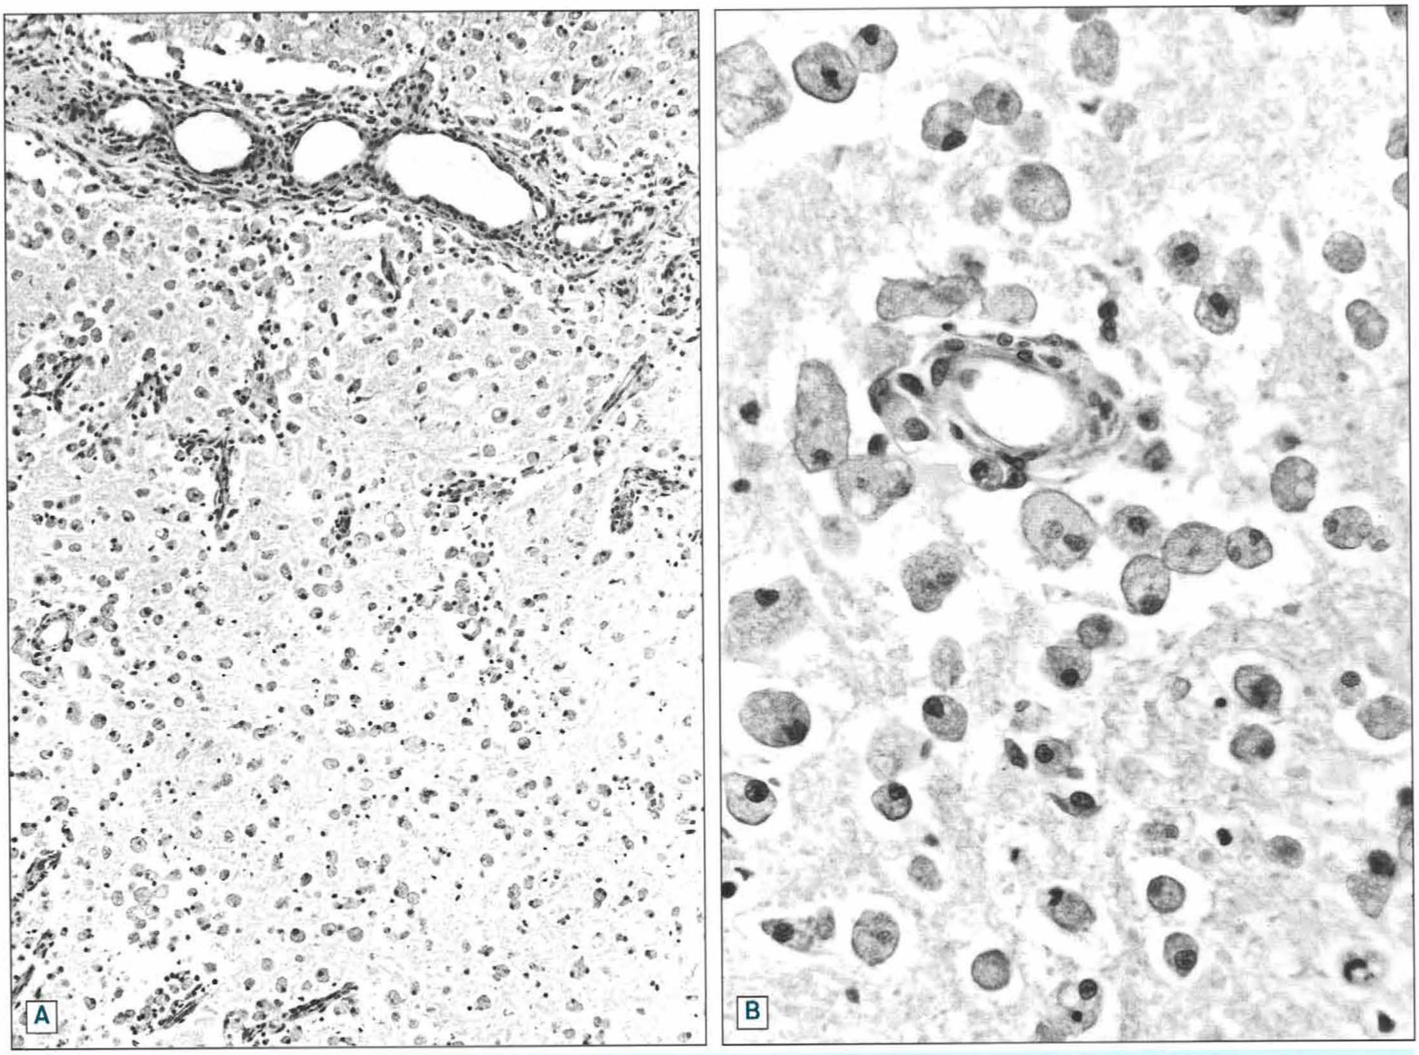

Figure 3.18 A. Gitter cells and reactive capillaries in recent cerebral infarct in a dog. **B.** High-power view of gitter cells.

infections. The veins are valveless and, as backflow of blood after death is usual, cerebral venous congestion can be difficult to assess.

Both arteries and veins have an outer adventitial layer of variable thickness, and a **perivascular Virchow–Robin space**. The space around veins is continuous with the subarachnoid space and is lined by an invagination of the pia-arachnoid. Around cortical arteries however, there is an investment of leptomeninges in a single layer, an arrangement by which the intracortical perivascular space communicates with the perivascular space about arteries in the leptomeninges. Arteries that enter through the rostral perforated substance may differ from those in the dorsal cortex in that the arteries are surrounded by two leptomeningeal layers with a space between them that communicates with the perivascular space around arteries in the subarachnoid space. The varied arrangements may reflect the need to allow passage of interstitial fluid to the local lymphatics.

In diffuse inflammatory or neoplastic diseases, this space, more potential than real under normal conditions, becomes patent and accumulates reactive and invading cells. The tendency for these cells to be confined to the space gives rise to the neuropathologic term **perivascular cuffing** (Fig. 3.19). The size of cuffs is usually related to the size of the space, and they may vary from one cell thick about the smallest venules to 10–12 or more cells thick around the larger vessels. *Perivascular cuffing is classically seen in inflammatory conditions*, and all classes of reactive leukocyte may be seen depending on the cause. While most of the cells are of hematogenous origin, there is no doubt that in some diseases, enteroviral infections for example, they may arise largely from the proliferation of adventitial cells or resident histiocytes. Lymphoid perivascular cuffing is a feature of many viral encephalitides. Some diseases too are characterized by the production of cerebral and/or spinal vasculitis, but these changes are discussed in a following section.

Mention must be made of the *nests of residual glia (islands of Calleja)* that are seen beneath the ependyma of the lateral ventricles and in the dentate fascia of the hippocampus. These cells are relics of the developmental period and possibly act as a supply of replacement cells in the adult. They occur in small aggregations and often as eccentric cuffs around vessels. Generally they are monomorphic and appear as small dark nuclei and may be mistaken for inflammatory cells.

MALFORMATIONS OF THE CENTRAL NERVOUS SYSTEM

Malformations of the central nervous system (CNS) are common in domestic animals, and their variety is perhaps greater than the variety of malformations in other tissues. There is abundant field and experimental evidence that the effects of teratogens are manifested in the nervous system with disproportionately high frequency. One explanation is that the high degree of differentiation and complexity of the CNS give it an increased susceptibility to developmental disturbances. In addition to inherited diseases, a large number of infectious and toxic environmental agents are capable of causing anomalies. The cause of malformation in an individual domestic animal fetus is seldom determined, in part because of the long time lapse between the initiating event and the fetal presentation. The most frequent sporadic anatomic abnormalities are neural tube defects, and these are initiated in a narrow time range: embryonic days 8.5–10.5 in the mouse, days 15–18 in the pig, days 21–28 in humans.

Congenital abnormalities of the CNS consist of deviations in either the nature or velocity of the developmental process. Several main patterns of abnormal development can be recognized.

- The largest category includes those disorders with a morphological basis that are a consequence of *failure or disorder of structural development.* Many such abnormalities are recognizable by distinctive gross changes, but others require microscopic examination.
- Some conditions appear to represent *retardation of normal development* rather than structural aberrations.
- Disturbance of the normal development may also manifest as *premature senescence or degeneration of formed tissues* such as the various forms of neuronal abiotrophy.
- Some congenital abnormalities appear to represent *primary disturbances of function* rather than of tissue structure. The most frequently recognized functional disorders are those that arise as a consequence of inherited biochemical defects and that cause distinctive neurohistologic changes. This category is exemplified by the various lysosomal storage diseases and the leukodystrophies.
- Neither an anatomical nor a biochemical basis has yet been identified for a number of congenital neurological diseases that often *appear to be inherited*, e.g., idiopathic epileptiform conditions in various species.

The initial steps in the formation of the CNS take place early in embryogenesis. As soon as the germ layers are established, the **neural plate**, a thickened band of ectoderm, develops along the mid-dorsal line of the embryo, and is the primordium for the brain and spinal cord. Differential growth at the margins and in the midplane result in folding of the plate to form a *neural groove* bounded on each side by an elevated *neural fold*. The groove continues to deepen, and the neural folds meet dorsally and fuse, likely beginning at multiple sites, to form the **neural tube**, which simultaneously separates from the superficial ectoderm. Physical properties of cells and tissues both inside and outside the neural plate determine the formation of the neural tube (*neurulation*). Cellular proliferative activity within the neural tube is concentrated within an inner subependymal or germinal layer of actively dividing neuroectodermal cells that, with differentiation and outward migration, gives rise first to neurons and later to glia.

The neural tube extends the full length of the embryo and is the progenitor of the entire CNS. **Neural tube defects** (NTD), which result from failure of a portion of the neural tube to close or from reopening of a successfully closed segment, may be cranial or spinal or concurrent in both locations. Shortly after formation of the neural tube, the rudiments of the cranium and vertebrae appear in accord with the fundamental plan of segmental organization. *Segmentation and development of the axial skeletal investment of the nervous system depend on the developmental integrity of the neural tube.* Hence, NTDs also involve malformations of overlying bony or soft tissues. The spectrum of NTDs includes anencephaly, encephalocele, spinal dysraphism, and meningomyelocele. Incomplete closure of a raphe, especially the neural tube, is referred to as *dysraphism.*

The genes controlling neurogenesis are very strongly conserved in evolution and much effort is placed on analysis of responsible genes and gene actions in human embryos and in the many models of NTD in mutant and transgenic mice. Notwithstanding the shared gene arrays of the many mouse models and humans, only one mouse phenotype, the *curly tail* mouse, exhibits the anencephaly/meningomyelocele phenotype that is the most frequent NTD in human fetuses. The phenotype results from failure of closure of cranial and caudal neuropores, the ends of the neural tube. The *Sonic hedgehog gene* (Shh), secreted initially from the notochord and later from the floorplate, is implicated in inducing development of the floor of the neural plate and differentiation of neurons in the ventral sections of the developing cord. Development of the dorsal roof plate of the cord, differentiation of neural crest cells and formation of neurons within the dorsal cord are the responsibility of members of the *bone morphogenetic protein* (BMP) family derived from surface ectoderm.

The normal pattern of development of the CNS is not smoothly progressive but comprises a complicated interdependent series of growth spurts of organs and tissues. Birth does not mark a single stage in the structural development of the brain and there is considerable species variation in the stage of CNS development at birth. *Cattle, horses, sheep, and pigs are born with nervous systems having a remarkable degree of structural and functional maturity; kittens and puppies are born with their nervous systems relatively immature.* After the nervous system is fully formed, the capacity for further production of nerve cells is lost and subsequent development comprises mainly progressive lengthening and myelination of axons and extension of neuronal dendrites and glial processes.

For each species, neural development thus proceeds along a characteristic predetermined pathway. When mature, the nervous system possesses considerable inherent stability, but a time-linked process of decay is also part of the total system of development. Aging neurons tend to accumulate ceroid pigments that almost certainly reduce their functional efficiency. There is also a continual normal loss of neurons, and in normal animals neuraxonal degeneration is an insignificant but not infrequent finding.

Abiotrophy *designates the occurrence of intrinsic premature degeneration of cells and tissues.* In the hereditary abiotrophies affecting the nervous systems of animals, such premature loss of vitality is manifested by accelerated and exacerbated degeneration of neurons and their processes.

Investigation of the etiology of neural effects is complicated by the fact that *the same type of abnormality may be produced by both genetic and exogenous causes,* and in many instances, particularly those of sporadic occurrence, the cause remains unidentified. A variety of transplacental viral infections of the fetal nervous system at critical stages of gestation may result in neurological defects. Some viruses can produce changes such as symmetrical cavitating lesions that lack pathological features that suggest antecedent infection and resemble malformations thought to be of genetic or toxic cause.

The outcome of fetal interactions with agents potentially teratogenic for the nervous system depends on the species and age of the fetus and the nature of the agent. For the various patterns of malformations, there are corresponding critical periods during which developing neural tissue is vulnerable. The teratogenicity of the agent is dependent on its cellular tropism, which is commonly directed towards immature rapidly dividing cells but which often involves specific subpopulations of these cells. Thus, time sets the stage and presents the array of vulnerability, but the agent chooses from among the parts at risk those it has special affinities for damaging.

The most common mode of action for teratogens is selective destruction of cells. Such cytolytic effects have been demonstrated with neural defects induced by *viruses* and *chemicals* as well as by *physical agents* such as hyperthermia. In the case of viruses, cellular destruction can be a direct consequence of infection but may develop as part of the inflammatory reaction. The toxicities of many drugs are mediated not by the compounds themselves but by highly reactive metabolites. If they are not detoxified, these unstable metabolites interact covalently with cell macromolecules and may kill affected cells. Cytolysis seems to be the common operative mechanism in a number of important malformations that often have gross features such as the cavitating cerebral defects and cerebellar hypoplasia. Teratogens may sometimes act by inhibition or distortion of normal cellular development and function to produce more subtle developmental deviations such as hypomyelinogenesis. Infection of calves with *Bovine viral diarrhea virus*, of lambs with *Border disease virus*, and of piglets with *Classical swine fever virus* may provide instances of noncytolytic disturbance of fetal neural development of this type.

Some drug metabolites, rather than killing cells, result in mutations through binding to nucleoprotein. In view of the multiplicity of pathogenetic pathways that have been identified, it is not surprising that a spectrum of pathogenic effects can result from the action of one teratogen. All of the lesions may result from an exposure or any one effect may develop either alone or in combination. Such diversity of teratogenic expression is illustrated by the wide variety of neural and extraneural defects found in kittens born to cats exposed to griseofulvin in pregnancy. *A particular abnormality may arise as an expression of many different causes, sometimes disparate in character.* The cavitating cerebral defects provide examples of this.

Several attributes of fetal neural tissue are pertinent to the interpretation of malformations. Necrosis of groups of cells occurs in normal development and may be seen in association with remodeling processes. The immature nervous system does not react to damage in the same way as adult tissue. Parts may be absorbed without trace of connective tissue or neuroglial repair. Furthermore, severe malformations are unlikely to proceed directly from destructive processes since destruction of parts of the embryonal structure removes the inductor and inhibitor influences on neighboring cell groups. This may, in some instances, lead to arrest of normal processes and, in others, to exuberant reparative proliferation of neuroepithelium that is indicated histologically by the formation of distinctive neuroepithelial rosettes. *Thus, malformations may be compounded of degeneration, necrosis, inhibition, overgrowth, and repair.* There is at best only a general correlation between the nature of an anomaly and the time in development when it was initiated. In retrospective studies of malformations of unknown cause, it is only possible to identify the latest time at which the malformation may have been produced based on the normal development of the nervous system of the species in question.

In the event of infection of the developing nervous system by potentially teratogenic viruses, the outcome is determined primarily by age-related cellular susceptibility. However the immunological status of the fetus, particularly its capacity to produce neutralizing antibody, is likely to be important in determining the character of the neural lesions resulting from viral infection. *Lesions leading to major anomalies tend to occur prior to the fetal age at which the fetus can mount a serum neutralizing antibody response to infectious agents.* The fetal brain, especially in the early stages of development, has limited inflammatory potential, but viral-induced destruction of neural tissue in the early fetus may be accompanied by an intense macrophage reaction despite lack of immunological maturity. Such necrotizing processes typically produce gross anatomical defects with little or no evidence of inflammation because of subsidence of the inflammatory changes. In older fetuses, cytolytic processes are reduced mainly by absence of a susceptible cell population rather than by immune mechanisms, but nonsuppurative encephalitis frequently persists as a residual lesion.

Destruction of developing neural tissue may be effected by mechanisms other than those directly cytopathic for primitive neuroectodermal cells. *Vascular damage* with consequential edema and necrosis is one such mechanism. Although the fetus is resistant to hypoxia, except if prolonged or profound, there is evidence of the potential of circulatory disturbances in the genesis of cavitating CNS malformations such as hydranencephaly.

There are additional poorly understood pathogenetic influences that doubtless contribute to the outcome of fetal interactions with teratogens. Such factors include *maternal and fetal genotype*, and experimental evidence suggests that *pharmacogenetic differences* among fetuses of a particular species are important determinants of the results of in utero drug exposure. With viral infections, teratogenic potential may vary markedly depending on the *strain of the virus* and upon the *immune status* of the maternal host.

The detailed discussions of CNS malformations that follow are organized on an anatomical basis, from cranial to caudal.

Cerebrum

Cerebral aplasia, anencephaly

True **anencephaly**, which means *absence of brain*, is a rare event, and the term has been misapplied to cases of **cerebral aplasia**, or *prosencephalic hypoplasia*, in which the cerebral hemispheres are absent, but components of the brain stem (midbrain, pons, medulla) have formed (Fig 3.20). Anomalies of the same general or specific pattern vary considerably from case to case in the details of their expression, various

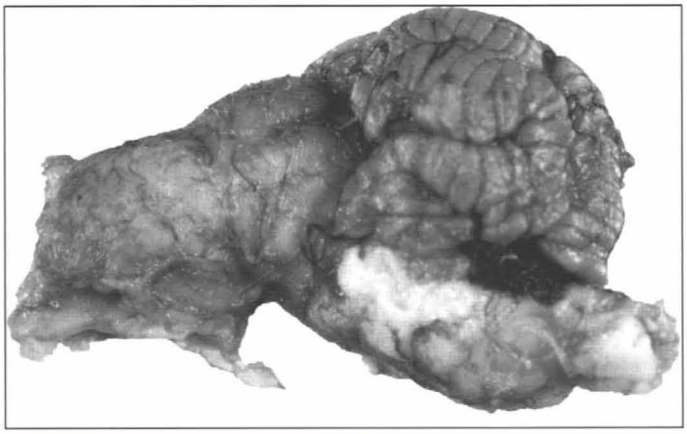

Figure 3.20 Cerebral aplasia ("anencephaly") in a calf. The cerebral hemispheres have failed to form, and only brain stem and cerebellum are present. (Courtesy of RF Slocombe.)

combinations of typical malformations occur, and there is considerable variability in the development of morphological sequelae.

The primary defect in cerebral aplasia is arrest of closure of the rostral portion of the neural tube. There is, in consequence, failure of development of the cranium and, with skin lacking over the lesion, the dysplastic rudiments of neural tissue are exposed to the exterior. Cerebral aplasia is seldom complete from the beginning because the eyes, either well developed or present as rudimentary vesicles, are present. When the eyes are rudimentary, ganglion cells and optic fibers may be missing. The cranial and neural defects are probably more or less proportionate. With severe degrees of cerebral aplasia, or true anencephaly, there may be complete failure of cranial development (**acrania**) or there may be rudimentary development of the occipital and adjacent bones. In those cases of cerebral aplasia in which the rostral portion of the brain stem is present, there may be a greater degree of cranial development but failure of fusion (**cranioschisis**). The base of the cranium is well developed, but there are a variety of anomalies of basal bones and no sella turcica. The neurohypophysis is absent and the adenohypophysis is either absent or unidentifiable. Failure of development of the neurohypophysis can be responsible for the failure of the adenohypophysis to develop normally, and this in turn may be responsible for prolonged gestation of some anencephalics. The caudal extent of the neural tube defect varies greatly. There may be involvement of the cervical vertebrae or of the entire neural tube (**craniorhachischisis totalis**); the defect is always continuous, not segmental. Even when the spinal cord is closed, it may be hypoplastic. When the cord is well developed, it is still small because of the absence of descending tracts.

In cerebral aplasia, the cerebral hemispheres are reduced to a tough formless mass of tissue on the exposed basal bones. The tissue is composed largely of blood vessels with some intermingled neural tissue and is termed the *area cerebrovasculosa*. Choroid plexuses may be recognizable, and the whole may be covered by a thin layer of squamous epithelium.

Encephalocele, meningocele

Encephalocele *(meningoencephalocele, cephalocele) is protrusion of the brain through a defect in the cranium* (**crania bifida**). The defect is termed **meningocele** if only fluid-filled meninges protrude. In *exencephaly*, the brain may be either exposed or protruding. These anomalies can be inherited in pigs and in Burmese cats, and have been associated with treatment of the pregnant queen with griseofulvin.

The morphogenesis of these defects is not simply a problem of defective ossification of the skull with secondary herniation of preformed intracranial tissue but, instead, *depends on a primary neural tube defect by which there is focal failure of dehiscence of the neural tube from the embryonic ectoderm* and, in consequence, focal failure of development of the axial skeletal encasement. The herniations are related to suture lines and are almost always median. They vary from 2–10 cm in diameter, and the largest diameter is always much larger than the diameter of the cranial opening. The skin forms the hernial sac, and ectopic bits of disorganized neural tissue may be attached to it; the dura mater does not form in the areas of defect. Encephalocele and meningocele occur usually in the frontal regions (Fig. 3.21) but some are occipital (Fig. 3.22), and these latter tend to be located below the

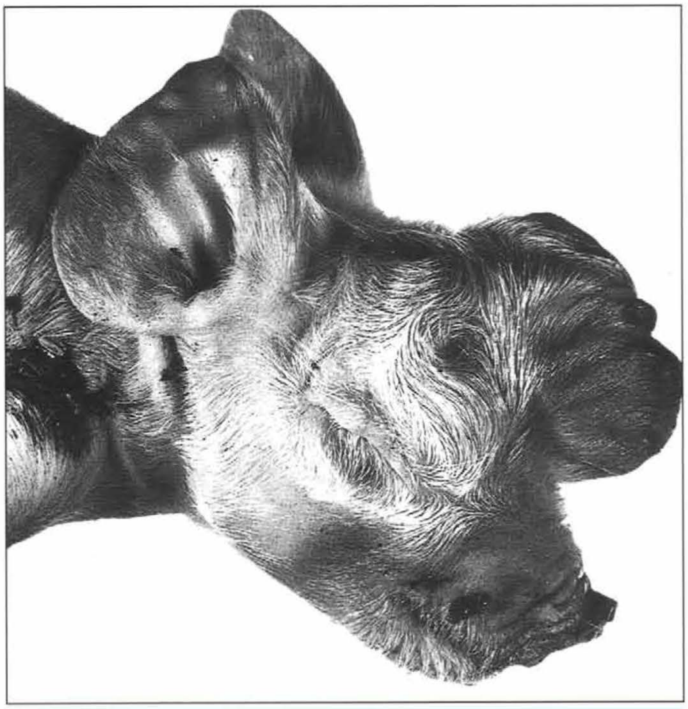

Figure 3.21 Meningocele in a piglet.

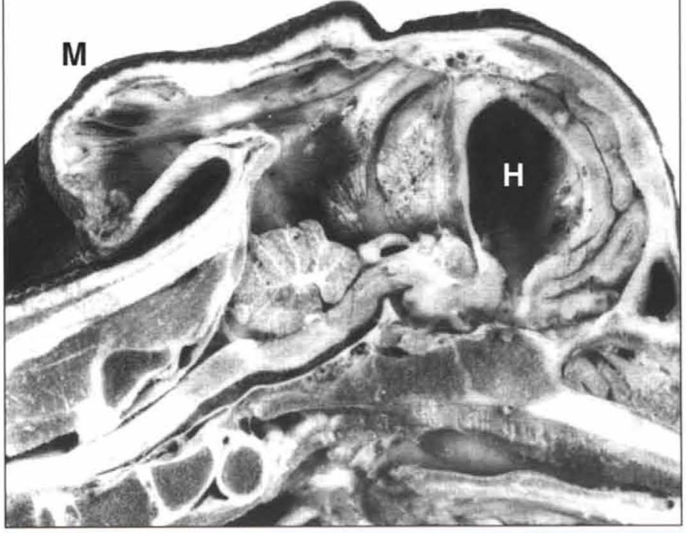

Figure 3.22 Hydrocephalus (H) and occipital **meningocele** (M) in a calf.

occipital crest. Occipital encephaloceles may also be associated with spina bifida of the upper cervical region, sometimes with enlargement of the foramen magnum and absence of the arch of the atlas.

Less well known in animals are *frontonasal or frontoethmoidal encephaloceles* that coexist with facial deformities.

Defects in cerebral corticogenesis

These malformations have their teratogenetic period early in fetal life following closure of the neural tube, and usually occur in association with other neural anomalies. With the establishment of the telencephalic vesicles, cortical neurogenesis begins from the germinal epithelium lining the neural tube, especially in those parts destined to become the lateral ventricles. Initially, cell division gives rise to similar daughter cells that also act as progenitors so that cell numbers increase geometrically. Later, the cell divisions become increasingly asymmetric as an increasing proportion of progenitors produce postmitotic precursors of neurons. The first postmitotic neurons migrate to the subpial plate along guides produced by radial glia that extend from the periventricular zone to the cortical surface. Successive waves of migratory neurons will leapfrog the preceding waves such that the first waves will reside in the deeper layers of the cortical plate corresponding to layer 6 of the mature cortex and the later waves will migrate to form the more superficial layers. Errors of proliferation of germinal epithelial cells may result in microencephaly or macroencephaly; errors of migration result in various patterns of disorder affecting the cerebral gyri.

Microencephaly *refers to an abnormally small brain.* The diminution affects particularly the cerebrum. The hypoplastic brain is accommodated within the cranial cavity, which is often smaller than normal so that the cerebellum appears relatively large. The gyri are of normal size but simplified pattern, and the brain stem structures are normal. *The deficiency is of cerebral gray and white matter.* It may be an isolated defect or associated with any of a variety of other defects. Microencephaly is manifested externally by an abnormally flattened and narrowed frontal part of the cranium. The cranial bones, particularly the frontal bones, are thicker than normal. Microencephaly occurs in fetal infections by *Akabane virus* in lambs and calves, *Bovine viral diarrhea virus* in calves, *Border disease virus* in lambs, and *Classical swine fever virus* in piglets. The condition has been produced experimentally in lambs exposed to prenatal hyperthermia.

Megalencephaly *refers to an abnormally large brain or excessive volume of the intracranial contents.* Enlargements as a result of excessive germinal cell proliferation are rare and tend to be asymmetrical with exaggerated degrees of heterotopia.

Cortical dysplasia *encompasses defects in the architecture of the cerebral cortex.* In its mildest expression, there is only histological evidence of lack of the normal orderly layered appearance of the cerebral cortex. *Neuronal heterotopia* is the presence of clusters of nerve cells at a site where they are normally absent, such as subcortical white matter. This condition represents incomplete migration of neuroblasts during fetal life and is usually associated with dysplastic development of the cortex. Scattered, rather than clustered, neurons are commonly present in subcortical white matter and are not of clinical significance. *The presence of aggregations of small dark primitive neuroglial cells is a normal finding in periventricular locations and in the rhinencephalic cortex.* Heterotopia may also involve glial elements, here taking the form of aberrant nests of glial cells.

In **microgyria** *(polymicrogyria), convolutions are small and unusually numerous, and the normal gyral pattern is lost in affected areas.* The lesion may be asymmetrical or patchy, abruptly demarcated from normal cortex, but its real extent may only be revealed on cut surfaces. It may be present near the margins of cavitating lesions such as hydranencephaly. **Ulegyria** also imparts a wrinkled appearance to the cortex but arises as a consequence of scarring and atrophy in otherwise topographically normal gyri. It is a *result of laminar necrosis*, particularly affecting sulci, caused by prolonged ischemic/anoxic injury in the perinatal period.

In **lissencephaly** (agyria), the primitive pattern of the telencephalon persists due to arrested migration of neuroblasts from the ventricular zone along radial glial fibers to the appropriate cortical lamina. *Convolutions are almost entirely absent* and the brain surface may be smooth except for slight grooves in which the meningeal vessels are situated. The cerebral cortex is excessively thick. In humans with *LIS1* or *DCX* gene mutations, failure of dynein-mediated nucleus–centrosome coupling leads to abnormal neuronal migration. Lissencephaly occurs in Lhasa Apso dogs.

Pachygyria (macrogyria) is characterized by *excessively broad brain convolutions* resulting from fewer secondary gyri and increased depth of the gray matter underlying the smooth part of the cortex. Pachygyria is a transitional malformation of the cortex, less severe than agyria but akin to it.

Disorders of axonal growth

As neurons migrate from the periventricular germinal zone along radial glia, they begin to form axonal and dendritic processes. The growth and direction of growth of these processes are guided by complex cues including molecules of the extracellular matrix and there is an extensive literature relating to the molecular genetics that regulate these processes.

Agenesis or hypoplasia of the corpus callosum is an *uncommon anomaly* but is recorded in most domestic species. It is the most studied of the disorders of axonal growth in human and animal models. It may occur alone or in association with other anomalies of the brain (Fig. 3.23). The septum pellucidum is absent as a collateral

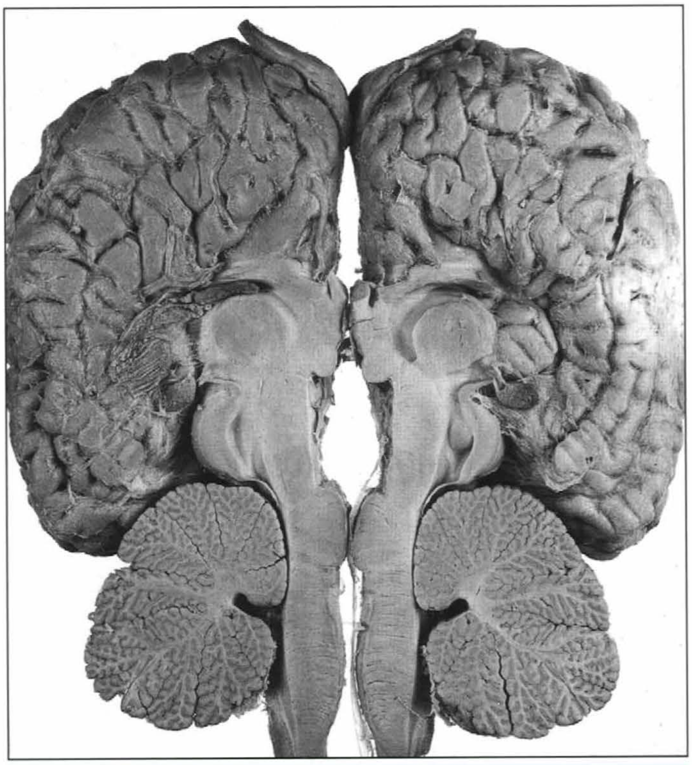

Figure 3.23 Agenesis of corpus callosum in a horse.

defect; the leaves are separated and displaced laterally to the roof of the lateral ventricles. There is no cingulate gyrus, the interhemispheric gyri appearing to radiate from the roof of the third ventricle.

The corpus callosum is formed by the crossing-over of fibers from one hemisphere to the other, a migration that begins at the lamina terminalis, which is the most rostral point of the neural tube. Dysgenesis of the prosencephalic vesicle in its midline may impair the lamina terminalis, or there may be disordered outgrowth of axons from the cerebral cortex. The migration of fibers is guided by a glial scaffold, which may be absent as the primary defect. The corpus may be entirely absent or the commissures may be present and the corpus defective in its central part.

The development of the septum lucidum is linked to that of the corpus callosum and its residue may form a **cystic septum pellucidum**. The cavum septi pellucidi is always present in the fetus as a midline cavity that originates within the commissural plate by tissue resorption. In the normal course, the cavity is obliterated, resulting in a glial midline raphe, but *failure of fusion of the leaflets results in a cystic fluid-filled cavity that varies from a thin slit to a rounder cavity*. The cyst is covered externally by ependyma and lined by a glial mesh. This condition occasionally accompanies defects caused by fetal infections with viruses such as those of Akabane disease, bluetongue, bovine viral diarrhea, and Border disease.

Holoencephaly

Immediately on closure of the rostral neuropore, the rostral end of the tube enlarges to form three vesicles, the rostral of which, or *prosencephalon*, will become the forebrain, the intermediate vesicle will form the *mesencephalon* or midbrain, and the caudal vesicle will form the hindbrain or *rhombencephalon*. The dorsal wall of the rostral vesicle becomes thickened dorsally in the midline to form the commissural plate, eventually the corpus callosum, and the vesicle expands laterally to form the paired cerebral vesicles, which will become the cerebral hemispheres.

Holoencephaly (holoprosencephaly) refers to a spectrum of deformities involving the hemispheres and typically including aplasia of the olfactory bulbs and tracts (arhinencephaly), as a result of failure of cleavage of the prosencephalon. The dysplasia is typically associated with facial deformities, and the extent of the nervous and facial deformities correspond closely. The most severe expression is cyclopia (synophthalmus), but the spectrum ranges through intermediate expressions such as cebocephaly to lesser deformities in which the orbits and nose may be normal or the nares are retruded with variably expressed clefts of lips and palate.

Cyclopia, referring to the presence of a *single large median eye*, emphasizes the most obvious and remarkable abnormality of a very complicated defect. The condition is not uncommon in domestic animals, especially pigs, and it can be reproduced experimentally simply and in many different ways.

The causes of sporadic cases are largely unknown, but many instances in humans are due to chromosomal anomalies. Various degrees of cyclopia are present in Guernsey and Jersey fetuses that are the subjects of *prolonged gestation. Veratrum californicum* is responsible for congenital cyclopian malformations that occur endemically in lambs in the western livestock grazing areas of the USA. The teratogenic agent in the plant is *cyclopamine*, a steroidal alkaloid. Induction of the cyclopian deformity in lamb fetuses is dependent on pregnant ewes ingesting *V. californicum* on day 14 of gestation. Cyclopia has also been produced experimentally in cattle and goats, with a similar narrow interval of susceptibility to maternal ingestion of *Veratrum* on or about day 14 of gestation. Cyclopamine-induced teratogenesis may result from antagonism of Sonic hedgehog gene signal transduction that is necessary for normal dorsoventral patterning of the neural tube and somites. The primary defect occurs at the neural plate stage of development and involves the rostral extremity of the notochord and the mesoderm immediately surrounding it. Failure of proper induction accounts for the changes in the skull, in soft tissues of the face, and in the brain. The optic defect, consisting of greater-or-lesser division of a single anlage, is probably secondary to the defects of the forebrain.

The orbits may be approximated (Fig. 3.24) but, typically, there is one large orbit and a single optic foramen. Several bones, including the ethmoids, nasal septum, lacrimal bones, and premaxillae, are usually absent. The globe may be absent, rudimentary, or may form a single structure of near-normal conformation, or be partially divided or completely duplicated. The nose is a proboscis or tube that does not communicate with the pharynx and that is typically situated above the median eye. The forebrain is always severely malformed; the hemispheres are not fully cleft but are present instead as a single thin-walled vesicle with a smooth surface and common ventricle and lacking olfactory nerves and tracts, corpus callosum, septum pellucidum, and fornix.

The hindbrain is usually normal. The pituitary may be displaced or absent and fetal gigantism associated with prolonged gestation (see Vol. 3, Female genital system) occurs in some deformed lambs and calves. The optic nerve is single, atrophic, or absent. The oculomotor and abducens nerves are hypoplastic or absent. There is internal hydrocephalus.

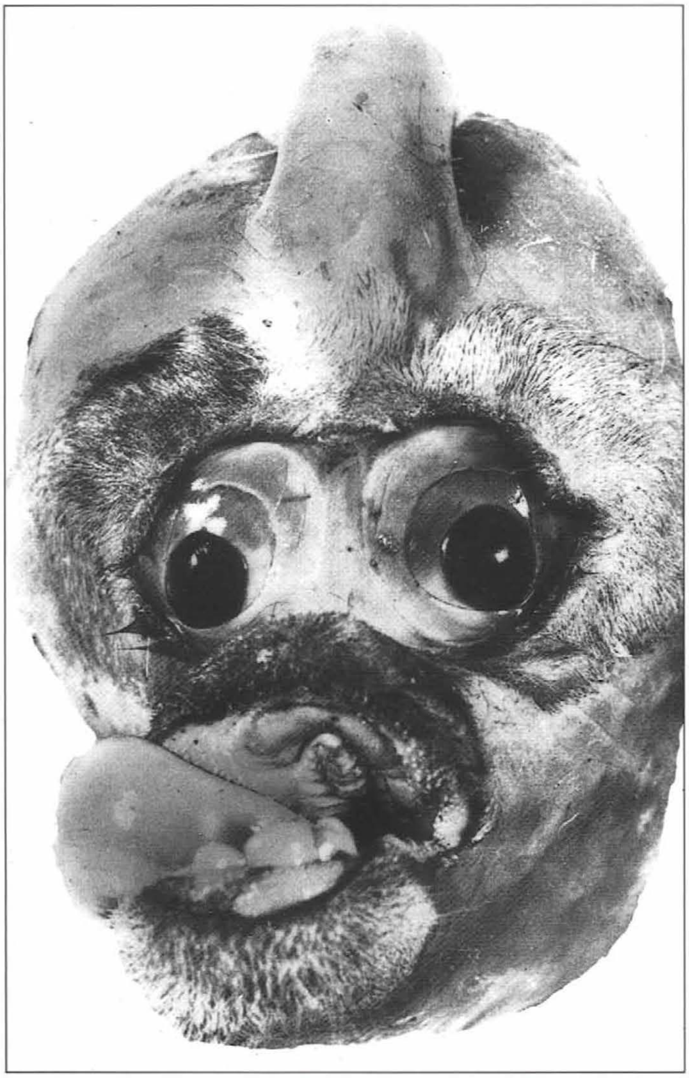

Figure 3.24 Cyclopia (synophthalmus) in a calf with inherited prolonged gestation.

Veratrum californicum also causes embryonic death. A wide range of other defects has been produced experimentally in lambs, with abbreviation of the metacarpal and metatarsal bones being the most distinctive.

Cebocephaly (monkey face) *is anatomically comparable to cyclopia, and probably represents a less severe expression of the same basic defects.* There are two eyes, severely hypoplastic, in separate but approximated orbits. The nose is in the normal position, but deformed and may not protrude. There is a single, small nasal cavity or a proboscis with no communication with the pharynx. The brain appears as in cyclopia but may have a slight median sulcus.

Hydrocephalus

Hydrocephalus is characterized by abnormal accumulation of fluid in the cranial cavity. In **internal hydrocephalus**, the fluid is within the ventricular system; in **external hydrocephalus**, the fluid is in the arachnoid space; and in **communicating hydrocephalus**, the excess fluid is present in both locations. The communicating and external types of hydrocephalus, the latter to be distinguished from cerebral atrophy, are quite rare in animals. Internal hydrocephalus, which is denoted by variably dilated ventricular cavities lined by ependyma, is quite common, may be congenital or acquired, but both forms may be considered here for convenience.

Cerebrospinal fluid (CSF) is produced by the ventricular choroid plexuses by means of filtration and secretion. There are significant contributions by ependyma and extraventricular structures. Because of the permeable nature of the ependymal lining of the ventricular system, the CSF is in effect an extension of the extracellular fluid of the CNS, and its composition is affected by metabolic and pathological changes within the brain.

The flow of CSF is from the lateral ventricle through the interventricular foramen to the third ventricle and then via the mesencephalic aqueduct to the fourth ventricle. From here, most of the fluid leaves the ventricular system and passes by way of the lateral cerebellomedullary apertures into the subarachnoid space. A small amount of CSF passes into the central canal of the spinal cord from the fourth ventricle. The greater part of the fluid flows forward into the cerebral subarachnoid spaces and basal cisterns; the balance circulates in a restricted fashion in the spinal subarachnoid space. The energy required to circulate CSF is imparted largely by the choroid plexuses through their production of fluid. The arterial pulse also contributes to CSF movement through associated variations in hemispheric volume. Venous resorption of CSF occurs where arachnoid villi form in the walls of the larger meningeal veins. Transfer of fluid is effected by hydrostatic pressure, with reflux being prevented by the valvular nature of the villi. The arachnoid villi are normally highly permeable, being able to permit the passage of red blood cells. Impedance of this resorption appears to contribute to the increased intracranial pressure of hypovitaminosis A in calves. Some outflow in dogs can occur via the cribriform plate and in cats along the subarachnoid space of olfactory, optic, and acoustic nerves, but significant outflow may possibly occur only in association with raised intracranial pressure. The spinal subarachnoid space appears to communicate freely with the lymphatic system opening in the intradural nerve roots.

Familiarity with the normal directional flow of CSF is basic to an understanding of the pathogenesis of hydrocephalus because in most cases it is probably of obstructive origin. Certainly, *an obstruction can be demonstrated in most instances of acquired hydrocephalus in animals.* In congenital hydrocephalus, obstruction is quite often not demonstrable, but stenotic aqueductal malformations may be found (Fig. 3.25). Obstructive hydrocephalus has been induced experimentally in many species of immature laboratory animals with a range of viruses ubiquitous in animals and man. The selective destructive action of these viruses on ependymal cells with subsequent reparative gliovascular

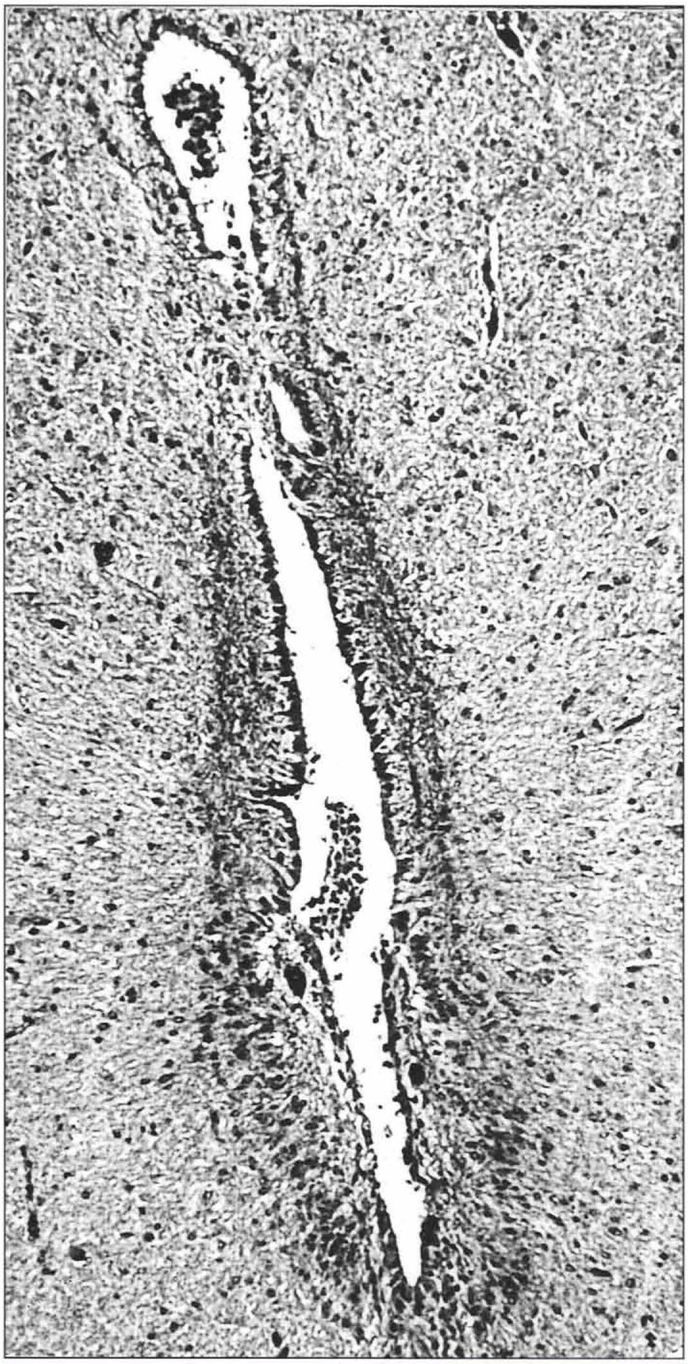

Figure 3.25 Malformation of aqueduct in a calf.

proliferation results in obstruction of CSF pathways, usually in the mesencephalic aqueduct. Thus far in domestic animals, viral-induced hydrocephalus of this genesis has been demonstrated only in experimental canine parainfluenza virus infection in dogs.

Hydrocephalus is "physiological" in the early fetus when the hemispheres are largely thin-walled vesicles. *Congenital hydrocephalus exaggerates this physiological degree of ventricular dilation.* Even in the absence of obstruction, physiological hydrocephalus may persist or be exaggerated in instances of neural dysplasia such as, for example, in cyclopia and cebocephaly. The cavitating cerebral defects, hydranencephaly and porencephaly, are associated with internal hydrocephalus. This is likely to be an *ex vacuo* or compensatory hydrocephalus

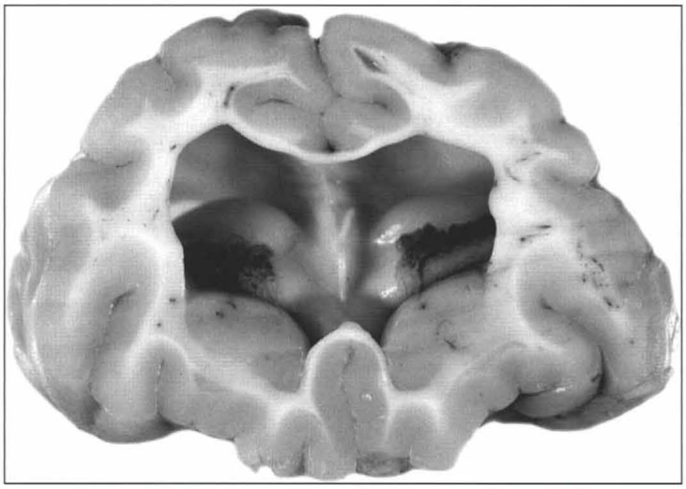

Figure 3.26 Hydrocephalus in a cat, due to vitamin A deficiency. (Courtesy of RF Slocombe.)

occurring secondary to loss of cerebral tissue as in the inherited leukodystrophies and storage diseases, but a hydrostatic component arising from deranged circulation of CSF is also possible. Hydrocephalus may accompany other neural anomalies, but chiefly the rather rare Arnold–Chiari and Dandy–Walker malformations in which hydrocephalus is obstructive in origin and associated with abnormalities of the cerebellum and medulla.

With the exception of the few examples just given, *congenital hydrocephalus remains anatomically obvious but pathogenetically obscure*, and such cases are common. Pups, calves, foals, and piglets are chiefly affected, with a familial incidence, possibly genetic, in pigs. The defect is quite uncommon in cats.

Congenital hydrocephalus is well known in **pups**, especially those of the brachycephalic breeds. This should not imply that the hydrocephalus is correlative to, or a product of, brachycephaly because within breeds there is not much variation in the degree of the skeletal defect, and no obvious relation between it and the presence and severity of hydrocephalus. Malformation of the mesencephalic aqueduct may be a significant pathogenetic factor. The anatomic expression of the hydrocephalus also varies considerably; one lateral ventricle may be involved or both may be dilated symmetrically or asymmetrically, the third ventricle and rostral portion of the aqueduct are usually, but not always, involved, and the fourth ventricle is normal.

Sporadic cases of congenital hydrocephalus occur widely in **cattle**. Many appear to be secondary to aqueductal stenosis. An autosomal recessive gene is considered responsible for many apparently hereditary cases, but the possible roles of fetal infections and nutritional factors must be considered.

Outbreaks of congenital hydrocephalus are recorded in calves in which slit-like deformation of the aqueduct of Sylvius was associated with lateral narrowing of the midbrain, in the peripheral areas of which there was vascular proliferation and perivascular gliosis. Hydrocephalus also occurs in association with chondrodysplasias, especially of the "bulldog" type, but the primary neural defect in these is not known. Several hydrocephalic syndromes have been described in Hereford and Shorthorn cattle; features include cerebellar hypoplasia, microphthalmia, myopathy, and ocular anomalies.

Experimentally, *dietary deficiency of vitamin A* can cause congenital and neonatal hydrocephalus (Fig. 3.26), but spontaneous outbreaks occur only in cattle which have fed for prolonged periods on dry pasture or in feedlots. The hydrocephalus is ascribed to functional impairment of absorption of fluid from arachnoid villi but there is frequently severe compression of the brain and herniations in the caudal fossa, which is expected to provide mechanical obstruction to drainage.

Acquired hydrocephalus is fairly common in animals. It does not approach in severity the congenital defect. The causes are almost always obstructive, but minor degrees of ventricular dilation occur in association with cerebral atrophy in old dogs. Meningeal lesions that destroy the arachnoid villi can lead to external hydrocephalus. This is, however, quite rare, although it has been observed in diffuse meningeal carcinomatosis. Most diffuse meningeal lesions are inflammatory, but these are typically associated with internal rather than external hydrocephalus because meningitis tends to involve the basilar regions and the caudal fossa chiefly and there interferes with the patency of the lateral cerebellomedullary apertures. Most cases of bacterial meningitis are fatal before the changes of hydrocephalus develop unless, as frequently happens, concurrent inflammation of the choroid plexuses extends to the ependyma of the aqueduct and obstructs that channel. Even relatively chronic cases of meningitis, such as may be observed in cryptococcosis, are associated with internal rather than communicating or external hydrocephalus. Additional causes of acquired hydrocephalus are intracranial neoplasms, usually primary but sometimes metastatic, and including papillomas and carcinomas of the choroid plexus, parasitic cysts such as hydatids and coenurids, and the late effects of chronic or healed inflammation that involve the ependyma or cause inflammatory softening or atrophy of paraependymal tissue. The pyogranulomatous ependymitis and meningoencephalitis of feline infectious peritonitis occasionally results in hydrocephalus. In horses, the so-called cholesteatomas or cholesterol granulomas that develop in the choroid plexuses of the lateral ventricles may occlude the interventricular foramen and cause internal hydrocephalus.

Hydrocephalus does not regress. Whether it progresses or not is difficult to determine. Congenital hydrocephalus cannot be easily diagnosed in the newborn in the absence of secondary changes in the cranium, and diagnosable cases seldom live long enough for the course of the defect to be ascertained. Probably, however, congenital hydrocephalus of mild or moderate degree can remain static because, although a severe and fatal defect is common enough in puppies, *hydrocephalus in brachycephalic breeds of dogs is frequently an incidental finding at necropsy*, and the degree of ventricular dilation may be minor or moderate irrespective of the age of the animal. Acquired hydrocephalus in postnatal life tends to be progressive when of obstructive type, the course depending on the site and nature of the obstructing lesion. Compensatory hydrocephalus occurring as a response to cerebral atrophy is static or at the most slowly progressive; it is never severe, except perhaps in familial lipofuscinosis of dogs.

Congenital hydrocephalus is frequently associated with malformation of the cranium. The degree of cranial malformation varies from slight doming, which may be difficult to appreciate, to enormous enlargement, which may cause dystocia. Cranial malformation is not invariable however, and many cases of congenital hydrocephalus of considerable severity may occur with a skull of normal contour. Whether cranial malformation occurs or not probably depends on the time of onset of the hydrocephalus relative to the degree of ossification of the cranial bones and the development and strength of the sutures, and also on the rate at which the fluid is accumulated.

It is often difficult to be certain of the presence of minor degrees of hydrocephalus. The soft brains of the newborn collapse when removed from the skull so that dilation of ventricles may not be apparent. In older, firmer brains, asymmetry of the lateral ventricles and relative dilation of the rostral end of the aqueduct when compared with the caudal end are useful indices. *The septum pellucidum, however, is the structure most sensitive to the effects of fluid accumulation*; it may be fenestrated or may persist as an irregular lacework of connective tissue, but typically, it is absent. Even in mild hydrocephalus, there is usually atrophy in Ammon's horn readily detectable by the ease with which the piriform lobes dimple under slight pressure. With hydrocephalus of greater severity, there is ventricular dilation of corresponding degree. The lateral and third ventricles are most severely affected, and there may be no alteration in the fourth. With ventricular dilation, parenchymal atrophy affects chiefly the white matter and the cerebral cortices; ventrally, the increased pressure is buttressed by the basal ganglia. The corpus callosum is elevated and thinned, and the cerebral cortices over the vertex may be reduced to thin shells of gray matter. The floor of the third ventricle is extremely thinned, the hypophysis is atrophied, and the cerebellum is compressed and displaced caudally.

The extensive cranial malformation of congenital hydrocephalus can occur only if the sutures are ununited. The temporal, frontal, and parietal bones are enlarged and thin and are separated from each other by broad membranes of connective tissue in which accessory bones may form. In these severe cases, the base of the cranium is flattened, the fossae are enlarged and smoothed out, and the orbits are separated but individually reduced in size so that the eyes may protrude.

Gray matter is remarkably resistant to the effects of the pressure exerted by the fluid, but the subcortical white matter degenerates rapidly. It is edematous, the oligodendrocytes and astrocytes are reduced in number, and compound granular corpuscles can be found sometimes in short bands lying deep and parallel to the ependyma. The ependyma, tela choroidea, and meninges are usually not altered significantly.

Hydranencephaly, porencephaly

In **hydranencephaly**, *there can be complete or almost complete absence of the cerebral hemispheres, leaving only membranous sacs filled with CSF and enclosed by leptomeninges.* The cranial cavity is always complete, in contrast to hydrocephalus, and usually of normal conformation, although occasionally there is mild doming of the skull or thickening of the cranial bones. The dorsal, and often the caudal parts of the hemispheres, are the portions most severely defective (Fig. 3.27A, B, C). The leptomeninges may easily be damaged on removing the calvaria but are in their usual position and form sacs enclosing CSF, the fluid occupying the space normally occupied by parenchyma. Discrete remnants of parenchyma may be present in the meninges. When the leptomeninges are incised, it is apparent that the brain stem is of near-normal conformation with well-developed hippocampus and choroid plexuses. The rostral portion of the corpus callosum and septum pellucidum may be intact although attenuated. Cerebellar hypoplasia may be present as a concurrent defect as may the histologic deficits of hypomyelinogenesis.

Hydranencephaly is the residual lesion of full-thickness necrosis of the cerebral hemisphere. In animals, the lesion develops in early fetal stages and before the mature arrangements of the cortex are present. The marginal tissue is dysplastic, flat, and microgyric or the gyri have a radial arrangement from the defect. Although a diagnosis of hydranencephaly is readily made on macroscopic inspection, histological study

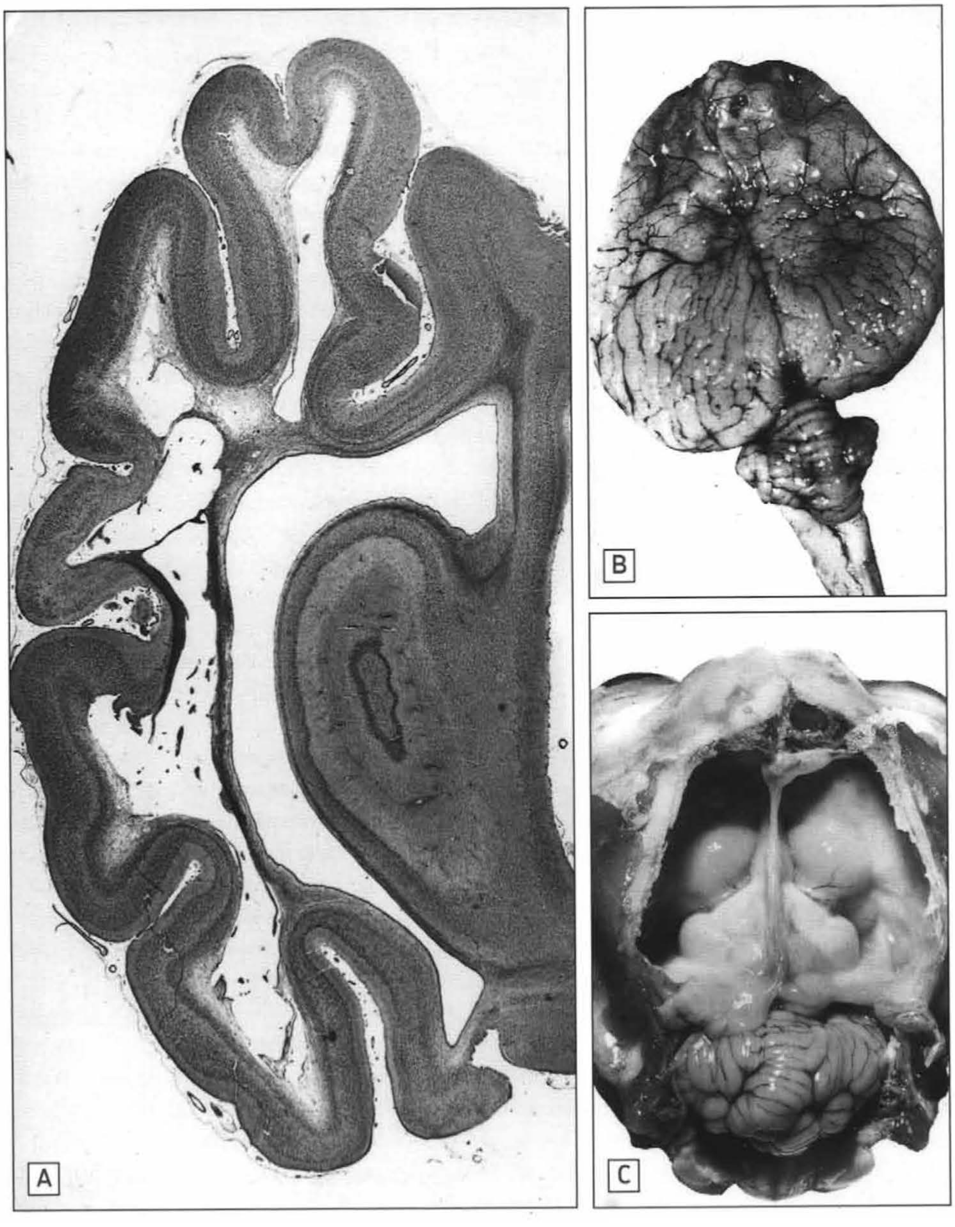

Figure 3.27 A. Hydranencephaly in a lamb with swayback. (Courtesy of J McC Howell.) **B. Hydranencephaly** and cerebellar hypoplasia in a lamb, subsequent to intrauterine *Bluetongue virus* infection. **C. Hydranencephaly** in a cat; meninges removed to expose the brain stem structures.

may provide some insight into the nature of the disease process. The membranous coverings of the remnants of the hemispheres comprise arachnoid, pia, and a thin mantle of residual cortex in normal juxtaposition. The residual cortical tissue may be lined by attenuated ependyma displaced outwards with expansion of the lateral ventricles, but this ependymal lining is frequently incomplete or absent, and the cavity abuts directly on cortical tissue which may be unremarkable except for mild astrocytosis.

Hydranencephaly occurs in all species but is most common in calves, in which it occurs either sporadically or as minor epizootics. The lesion occurs similarly although less frequently in *lambs*. The species occurrence of hydranencephaly reflects its etiological associations with certain viruses infecting the fetus at a critical stage of gestation. In these cases, *hydranencephaly is often part of a spectrum of neural lesions*, the expression of which depends mainly on the age of the fetus at infection. Viruses that are well established as causes of hydranencephaly tend to be either arboviruses, such as *Akabane virus, Bluetongue virus, Rift Valley fever virus* and *Wesselsbron virus*, or pestiviruses, such as *Bovine viral diarrhea virus* and *Border disease virus*.

The *pathogenesis* of hydranencephaly has been clarified through studies of the cavitating encephalopathies caused by fetal viral infections, particularly bluetongue and Border disease in lambs. These infections at critical periods of gestation produce *subventricular zones of necrosis* of the developing cerebral hemispheres. These zones, which may have a vascular basis, involve the neuroblasts in their outward migration and result in cavitation and deprive the cortex of its normal complement of neurons. These cavitations range in size from small cysts with only minor changes in the overlying cortex (porencephaly) to large confluent spaces with the hemispheres reduced to fluid-filled sacs (hydranencephaly). During the necrotizing process, there may be an intense macrophage response, but it is usual for this reaction to have subsided by the time the animal is born and examined.

Mechanical factors also contribute to the development of hydranencephaly. A dissecting effect associated with escape of CSF into the parenchyma may also be important since segmental loss of ventricular ependyma is an early feature of the cavitating process.

Compensatory expansion of the lateral ventricles secondary to loss of brain substance occurs and rapid expansion of the fetal calvaria during the gestation period allows stretching and rupture of residual cortical tissue. In less severely affected areas, the outer rim of cortex overlies a band of subependymal tissue, the intervening cavity being occupied by trabecular parenchymal remnants. Rosette formations of cells that resemble ependymal epithelium may be found in the subependymal area. Accumulations of mineralized debris may be present in the meninges.

Porencephaly *is cystic cavitation of the brain evolving from a destructive process in prenatal life.* The defect typically involves the white matter of the cerebral hemispheres. An affected brain may contain a single cyst or there may be multiple cystic lesions. The temporal portion of the cerebral hemispheres is an area of predilection, but porencephalic change may be found throughout the cerebral hemispheres, although typically sparing the basal nuclei. Occasionally, lesions are found in brain stem and cerebellum. The cysts are usually randomly located, but evidence of bilateral symmetry is sometimes apparent, particularly in well-developed lesions of the cerebral hemisphere. Rarely cysts may communicate with ventricular cavities or with the subarachnoid space. The cysts may be apparent from the meningeal aspect as focal fluctuant areas of attenuated cerebral cortex or as superficial, clear submeningeal cysts. The cysts range in size from microscopic to several centimeters in diameter. The cysts are variable in shape, but roughly spherical or cleft-like outlines are common. On section, they are filled with clear fluid and are smooth walled, but are traversed by variable numbers of trabeculae. Less well-developed lesions may appear as gelatinous softenings.

The porencephalic cavities, particularly the larger defects, are often unremarkable microscopically, being lined by a layer of flattened glia. Apart from some mild marginal astrocytosis, they show surprisingly little evidence of reactive or inflammatory change. In other cases, there is accumulation of hemosiderin-containing gitter cells about the margins of the cyst and within the cavity. The trabeculae comprise residual brain parenchyma, usually oriented about a blood vessel. Some small lesions, evident grossly as focal gelatinous areas, appear as focal leukomalacia comprising white matter in the process of dissolution associated with accumulation of macrophages and gitter cells. Sometimes the inflammatory nature of the lesions is indicated by the presence of mild nonsuppurative meningoencephalitis with gliosis, perivascular cuffing and focal mineralization about the margins of the cysts, and mononuclear infiltration in the meninges overlying the defects.

The etiopathogenesis of porencephaly parallels, but is a less severe expression of, the pathological process seen in hydranencephaly. Both lesions are commonly recorded in the course of outbreaks of cavitating cerebral defects and may occur together in the same brain. In the case of cavitating viral infections of the fetal brain, termination of the disease process in either porencephaly or hydranencephaly is influenced by gestational age at infection, with porencephaly tending to follow infection at a later stage than is the case with hydranencephaly.

Porencephaly is a common manifestation of prenatal infection of *lambs* with some strains of *Border disease virus* and is seen in calves infected in utero by *Bovine viral diarrhea virus*. The cystic or gelatinous transformations of the cerebral white matter that occur in some cases of copper deficiency in lambs (swayback) are porencephalic in nature. The lesion has also been induced experimentally in lambs by exposure of pregnant ewes to hyperthermia during the last two-thirds of pregnancy.

Periventricular leukomalacia of neonates

Interrelated lesions dominated by intraventricular hemorrhage, ventriculomegaly, and malacia of white matter are quite frequent in neonates. In domestic animals, the lesion has not been distinguished from hydrocephalus and hydranencephaly, which is the reason for considering it here with the malformations from which it needs to be distinguished, rather than with malacic diseases. The application of imaging technology has identified a surprising incidence of the complex in human neonates with later minimal to severe neurological deficits. The lesions in human neonates are most frequently associated with placentitis, prematurity, and growth retardation, suggesting that placental insufficiency may be critically important. In lambs, there is an association with placentitis of toxoplasmosis, tick-borne fever, and chlamydiosis.

Periventricular leukomalacia typically refers to necrosis of white matter adjacent to the lateral ventricles that results in the formation of cysts in the cerebrum or in more extensive lesions simulating hydranencephaly or hydrocephalus *ex vacuo*. In animals, the lesion is not limited to the cerebrum but may extend to affect also periventricular white matter of the cerebellum, cerebellar roof nuclei, and white matter of the cerebellar folia.

Intraventricular hemorrhage may extend caudally as far as the central canal of the spinal cord causing ventricular dilation. The hemorrhage of variable severity may remain intramural in the hemispheral white matter.

Periventricular leukomalacia may allow survival in pups for several weeks. The cavitating cerebral lesion, and the cerebellar lesion if present, is lined internally by ependyma and a thin layer of white matter. There may be local defects allowing communication with the dilated ventricle. Clustered cases are observed in kids and lambs. Affected neonates tend to be small for age, stillborn, or die immediately after delivery, although some with minor neurologic defect may survive and develop normally.

The pathogenesis of these defects is unknown. The mechanisms appear to involve the structural fragility of blood vessels in the periventricular subependymal zone and instability of blood flow in the vulnerable areas. Perivascular hemorrhages may be confined to this zone. The malacic lesion in white matter is coagulative necrosis with vacuolation of the tissue and acidophilic swollen retraction balls on axonal fragments. Microglia provide the only inflammatory cells. Cystic lesions have peripheral sprigs of capillaries and marginal and luminal macrophages expected to contain hemosiderin. In individual cases in lambs and kids, the lesions may be of different ages and, in clustered cases in these animals, some may show hemorrhage only and some may show established cavities.

Cerebellum/caudal fossa

The cerebellum develops from the lips of the rhombencephalon in the region of incomplete closure of the neural tube. There are *two major germinative zones*. The rostral lips give rise to precursors of the cerebellar granule cells. In their first migration, granule cell precursors cover the whole of the cerebellar pial layer at about the time of closure of the rostral neuropore. This is a germinative layer that produces a second generation of germinal cells, some of which remain as daughter cells and others undergo lateral migration in the developing molecular layer. In a third migratory wave, postmitotic cells send axons vertically down through the molecular and Purkinje-cell layers under guidance of radial glia; the cell body then moves along the axon to the maturing granular layer.

Disorder of the granule cell layer is frequently part of the disruption caused by fetal viral infections. *Focal heterotopias* are frequent in neonates usually without clinical effect. These cells may be the origin of the medulloblastomas of young animals.

The caudal rhombic lips produce a highly proliferative neuroepithelium from which neuronal precursors migrate along several pathways to form the Purkinje cells of the cerebellar cortex, the cerebellar roof nuclei, and to the precerebellar nuclei including the olivary, cuneate, and reticular nuclei of the medulla, and to the pontine and tegmental nuclei of the pons; axons from these nuclei project back into the cerebellum.

The cerebellum has three functionally distinct regions. The *vestibulocerebellum* regulates balance and eye movements. It is the oldest part of the cerebellum (paleocerebellum) and occupies the flocculonodular lobules where it receives afferents from the vestibular nuclei. The *spinocerebellum* regulates limb and body movements, receiving somatosensory information via the spinocerebellar tracts and precerebellar nuclei, and occupies the vermis and medial aspects of the hemispheres. The lateral hemispheres, the *cerebrocerebellum*, receive input from the cerebrum via pontine nuclei and are involved in the composition of complex movements. Within these main cerebellar regions, there is further regional patterning corresponding to body parts.

Disorders of migration and survival of Purkinje cells underlie many of the cerebellar malformations, and premature loss is the most common component of the abiotrophies. Correlative changes may be present in the precerebellar nuclei and in the cerebellar roof nuclei.

Cerebellar defects are among the more important of the developmental anomalies of the CNS because of their frequent occurrence and almost invariable accompaniment by significant and distinctive clinical manifestations. They may be expressions of failure of intercellular communication and support whereby a defect in one cell lineage may adversely affect the organizational pattern and function and viability of other cell types. *Cerebellar defects are quite common in cats and calves, relatively so in pigs, dogs, and lambs, but uncommon in foals.* Most defects of morphogenesis can be divided into two broad categories and the entities are discussed below as being examples of either *cerebellar hypoplasia* or *cerebellar abiotrophy (atrophy)*. This distinction into hypoplastic and atrophic types is somewhat artificial, because it is apparent that many cases are compounded by both processes.

Minor dysplastic lesions of no consequence are quite common in young animals but are fewer or less conspicuous in adults. They are most common in the flocculonodular lobules and where the cortex terminates at the peduncles. The foci are microscopic and consist of tangled islands of germinal, molecular, and granular layers with Purkinje cells distributed haphazardly. The dysplasias of the Arnold–Chiari and Dandy–Walker syndromes, of copper deficiency, and the metabolic storage disorders are discussed separately.

The name of the teratological condition merely emphasizes the major component, in these cases the cerebellar defect. There may, however, be coincident malformations such as agenesis of the corpus callosum or hydranencephaly. *There are always correlative changes*, this term grouping together those structural changes that occur in nuclear masses that send fibers to, or receive fibers from, the cerebellum as well as in the particular tract of fibers themselves. The term implies that there is a causal connection, the cerebellar defects being primary and the subcerebellar defects being secondary, but such an implication is less likely to be valid for the cerebellar hypoplasias than for the cerebellar atrophies. Anatomic classifications of the cerebellar hypoplasias tend to take into account the distribution and severity of correlative changes, especially those in the deep cerebellar nuclei, the pontine nuclei, the inferior olives and in the cerebellar brachia, the restiform bodies, and the spinocerebellar tracts. The pattern of correlative changes varies from case to case, and there is not a quantitative correspondence between the cerebellar defects and the correlative defects. There are also very wide variations in the severity of the cerebellar hypoplasias, which is reasonable if the severity is properly to be related to the time of onset, duration, and severity of the arrest of development. From these viewpoints, *anatomical classification of cerebellar hypoplasias is artificial because the defects are quantitative.*

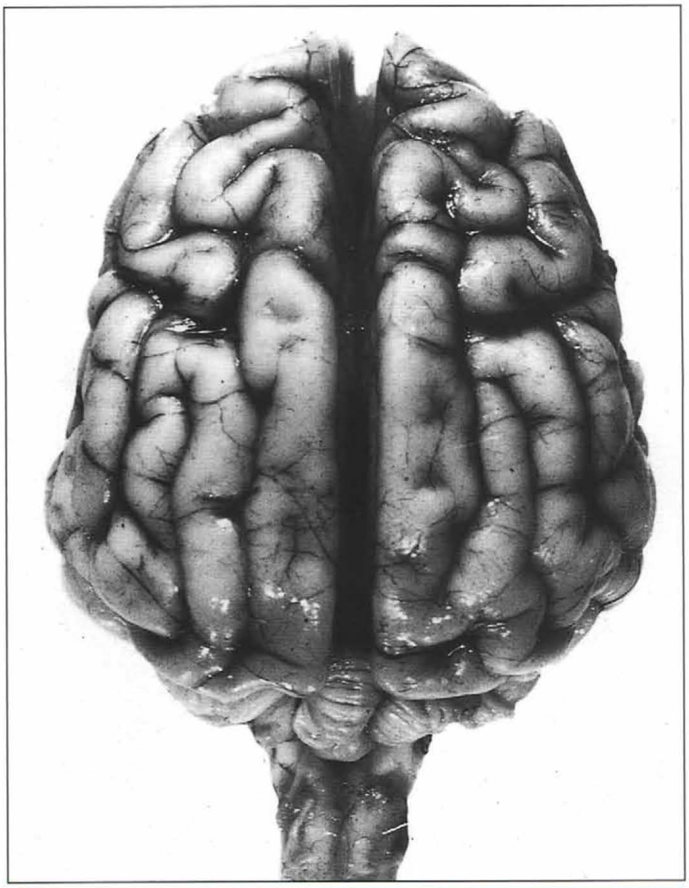

Figure 3.28 Cerebellar hypoplasia in a dog.

Cerebellar hypoplasia, abiotrophy

Cerebellar hypoplasia *is one of the most common congenital nervous system defects of domestic animals and is seen in all domestic species* (Fig. 3.28). There is persuasive evidence for genetically determined occurrence of the disease in calves of various breeds, particularly beef shorthorns, in Arabian and Arabian cross foals, and in Gotland ponies and Chow Chow dogs. A novel form of cerebellar hypoplasia with intraneuronal inclusions is reported from New Zealand in Cocker Spaniel dogs with progressive ataxia and seizures. Cerebellar hypoplasia has been reported in piglets born to sows treated with the organophosphate trichlorfon during pregnancy, and may be detected microscopically in goat kids and lambs affected by hypocuprosis. The most prevalent and best-defined cerebellar hypoplasias are those that follow infection of the developing cerebellum by *Feline panleukopenia virus, Bovine viral diarrhea virus, Border disease virus,* and *Classical swine fever virus.* Canine parvoviral DNA has been detected in cerebellar hypoplasia in dogs. The occurrence of cerebellar hypoplasia as a consequence of viral infections of the developing nervous system is further discussed in the section Viral causes of developmental defects of the central nervous system.

Cerebellar growth patterns determine the gestational or perinatal periods during which cerebellar hypoplasia may follow the action of a teratogen and influence the nature and scope of the structural aberrations marking the hypoplastic process. The cerebellum originates as a dorsal growth of the alar plate of the metencephalon over the fourth ventricle. Germinal cells adjacent to the fourth ventricle differentiate into neurons that migrate into the developing cerebellum to form the deep nuclei and Purkinje neurons. This differentiation occurs prior to mid-gestation. A population of germinal cells migrates to the surface of the developing cerebellum and forms a layer several cells thick. This is the external granular layer that covers the folia as they develop. In this layer, cells proliferate rapidly and differentiate into microneurons such as basket cells, stellate cells and granule cells, which migrate into the folium to their definitive locations. This proliferation, differentiation, and migration begins late in gestation and continues for a few weeks postnatally in most species. Normal cerebellar cytoarchitectural development, including the maturation and localization of Purkinje cells, is dependent upon these microneurons establishing orderly synaptic connections.

It is the actively mitotic germinative cells of the external granular layer that are especially vulnerable to the effects of teratogenic agents. *Feline panleukopenia virus, Bovine viral diarrhea virus, and Border disease virus cause selective necrosis of external granular layer cells.* That the destructive process may be augmented by vascular damage has been demonstrated for *Bovine viral diarrhea virus. Classical swine fever virus* possibly acts through inhibition of cell division and maturation. In puppies, segmental cerebellar dysplasia may result from postnatal infection with canine herpesvirus. Since the growth behavior of the subependymal cell plate has features in common with the external granular layer of the cerebellum, residual lesions attributable to this site of infection, such as cavitating defects, may be associated with cerebellar hypoplasia, particularly in cases of viral origin.

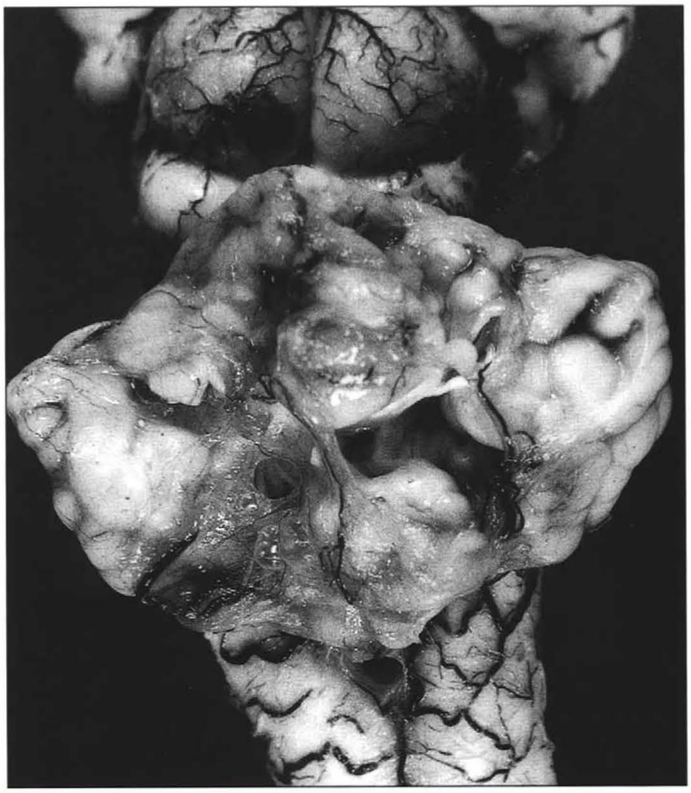

Figure 3.29 Cerebellar hypoplasia (cerebrum removed to expose cerebellar lesion) in a cow; asymptomatic over 5 years.

The anatomic expressions of hypoplasia, both in the cerebellum and subcerebellar structures, are very variable in degree. In some cases, the cerebellum may appear grossly normal, the hypoplastic defects being detectable only on microscopic examination. In such cases, the defects are irregular in distribution although there is a more or less severe loss of Purkinje cells. The granular layer is here and there narrowed and deficient in cells, but the molecular layer is normal. Correlative lesions may be present or absent and when present may be asymmetrical; they occur chiefly in the deep cerebellar nuclei, olives, and cerebellar peduncles. At the other extreme, the cerebellum may be represented only by a small nubbin of tissue or two unconnected nubbins each related to a hypoplastic peduncle (Fig. 3.29). In these severe defects, there is no folial pattern or division into lobes. Intermediate degrees of cerebellar hypoplasia are, however, the most common. It is usually possible to recognize with the naked eye that the cerebellar peduncles are diminished in size, especially the brachium pontis, that the medullary pyramids are flattened and that the small size of the restiform bodies gives the fourth ventricle a flattened appearance. Microscopically, the cerebellar cortex is disorganized. A brief description is not possible because the pattern varies greatly from case to case and place to place in the one animal. The Purkinje cells and the cells of the granular layer are the most obviously deficient and, in those that are present, regressive changes are common.

Cerebellar atrophy (or **abiotrophy**) *refers to premature or accelerated degeneration of formed elements, presumably caused by some intrinsic metabolic defect.* The Purkinje cells appear particularly susceptible to spontaneous degeneration; there may be secondary depletion of granule cells but other cortical layers are normal.

Cerebellar atrophy occurs in lambs, dogs, cats, various breeds of cattle, piglets, and foals. The disease in **lambs**, which are commonly known as "*daft lambs*," is reported from England and Canada. It is not restricted to any breed but is presumed to be inherited. The dams are normal. Affected lambs show signs of cerebellar dysfunction at birth, which include abnormalities of muscle tone, disorders of equilibrium, and tremors. The cerebellum is however normal in size and gross form. The histological changes affect primarily the Purkinje and Golgi cells, and these especially in the median lobe. Degeneration and loss of these cells leave some empty baskets and a replacement astrogliosis. In the early stages of degeneration, the Purkinje and Golgi cells are shrunken and hyperchromatic or swollen and pale with cytoplasmic vacuolation. They ultimately undergo lysis and disappear, leaving a spongy zone between the granular and molecular layers. There is, simultaneously, a diminution in the population of granule cells. Regressive changes with gliosis may be apparent in the deep cerebellar nuclei and olives.

Progressive cerebellar degenerations are common in **dogs,** and abiotrophic defects have been recorded in a variety of breeds including Airedales, Gordon Setters, rough-coated Collies, Border Collies, Finnish Terriers, Beagles, Australian Kelpies, and Bernese Mountain Dogs. Signs in the pups become evident at about 3 months of age. The cerebellum may be normal in size and shape or slightly diminished in size and somewhat flattened. Microscopically, there is degeneration and loss of Purkinje cells and granule cells (Fig. 3.30A, B). The Purkinje cells degenerate, being either shrunken and hyperchromatic or pale, swollen and vacuolated (Fig. 3.31A); most disappear, leaving empty baskets and a fenestrated ground layer (Fig. 3.31B). The atrophic process may show evidence of regional predilection. In Gordon Setters, the dorsal portions of the median lobe and vermis are most severely affected, while in Collie dogs selective involvement of the rostral folia of the vermis is reflected in macroscopic diminution of this area. Collateral changes in the subcerebellar nuclei are minor, but in this regard it may be pertinent that affected dogs are usually euthanized shortly after the defect becomes apparent. Nonprogressive cerebellar ataxia noted at 2 weeks of age is reported in Coton de Tulear dogs.

Hereditary striatonigral and cerebello-olivary degeneration occurs in the *Kerry Blue Terrier.* Pedigrees of affected dogs indicate autosomal recessive inheritance. Clinical signs begin between 9 and 16 weeks of age and are characterized by ataxia and dysmetria. *The inherent defect is neuronal degeneration,* and the brain changes follow a definite anatomical and temporal pattern of development. Degeneration and loss of Purkinje cells in the cerebellar cortex is evident at the onset of clinical signs. Subsequently there is sequential involvement of the olivary nuclei, caudate nuclei and putamen, and finally the substantia nigra. In the cerebellar cortex, chromatolytic degeneration and loss of Purkinje cells is attended by astrocytosis involving Bergmann's glia and depletion of granule cells. In the cerebellar white matter and contained nuclei, there is status spongiosus and axonal swelling. Changes in the olivary nuclei, basal nuclei, and substantia nigra tend to be symmetrical and initially (Fig. 3.32) feature neuronal degeneration, axonal swelling, spongiosus and fibrous astrocytosis, with progression to malacia and cavitation. Olivary neurons undergo chromatolysis, while in the remaining nuclear structures the nerve cells accumulate intracytoplasmic eosinophilic granules and undergo ischemic change.

Macroscopic evidence of the disease process in the cerebellum is limited to a modest degree of folial atrophy but, with progression

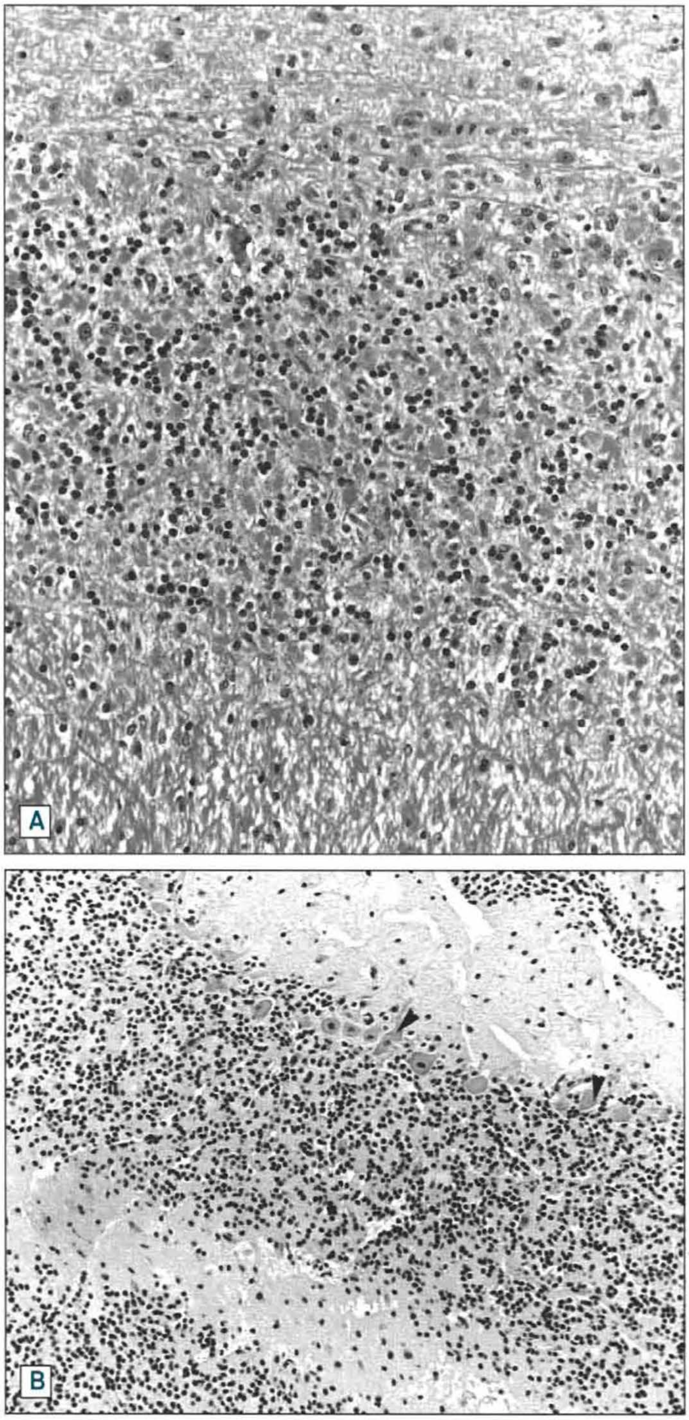

Figure 3.30 A. Cerebellar abiotrophy in a puppy; note severe hypoplasia of the molecular layer with almost complete absence of Purkinje cells. **B.** Cerebellar cortex of an age-matched puppy showing normal molecular layer and abundance of Purkinje cells (arrowheads).

of the condition, involvement of the basal and brain stem nuclei is manifest grossly by bilateral focal malacic lesions. Gross lesions are most severe in the caudate nucleus, which, after 7–8 months of clinical illness, may be reduced to numerous microcystic cavities. *It is proposed that the cerebellum and basal nuclei are the primary areas of involvement*, with the lesions in the olivary nucleus and substantia nigra being attributed to transynaptic neuronal degeneration along glutaminergic neurotransmission pathways.

The Kerry Blue Terrier condition is not the sole cerebellar abiotrophy in which accompanying extracerebellar lesions may be found. Olivary nuclei may be affected in the Bernese Mountain Dog, the cerebral cortex in the miniature Poodle, and spinal Wallerian degeneration may be found in rough-coated and Border Collies and in Merino sheep. In the Swedish Lapland Dog, there is a neuronal abiotrophy involving Purkinje cells; however, the effects of this are overshadowed by motor neuron degeneration and the disease is discussed below with others of that group.

Bovine familial convulsions and ataxia *is a heritable disorder of purebred and crossbred Aberdeen Angus cattle in the United Kingdom.* The clinical syndrome is characterized by intermittent episodic seizures in newborn and young calves and by the gradual development of ataxia with spasticity and hypermetria in calves surviving bouts of seizures extending over 2–3 months. The distinctive microscopic change is Purkinje cell axonal swelling in the cerebellar granular layer. There is also degeneration and loss of Purkinje cells. An apparently similar disorder has been described in Charolais cattle in the United Kingdom.

Sporadic cases of various forms of juvenile and adult-onset cerebellar degeneration, including **olivopontocerebellar atrophy**, have been reported in **cats**.

Cerebellar abiotrophy occurs in **horses**, particularly Arabian and part-Arabian horses, as well as in the Swedish Gotland pony and the American miniature horse, and is an inherited, likely autosomal recessive, condition. Head tremors and ataxia develop in affected Arabian foals between birth and 6 months of age, as a result of loss of Purkinje cells and granule cells from the cerebellar folia. An additional finding in an American miniature horse was degeneration of dorsal accessory olivary and lateral (accessory) cuneate nuclei and focal necrosis in the putamen.

Gomen disease *is a cerebellar degeneration and ataxia of horses in New Caledonia.* Some folial atrophy in the cerebellar vermis may be evident on gross examination. Microscopically, there is thinning of the cerebellar molecular layer and loss of Purkinje and granule cells. There is also considerable deposition of a pigment resembling lipofuscin in many of the surviving Purkinje cells as well as in the neurons of the brain and spinal cord. This material is also present in macrophages seen in areas where Purkinje cells are missing. The cause is unknown, but is thought to be an environmental toxin.

Arnold–Chiari malformation

In the Arnold–Chiari malformation (Chiari type II malformation), the cerebellar vermis is herniated as a tongue-like process of tissue into the foramen magnum and cranial spinal canal where it overlies an elongated medulla that is also displaced caudally (Fig. 3.33). The cranial nerves from the medulla alter their trajectory. The tentorium is inserted caudally towards the foramen magnum, the tentorial hiatus is shallow and wide, and the pons and occipital poles are displaced through it. The displaced occipital poles show sagittal, parallel gyri. Internal hydrocephalus may be a secondary effect, and spina bifida or meningomyelocele may be concurrent.

The caudal fossa in particular, but perhaps also the rostral fossa, is too small for the normal volume of brain tissue, suggesting that there has been failure of neurogenic induction of osseous growth. The defect is observed occasionally in calves. In the Cavalier King Charles Spaniel dog, occipital bone hypoplasia with obstruction of the foramen magnum and secondary syringomyelia is common, and is similar to human *Chiari type I malformation*.

Dandy–Walker syndrome

In the Dandy–Walker syndrome, seen in various species, *there is a midline defect of the cerebellum with the vermis largely absent and the cerebellar hemispheres widely separated by a large fluid-filled cyst in an enlarged caudal fossa*. The roof of the cyst, which ruptures easily when the brain is removed, consists of ependyma, a disorganized layer of glial tissue, and an outer layer of leptomeningeal tissue. An expanded fourth ventricle forms the floor of the cyst. The vermal malformation is thought to be the result of a primary midline developmental defect.

Spinal cord

Myelodysplasia

Myelodysplasia refers to abnormal development of the spinal cord. **Segmental aplasia** and **hypoplasia** may occur at any level of the spinal cord (Fig. 3.34), but *the lumbar region is most frequently affected.* Some cases are associated with fetal *Akabane virus* infection.

Perosomus elumbus, which occurs in calves and lambs, *is characterized by partial agenesis of the spinal cord.* The lumbar segment is involved, and there is failure of induction of the related vertebrae. The cranial part of the body is normal, but *the vertebral axis ends at the caudal thoracic region, and lumbar, sacral, and coccygeal vertebrae are absent* (Fig. 3.35). The spinal cord ends in the thoracic region in a blind vertebral canal. The caudal part of the body remains attached to the cranial part by soft tissue only; the limbs are arthrogrypotic and their muscles atrophic. Atypically, only some lumbar segments are absent, or severely hypoplastic with absence of arches and spinal muscle, and a remnant of cauda equina may be found in the sacral region.

The most severe forms of myelodysplasia, affecting especially the potential dorsal regions of the cord, occur *in association with the forms of spina bifida* described below. Myelodysplasia, not associated with the skeletal manifestations of spina bifida but probably best included in this classification, occurs quite commonly in animals particularly *in association with arthrogryposis in calves and lambs.* The dysplasia, which is readily detectable by the presence of *aberrant central canals* (sometimes as many as six), chiefly involves limited lengths of the lumbar segment of the cord but occasionally is localized to cervical or thoracic regions. *Denervation atrophy of appendicular muscle is constantly present and is the probable basis of the arthrogrypotic changes.* The degree of dysplasia is quite variable, but it is characterized by aberrations of the central canal (Fig. 3.36), by the absence of dorsal or ventral septa, the presence of ectopic septa and clefts, and by distortion, asymmetry, and

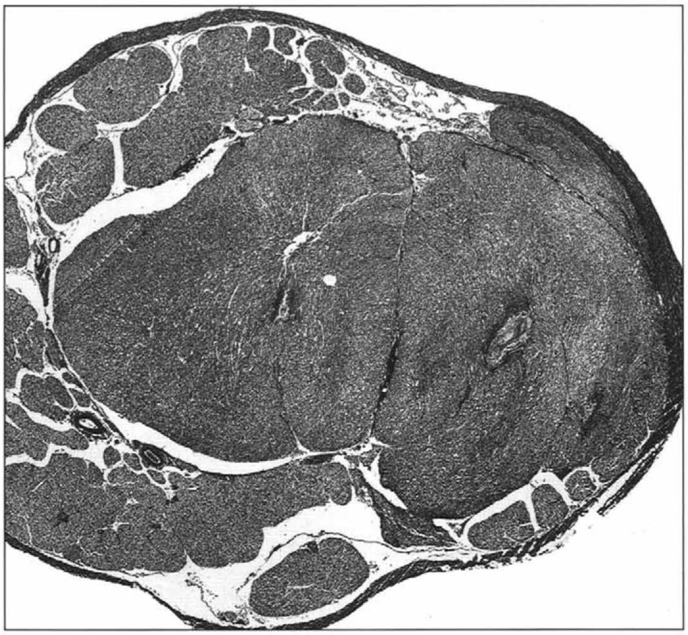

Figure 3.37 Diplomyelia in a dog.

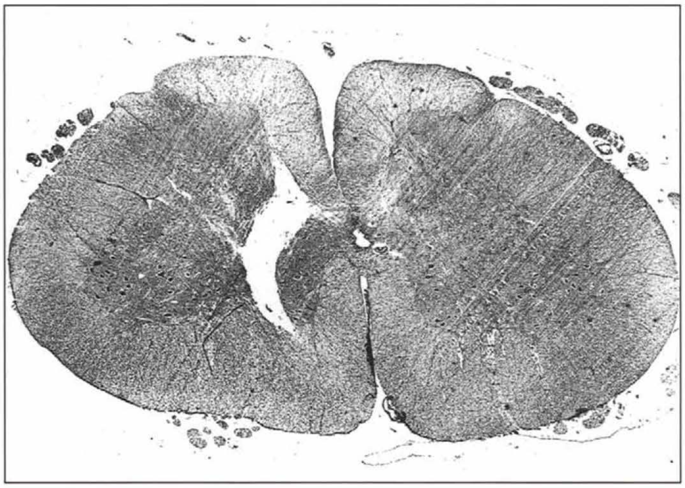

Figure 3.38 Syringomyelia in a dog.

partial duplication of the ventral and dorsal horns of gray matter. In some cases the cord is duplicated completely within common leptomeninges and dura (*diplomyelia*) (Fig. 3.37), or within separate meningeal coverings and vertebral canals separated by a bony partition (*diastematomyelia*).

Syringomyelia *is tubular cavitation of the spinal cord that extends over several segments*; it is an uncommon anomaly in animals. Syringomyelia is rarely acquired and is best known as one of the lesions associated with the familial disorder of young Weimaraner dogs described below. When the cavitation involves the medulla, the defect is termed *syringobulbia*. Syringomyelia and syringobulbia may occur together.

Hydromyelia *is dilation of the central canal of the spinal cord*. It is not commonly detected but occurs in association with spina bifida and may be a precursor lesion for syringomyelia. Both hydromyelia and syringomyelia are found in the dysraphic spinal cord of arthrogrypotic Charolais calves. Hydromyelia may be acquired as a consequence of obstruction of cerebrospinal fluid flow in the central canal.

A syndrome of pelvic limb gait disturbance in young **Weimaraner dogs** is a manifestation of a spectrum of myelodysplastic and dysraphic lesions, and is inherited in a co-dominant mode with variable penetrance. The trait is lethal in the homozygous state. Affected animals exhibit a gait deficit from the time they begin to walk, but clinical signs in some cases may be barely noticeable. Severely affected dogs typically are unable to completely extend the hindlimbs so that their normal attitude is crouched. When walking, the hindlimbs are moved together in a "bunny-hopping" or "kangaroo-gait" fashion. Additionally, affected animals may show thoraco-lumbar scoliosis, depression of the sternum, and abnormal hair streams in the dorsal cervical region. There is no significant progression or regression of clinical signs with age, and there is not a good correlation between clinical signs and the degree of structural malformation.

Pathologically, the exposed spinal cord is grossly normal in size and conformation, but *a range of dysraphic defects may be present* including: anomalies of the dorsal septum, which may be absent; hydromyelia and other anomalies of the central canal, which may be absent; duplication or displacement of the central canal; anomalies of extent and distribution of the central gray matter; anomalies of the ventral horns consisting of deficient delineation and development of medial cell groups, and aberrant collections of neurons and gray neuropil; deficiency of the ventral median fissure, which may be total. Histologic studies on affected embryos suggest that the primary lesion is related to aberrantly positioned mantle cells ventral to the central canal in the floor plate area.

Syringomyelia is not present until about 8 months of age and involves lumbar segments. Cavitation may be barely visible to the naked eye. Microscopically, the cavity is usually found in the central gray matter dorsal and lateral to the central canal (Fig.3.38). There is not much encroachment on the white matter except for that in the white commissures when the cavitation extends from one side to the other. Connection with the central canal is difficult to demonstrate but may be found in serial sections. Ependyma does not line the cavity, the walls of which are formed of frayed nervous tissue with an appearance suggesting that the cord has been squashed or torn at necropsy. The tissue around the cavity is edematous and stains poorly.

Spina bifida and related defects

Spina bifida *refers to absence of the dorsal portions of the vertebrae*. It is, however, a rather imperfect name as the various forms of the defect represent differences in degree of defective closure of the neural tube, its separation from the ectoderm, and its induction of a skeletal investment. It is convenient to divide the defect into several classes on the basis of severity: *myeloschisis, spina bifida occulta, spina bifida cystica with meningocele, and spina bifida with myelomeningocele apply to the vertebral defect; amyelia, diastematomyelia, hydromyelia, and dysraphism apply to the spinal cord.*

In **total myeloschisis**, *neurulation does not occur*, the neural plate remaining open. By total is meant a defect that involves the whole of the vertebral axis with anencephaly an expected accompaniment. There is virtual amyelia (absence of spinal cord), neural tissue being present only as soft red masses in the residual groove. *Local myeloschisis* is a localized defect due to failure of closure of the neural tube. One or more vertebral segments may be defective. The defect may occur in any portion of the vertebral axis but is expected to be lumbosacral.

The defect occurs most frequently in brachycephalic breeds of dogs and is inherited as an autosomal dominant condition in Manx cats. Affected cats are heterozygotes of variable expression, while the homozygous state is lethal. *Sacrococcygeal agenesis* occurs in association with spina bifida in Manx cats, calves, dogs, and sheep.

Spina bifida occulta is perhaps the least rare form of the defect in animals, and it is occult because *it is not apparent except for the presence of dimpling or deeper invagination of the skin.* It may accompany defects in other remote tissues but the defect is otherwise limited to the absence of one or more vertebral arches. The cord may be grossly normal but dysplastic microscopically, usually with diastematomyelia. The spinous processes may be bifid or absent.

In **spina bifida cystica**, a cystic swelling protrudes through the vertebral defect. Because of differential growth of the vertebral and neural axes, the cranial–caudal position of the skin and bone lesions may not correspond, especially in the caudal regions where the defects are expected to occur.

When meninges protrude (**meningocele**), the roof of the cyst is comprised of skin and condensed meninges, including dura mater. The spinal cord may be normal grossly but dysplastic segments are detected microscopically. Macroscopic lesions in the cord include partial duplication and cystic distension of the central canal that communicates with the endodural space via a cleft in the dorsal funiculi. A meningocele may contain a large accumulation of adipose tissue (**lipomeningocele**).

When meninges and spinal cord protrude (**meningomyelocele**), the cyst tends to be broad-based. *Failure of dehiscence of the neural crest from surface ectoderm provides for a central area without epithelial covering.* This *medullovasculosa* corresponds to the cerebrovasculosa of anencephaly and consists of vascularized meninges, heterotopic cord tissue, and connective tissue. The defects in the cord include those mentioned as occurring with meningocele and, in severe cases, duplication or absence of the cord in affected segments. The *tethered cord* syndrome refers to attachment of the meningomyelocele that prevents the normal ascent of the spinal cord as the vertebral column grows.

A **dermoid sinus** is a congenital abnormality, inherited in Rhodesian Ridgeback dogs, in which incomplete separation of the neural tube from the overlying dorsal midline ectoderm allows persistence of a sinus connecting the skin surface to the supraspinous ligament, or it may extend as deep as the dura mater of the spinal cord.

Viral causes of developmental defects of the central nervous system

Akabane virus

Akabane virus (AKAV), a species of the genus *Orthobunyavirus*, is among the most potent of the viral teratogens of domestic animals, but the infection is otherwise asymptomatic. **Iriki virus**, a strain of AKAV, has similar pathogenic potential. Following maternal infection at critical stages of gestation, AKAV produces a range of predominantly neural abnormalities in calves, lambs, and kids, but *AKAV is best known for producing outbreaks of arthrogryposis and hydranencephaly in calves*. Epizootics of Akabane virus disease in cattle have been reported in areas of Japan, Israel, and Australia. The vector in Australia is the biting midge *Culicoides brevitarsis*, and the virus has also been isolated from mosquitoes in Japan. Buffaloes, horses, and pigs are additional vertebrate hosts. Although arthrogryposis and hydranencephaly may be the most obvious manifestations in field epizootics of bovine AKAV disease, a range of overlapping syndromes is observed in calves in affected herds. The pattern of fetal disease corresponds to the gestational age of the fetus at the time of infection. Infection late in gestation may cause abortion. The initial manifestation of neural abnormality in a field outbreak is the birth of incoordinate calves and, in this group, nonsuppurative encephalomyelitis is evident on histological examination. *Microencephaly* and *cerebellar hypoplasia* occur occasionally as manifestations of late infection. *Arthrogryposis*, sometimes associated with spinal deformities, appears early in the outbreak following fetal infection at 5–6 months of pregnancy. In arthrogrypotic calves, there is loss of spinal ventral horn neurons, loss of myelin in the motor tracts of the spinal cord and in ventral spinal nerves, and denervation atrophy together with fibrous and adipose replacement of skeletal musculature.

At least some strains of AKAV have the capacity to cause *polymyositis*, particularly in the early myotubular phase of skeletal muscle development, suggesting the possible involvement of this process in the arthrogrypotic change. *Severe hydranencephaly*, manifest clinically as blindness and stupidity, is seen towards the end of the epizootic, being the result of fetal infection at 3–4 months of gestation. With increasing age of the fetus at the time of infection, the cavitating cerebral changes are less severe and grade towards *porencephaly*.

The teratogenic potential of AKAV in **sheep and goats** is qualitatively the same as for cattle. Cavitating cerebral defects, arthrogryposis, microencephaly, and agenesis or hypoplasia of the spinal cord have been produced in lambs born of ewes inoculated on days 29–48 of pregnancy. Field observations in Australian flocks suggest that, in sheep, *microencephaly* is relatively more common as a consequence of AKAV infection than it is in cattle.

Aino virus, a serotype of species *Shuni virus*, genus *Orthobunyavirus*, can cause arthrogryposis, hydranencephaly, and cerebellar hypoplasia in bovine fetuses infected experimentally, and is suspected to be the teratogen in field cases of congenital bovine malformations in Japan.

Cache Valley virus (CVV), a serotype of species *Bunyamwera virus*, genus *Orthobunyavirus*, is a mosquito-borne bunyavirus that is endemic in North America. CVV is capable of infecting a variety of mammals, generally as subclinical infections but it is occasionally teratogenic in fetal lambs. The nature and pathogenesis of the abnormalities produced are comparable to those of *Akabane virus* in sheep. Three other members of genus *Orthobunyavirus* – **LaCrosse virus** and **San Angelo virus** (serotypes of *California encephalitis virus*), and **Main Drain virus** – also express bunyaviral tropism for fetal tissue infection and can induce lesions including arthrogryposis, hydrocephalus, fetal death, axial skeletal deviations, anasarca, and oligohydramnios.

Chuzan virus (CHUV), a strain of species *Palyam virus*, genus *Orbivirus*, family Reoviridae, is transmitted by *Culicoides* sp. CHUV is infective for several ruminant species, and in Japan has been incriminated as a teratogen of fetal calves with features similar to those of *Akabane virus* infection.

Bluetongue virus

Hydranencephaly and porencephaly have been reported in lambs and calves whose dams received a live attenuated bluetongue vaccine or contracted *Bluetongue virus* (BTV, species of the genus *Orbivirus*, family Reoviridae) infection during pregnancy (Fig. 3.27B). The type of congenital anomaly found depends on the fetal age at the time of infection with BTV. Lambs infected with bluetongue vaccine virus at 50–55 days gestation develop severe necrotizing encephalopathy and retinopathy, which at birth is manifest as *hydranencephaly and retinal dysplasia*. Infection of lambs at 75 days gestation causes multifocal encephalitis and selective vacuolation of white matter that is manifest as porencephalic cysts in the newborn; ocular lesions are not observed in these newborn lambs. Lesions in brains of lambs infected after 100 days gestation are confined to mild focal meningoencephalitis. BTV infection of fetal calves can cause hydranencephaly.

Rift Valley fever virus and Wesselsbron virus

These infections are considered more fully in Vol. 2 Liver and biliary system. In addition to *Wesselsbron virus* (WESSV), there are several other mosquito-borne flaviviruses (genus *Flavivirus*, family Flaviviridae) in South Africa, including *West Nile virus* and *Banzi virus*, to which sheep are experimentally susceptible and which result in abortion, stillbirths, and neonatal deaths; anomalies include *hydranencephaly, porencephaly, and internal hydrocephalus*.

Rift Valley fever virus and WESSV are mosquito-borne and tend to circulate together. They are both primarily hepatotropic, but the wild strain of WESSV and attenuated strains of both are neurotropic, and vaccine strains may be responsible for most outbreaks of congenital neurologic disease. The presenting features are similar to those of Akabane disease, but the high incidence of hydrops amnii and prolonged gestation is especially a feature.

The destructive changes in the CNS produced by one or other of these viruses, or both together, can be more severe than with other teratogenic viruses and result in segmental aplasia of the cord, aplasia of the cerebellum, and anencephaly. It is more usual, however, that the defects include brachygnathia, hydranencephaly or porencephaly, hypoplasia of cerebellum and spinal cord, and varied musculoskeletal stigmata of arthrogryposis.

Bovine viral diarrhea virus

The diseases caused by *Bovine viral diarrhea virus* (BVDV), genus *Pestivirus*, family Flaviviridae, are considered in detail in Vol. 2, Alimentary system. The ecology of BVDV depends on transplacental transmission and the establishment of immune tolerance and persistent infections. Horizontal transfer of infection occurs readily, but is seldom clinically significant. Persistently infected fetuses that survive to become pregnant transmit BVDV to the conceptus. Although viral strains differ in their pathogenicity, infection of susceptible cows during early and middle stages of gestation is likely to result in either fetal death or a variety of developmental defects, predominantly neural and ocular. Some congenitally affected calves also have erosive lesions in the upper alimentary tract and abomasum resembling those seen in adult cattle; brachygnathism also occurs.

The outcome of infection of the fetal calf is related to gestational age, advancing fetal maturity being associated with increased resistance to the virus. Infections occurring within the first 100 days of fetal life tend to be lethal resulting in *abortion or mummification*. Although the gross pathologic changes seen in these lethal infections lack unique features, the patterns of tissue response are characteristic, but are rarely seen as such fetuses die in utero and undergo autolysis. Necrotizing inflammation can involve a variety of tissues. The reactive changes are dominated by mononuclear, predominantly macrophage, infiltration of hepatic portal areas, myocardium, spleen, and lymph nodes, which is reflected grossly in enlargement, nodularity and mottling of the liver and enlargement of spleen and lymph nodes (Fig. 3.39). The presence of *growth-arrest lines in long bones* suggests that the fetus undergoes one or more intrauterine crises before death. Affected fetuses may have partial alopecia that spares the tail, the lower portion of the limbs, and the head, these being points of initial hair growth during fetal development. The microscopic skin changes that evolve from the initial necrotizing dermatitis and correlate with the alopecia are hypoplasia of hair follicles and cystic distension of adnexal glands.

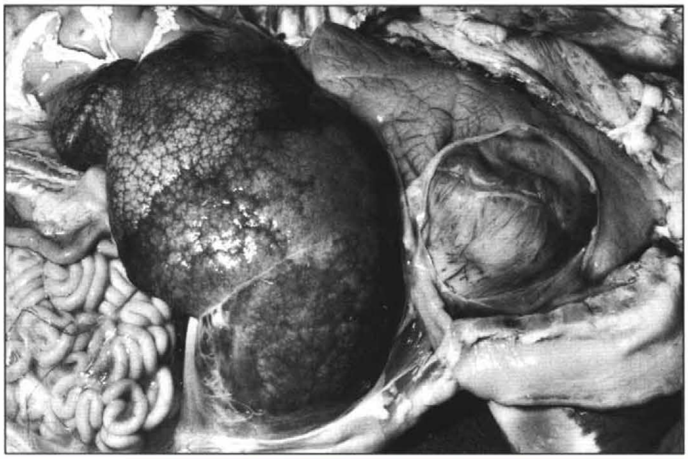

Figure 3.39 Myocardial pallor due to myocarditis and myocardial degeneration, and chronic hepatic congestion with ascites in a bovine fetus due to ***Bovine viral diarrhea virus* infection**, although *Neospora caninum* infection must also be ruled out in such cases.

The teratogenic effects of BVDV are manifest during the 100–170 day period. The period of susceptibility presumably varies with the strain of virus. *Cerebellar hypoplasia is the most characteristic defect* (Fig. 3.40). Gross cerebellar changes range from more or less uniform atrophy to irregular folial atrophy and agenesis accompanied by cavitation. The hypoplastic process is compounded by the effects of necrosis of external granular layer cells and parenchymal destruction as a consequence of folial edema resulting from vasculitis. The relative contribution of these processes is quite variable, but it appears that the vasculopathy may be more prominent in older fetuses. The nature and extent of involvement of individual folia also varies considerably. The evolution of the cerebellar changes has been studied experimentally. Acute lesions are evident 2 weeks after infection. Cellular necrosis in the external granular layer is accompanied by nonsuppurative meningitis. Vasculitis, marked by endothelial proliferation and perivascular leukocytic infiltration, is associated with folial edema, and there may be focal hemorrhages in the cerebellar white matter and cortex.

Folial edema, depending on its severity, may result in total folial destruction, cavitation or focal, often linear, areas of folial white matter deficient in myelin and axons. Where necrosis of the external granular layer predominates, the result is irregular atrophy of affected folia. Features of the atrophic process are marked depletion

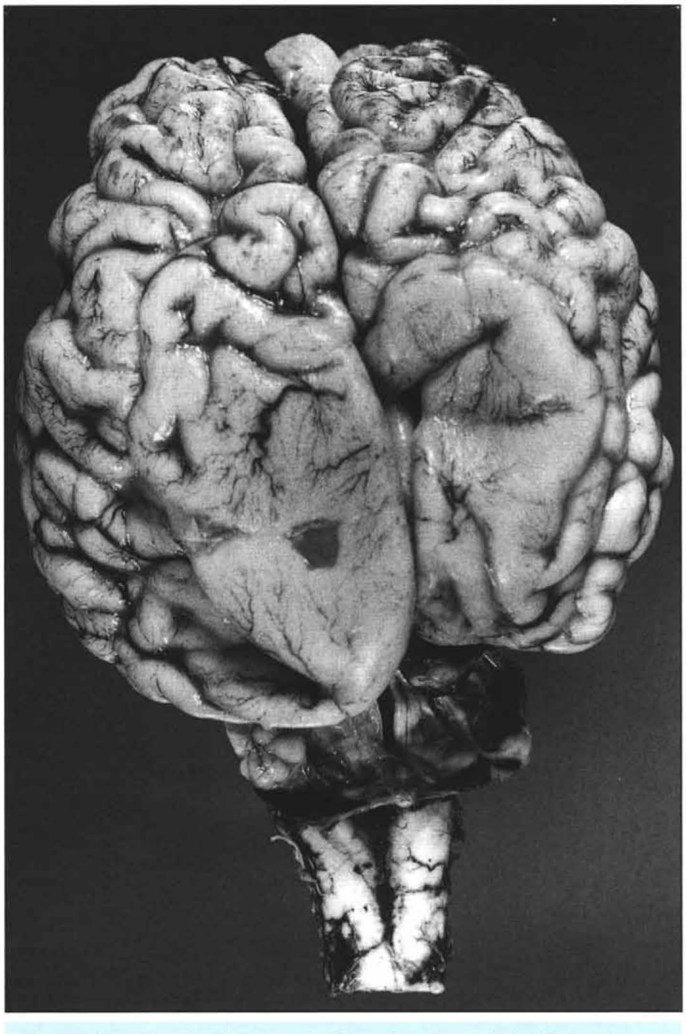

Figure 3.40 **Cerebellar hypoplasia** and **hydrocephalus** in a calf.

of granule cells, ectopia of Purkinje cells, and the presence of swollen Purkinje cell axons in the granular layer. The evolution of the cerebellar lesion in the fetal calf extends over 6 weeks and, by 10 weeks after maternal infection, inflammatory changes are not evident in the brain.

Other CNS defects that may be a consequence of fetal infection are porencephaly, hydranencephaly, microencephaly, hydrocephalus, cystic septum pellucidum, and dysmyelination. Ocular anomalies commonly accompany cerebellar defects, and include retinal dysplasia and atrophy, cataract, optic neuritis and atrophy, microphthalmia, and persistent pupillary membrane.

Infection of the fetus later than 170 days is unlikely to cause either intrauterine death or malformation. This increased resistance coincides with the fetus acquiring the capacity to produce neutralizing antibody to the virus. However, BVDV also has the capacity to induce more subtle developmental aberrations such as *intrauterine growth retardation* and *atrophy of the thymus and lymphoid tissues*. The regressive changes in thymus and lymphoid tissues offer a morphological basis for the immunological suppression and tolerance phenomena associated with congenital infections with BVDV.

Border disease virus

Border disease (BD) of lambs was first described from the border counties of England and Wales, and is now recognized in many countries. Affected lambs show gross tremors and long hairy birth coats ("hairy-shaker," or "fuzzy" lambs).

BD is caused by *Border disease virus* (BDV), genus *Pestivirus*, family Flaviviridae, which is very closely related to *Bovine viral diarrhea virus* (BVDV) and less closely to *Classical swine fever virus*. These viruses possess a similar host spectrum experimentally, and interspecies transmission, especially between ruminants, does occur naturally but the clinical expression in recipients may be modified or absent. The ecology of BDV and the pathogenesis of BD depend on the ability of the virus to cross the placenta and then either to produce disease in the fetus or a state of immunotolerance and *persistent infection (PI) that allows excretion of the virus continuously in postnatal life*. Strain variations of BDV, differing host responses depending on breed and genotype, and gestational age at which infection occurs contribute to the varied manifestations of the disease. Congenital disease and persistent infection are typically caused by the *noncytopathic biotype* of BDV; mucosal disease-like syndrome is caused by a *cytopathic biotype* of BDV. Sheep can also be infected naturally with BVDV types 1 and 2, and BVDV is capable of producing the BD syndrome in sheep and goats. Pigs can be naturally infected by BDV, e.g., strain Frijters, which can confuse identification of classical swine fever.

Primary infection of postnatal sheep by BDV is usually subclinical, immunity develops and the virus is eliminated. In pregnant ewes, the virus infects the fetus within the first week of exposure and is not then influenced by the immune status of the ewe.

BDV is a potential cause of a variety of developmental disorders, including *hypomyelinogenesis, cavitating cerebral defects such as porencephaly, hydranencephaly, and cystic septum pellucidum; cerebellar dysplasia; arthrogryposis and skeletal defects; mandibular brachygnathism, and thymic hypoplasia*. The pathogenicity of the virus is most freely expressed in experimental infections, the cavitating cerebral lesions and cerebellar dysplasia being common sequelae of experimental infections but only occasionally encountered in the natural disease.

Bovine viral diarrhea virus is capable of producing the Border disease syndrome in sheep and goats, and the syndrome in piglets caused by congenital infection with *Classical swine fever virus*.

The ovine fetus is liable to significant damage if the dam is infected with BDV between days 16–80 of gestation. *The age-related immune capacity of the fetus is the important determinant of the nature of the disease produced*. In the case of infections occurring within the first half of gestation, the result may be *fetal death and abortion*. Alternatively, the fetus may survive, frequently carrying an immunologically tolerated infection. In this event, the virus persists in fetal tissues and postnatally the lamb fails to produce specific antibody. Such PI sheep harbor the virus for prolonged periods, are chronic excretors of the virus, and readily transmit infection. Lateral spread is important in the field and, although the virus can be transmitted experimentally by a number of routes, the mode of lateral transfer of infection under natural conditions has not been identified.

Infections in the second half of gestation elicit both humoral and cell-mediated immune responses and it is this acquisition of immunocompetence that endows the fetus with substantial resistance to infection after day 80 of gestation. In the case of infections initiated between day 90 of gestation and the early days of postnatal life, the cell-mediated immune response is expressed morphologically as *nodular periarteritis*. The periarteritis affects medium to small arterioles, particularly in the meninges and substance of the CNS, but also occurs mildly in a wide range of other tissues.

The developmental anomalies arising from fetal infection are also related to the gestational stage at which the fetus encounters the virus, but lesions produced also vary markedly according to virus strain, dose, route of infection, and host genetic factors. *Hypomyelinogenesis, the characteristic neural lesion*, is diffuse in fetuses infected early in gestation but becomes progressively milder and more restricted to higher, later myelinating regions of the CNS in infections initiated later in gestation. The occurrence of porencephaly and cerebellar dysplasia has been confined to infections initiated at days 45–72 of gestation. The development of the cutaneous lesion requires that infection be initiated before day 80 of gestation.

Hypomyelinogenesis and clinical tremors may substantially resolve during the first few months of life notwithstanding that the animals have persistent replicating infection, suggesting that the normal processes of myelin deposition have been delayed or that cellular injury has been slowly repaired. The virus does infect myelinating oligodendroglia, astroglia, and glial progenitor cells, and it is reasonable to assume a direct effect on the differentiation or maturation of oligodendroglia. However, the virus also infects many non-neural cells, including thyroid epithelium. There are no morphological changes in the thyroid epithelium, but reduction in circulating thyroid hormone levels may contribute to delayed maturation.

The cavitating cerebral defects and cerebellar dysplasia arise from inflammatory destruction of developing neural elements, possibly secondary to vasculitis. These lambs may have severe locomotor and behavioral abnormalities and defects of vision, the latter probably of central origin rather than due to focal retinal dysplasias that may be present. They are serologically positive but not persistently infected.

The *abnormality of birth coats* occurs in fetuses infected before ~90 days gestation. There are no cytological changes in the papillae that can be ascribed to direct viral action. The primary follicles revert to a more primitive type, are enlarged and produce heavily medullated fibers that are most prominent after about 3 weeks. There are fewer secondary follicles and their development is retarded.

BDV infection also interferes with pre- and postnatal development of skeleton, musculature, and viscera. Tissues most affected are those that have their main growth spurt in the fetal period. *Growth-arrest lines in long bones* suggest periods of interrupted intrauterine development.

Lambs that are persistently infected at birth remain so but not all show neurological signs. Growth and viability may be depressed. Some PI sheep develop oculonasal discharges and respiratory distress or severe diarrhea and die in 2–4 weeks with inflammatory lymphoproliferative lesions in many organs. In the brain, these reactions occur particularly in the choroid plexuses and periventricular substance. Proliferative metaplastic changes in the intestinal mucosa affect mainly the cecum and colon, the hyperplastic glands penetrating the muscular mucosa. *The delayed disease has features resembling those of mucosal disease of cattle,* which is considered to be due to superinfection by a different strain of BVDV or by minor mutation of homologous virus in animals that are persistently infected.

Infection by BDV is widespread in **goats** but disease attributable to this virus is not. The characteristics of the natural and experimental disease are similar to those in sheep, but spontaneous neurological disease is not a feature. The fetal goat may be much more susceptible to infection than the fetal lamb; a high incidence of fetal death, mummification, and abortion is reported.

Classical swine fever virus

The disease is discussed in detail in Vol. 3, Cardiovascular system.

Both vaccine and certain low-virulence field strains of *Classical swine fever virus* (CSFV, hog cholera virus) are teratogenic for the fetal piglet. Fetuses are susceptible to infection regardless of the immune status of the sow. The apparent induction of immune tolerance results in the delivery of chronically infected piglets lacking antibody. The gestational interval during which fetal piglets are susceptible to the teratogenic effects of CSFV extends at least from day 10 to 97 of gestation, but the occurrence of malformation is favored by infection around day 30. The most characteristic anomalies involve the nervous system. The combination of *hypoplasia and dysplasia of the cerebellum and CNS hypomyelinogenesis,* most severe in the spinal cord, comprises one form of the *congenital tremor syndrome* of piglets. *Microencephaly* is also a rather characteristic sequel. The mechanism by which these lesions evolve is compatible with a persistent neural infection resulting in selective inhibition of cell division. Additional effects noted in affected litters include fetal mummification, stillbirth, pulmonary hypoplasia, nodularity of the liver, ascites, anasarca, cutaneous purpura, arthrogryposis, and micrognathia.

Feline panleukopenia virus

This disease is discussed in detail in Vol. 2, Alimentary system.

Feline panleukopenia virus (FPLV), a species of the genus *Parvovirus,* family Parvoviridae, is pathogenic to the cerebellum of kittens before and shortly after birth, at which time the cerebellum is growing and differentiating rapidly. FPLV has tropism for cells that have a high mitotic rate, and its site of action is the external germinal layer of the cerebellum. The formation of *intranuclear inclusion bodies* is an early feature of the infection; they disappear by day 14 of infection. The infected cells are destroyed and with them the growth potential of the cerebellum; hence *cerebellar hypoplasia* results. The Purkinje cells, which are postmitotic but immature, are also affected although inclusion bodies do not form in them. The nuclei of the Purkinje cells show vesicular ballooning, eosinophilia, and condensation of the membrane. One or more large vacuoles form in the cytoplasm. Some Purkinje cells undergo coagulative necrosis.

In view of the tropism of FPLV for rapidly replicating cells, a wide spectrum of abnormalities might be expected to result from infection of kittens in utero. The virus will cross the placenta and produce generalized infection of the fetus as indicated by the distribution of inclusion bodies. The subependymal cell plate shares growth behavior with the external granular layer of the cerebellum, and, although heavily infected, only one instance of hydranencephaly attributable to damage at this site of infection has been recorded. In visceral organs, only slight degrees of renal hypoplasia have been observed in infected kitten fetuses.

STORAGE DISEASES

As most storage diseases involve neurons and neurologic impairment, they are discussed here. Within all cells, except mature erythrocytes, normal catabolism directs a steady stream of endogenous macromolecules into vesicular compartments for degradation to simple molecules that may be re-used or excreted. These essentially autophagic pathways, through which each cell recycles its own constituents, may also receive endogenous and exogenous molecules from the extracellular milieu, taken up by endocytosis or phagocytosis.

Storage states, or disorders, are characterized by the accumulation of material(s) resistant to or exceeding the capacity of the machinery of intracellular digestion, disposal, or transport. Hemosiderosis and some types of hepatic lipidosis are common examples of the storage of physiologically normal substances due to the overloading of essentially normal, biochemically competent cells. A storage disease, by contrast, can be regarded as a storage process with a primary pathologic basis within the storing cells, and with potential for the perturbation of their function. The implication is that the catabolic machinery of the cells is fundamentally incompetent. This is generally demonstrable, but it is difficult to provide a neat definition that clearly distinguishes this situation in all circumstances.

Practically all cell types are potentially vulnerable to storage-induction, but those most vulnerable are long-lived postmitotic cells, such as neurons and cardiac myocytes. Cells in dynamic renewal systems, such as enterocytes, scarcely have the chance to become involved before their time is over.

The lysosomal apparatus provides the machinery for a great deal of intracellular degradation; most storage diseases involve intralysosomal accumulation and are hence termed **lysosomal storage diseases**. The 40 or so lysosomal acid hydrolases are capable of digesting completely the complex macromolecules synthesized for cell membranes, organelles, secretory products, etc. This enzymic destruction must be sequestered away from the rest of the cell, and is carried out in vesicles provided with an ion pump in their limiting membranes that maintains an acidic interior, or lysosol, for the optimal activity of the hydrolases.

Newly synthesized lysosomal enzymes are carried from the trans-Golgi region within primary lysosomal vesicles, and are delivered to substrate-containing vesicles (endosomes, heterophagosomes, autophagosomes, secretory vesicles) by fusion of vesicle membranes. The end products of digestion, which are simple lipids, amino acids, and sugars, are transported from the vesicular lysosol back into the cytosol. There may be small quantities of indigestible residues that, in cells such as hepatocytes, may be extruded by a process of exocytosis.

The lysosomal hydrolases tend to be "*exoenzymes*," sequentially breaking linkages at the ends of large molecules, but unable to act on linkages within them. This means that if the sequence is blocked at some point, further digestion cannot proceed. Should the digestive sequence be impaired, the cell will steadily accumulate a mass of vacuoles containing undegraded substrate. One type of molecule will be the major stored substance, but often the stored material will be somewhat heterogeneous, as the enzymes are linkage-specific rather than substrate-specific. Thus, *the morphologic hallmark of lysosomal storage disease is the presence of distended cells, crowded with vacuoles bounded by single membranes containing the stored material*; these vacuoles react enzyme-histochemically for acid phosphatase or other lysosomal hydrolases. They represent the adaptive hypertrophy of the lysosomal apparatus. In some cases, the morphology and histochemical reactivity of the stored substance may fairly clearly indicate its nature, for example glycogen. Lectin histochemistry may also be useful for characterizing stored material, exploiting the avid carbohydrate-binding properties of these agglutinating proteins in combination with a visualizing system.

Lysosomal digestion can be impaired in several ways. The most relevant here is *deficient activity of a specific lysosomal hydrolase because of a* **genetic defect**. This is the basis of the inherited lysosomal storage diseases in humans and animals, most of which are transmitted as autosomal recessive, and some as X-linked, traits. The deficiency in activity may come about via a total absence of enzyme protein, via the production of a defective or unstable enzyme, or via the absence of a specific activator protein required by some enzymes for the initiation of activity. These activators are small-molecular-weight, heat-stable proteins that function as detergents. They may interact with either the enzyme or its substrate. In the category of defective enzyme protein, one could also include the rare mechanism in which the enzyme lacks the specific molecular tag required to direct it, following its synthesis, to the lysosomal compartment; it is therefore immediately excreted from the cell, and the lysosomes remain deficient in that enzyme activity.

In most *autosomally inherited conditions*, the gene dose effect results in heterozygous individuals being generally phenotypically normal, but usually having demonstrably subnormal tissue activity of the particular enzyme in question. Tissues of homozygous affected individuals will contain swollen vacuolated cells, and chemical analysis reveals large amounts of the stored substance, and variable amounts of other metabolically related substances. *Multisystem involvement is likely to occur*, with storage being evident in many cell types in many organs. The cells and tissues most affected will be those most active in turning over the substrate in question, but usually the fixed and mobile macrophages are also prominently involved. This is because they avidly accumulate substrate from tissue fluids and plasma. The process begins in utero and in many cases is well developed at birth, although clinical impairment may be mild at that time. The age of onset and speed of progression of disease can vary, probably on the basis of the amount of residual enzyme activity, and often involving the ratio between various isoenzymes. In several human entities, subtypes are described on this basis.

As pointed out above, the *in vitro* tissue activity of the enzyme involved can usually be demonstrated to be negligible. However, if there was, for example, *deficiency of an activator protein*, the in vitro assay of tissues for the subject enzyme might reveal paradoxically high levels of activity, reflecting the hypertrophy of the lysosomal apparatus. The enzyme, however, would be inactive in vivo in the absence of the activator protein. In addition, and especially if the assay involves synthetic substrates, various isoenzymes may give the impression of adequate activity in vitro, which has no relation to the in vivo situation. In spite of this, assay of enzyme activity in skin fibroblasts or peripheral blood leukocytes has been diagnostically useful in many genetic storage diseases, identifying both homozygous and heterozygous individuals. Molecular genetic methods can be expected to play an increasingly important role in this area.

In an alternative mechanism of storage, *an* **exogenous toxin** *may specifically inhibit a lysosomal enzyme*, and temporarily induce a state analogous to a genetic enzyme deficiency. This is the established basis of at least one plant intoxication, "locoism," and is suspected in others. The morphologic and chemical characteristics are typical, but tissue activity of the subject enzyme may be quite high when it is separated from the inhibitor and assayed.

In a final general mechanism, *substrate that is resistant to a normal and intact enzymic battery may enter degradative pathways*. This may be an exogenous substrate, or a modified endogenous substrate. By this mechanism, several amphophilic drugs, such as chloroquine, have been found to induce storage diseases by complexing with endogenous molecules to produce indigestible products. Theoretically this mechanism could also have a genetic basis, by which an indigestible substrate is produced.

The lysosomal basis of some storage diseases is uncertain, and *non-lysosomal entities*, such as several of the glycogenoses, are clearly defined. Further, although many storage diseases have been defined in molecular terms, some have not and, in most cases, the basis of cellular dysfunction is far from clarified. There is more involved than simply the mechanical crowding out of other organelles. In most instances the storage process seems to have little primary cytotoxic effect. It seems rather that the induction of secondary and tertiary metabolic and structural effects is responsible for functional disturbances.

In many of the **neuronal storage diseases**, the process is multisystemic, and all neurons are involved, including those of the retina and peripheral ganglia, together with cells in most other organs. But neither of the two preceding conditions is invariable. When neurons are involved in storage disease, clinical signs of neurologic impairment eventually become evident, but, in general, this does not correlate with significant neuronal death, and the mechanisms of dysfunction are still largely unresolved. Regional neuronal death begins at an early stage in a few storage diseases and is progressive; it probably contributes significantly to functional disturbance at the end stage of many storage diseases.

In the face of a progressive storage process, neurons have no recourse but to accumulate storage vacuoles until they, or the animal, die. It seems probable that there is some limited capacity to discharge some of the stored load by exocytosis but, *in general, intractable constipation is inevitable as long as enzymic activity is deficient.* In spite of this, the cell limits the sites of storage to the soma and some of the larger dendritic stems. As a result, the soma becomes greatly distended and the cell outline rounded and swollen, rather than angular (Fig. 3.41). However, even within the soma, storage may be somewhat polarized, often adjacent to the axon hillock; differing planes of section may suggest that some neurons are not affected, particularly if examined early in the course of the disease. The multitude of storage vacuoles crowds and displaces other organelles, and the neuron takes on a chromatolytic and foamy appearance. Glial, endothelial, and perithelial cells are generally similarly affected.

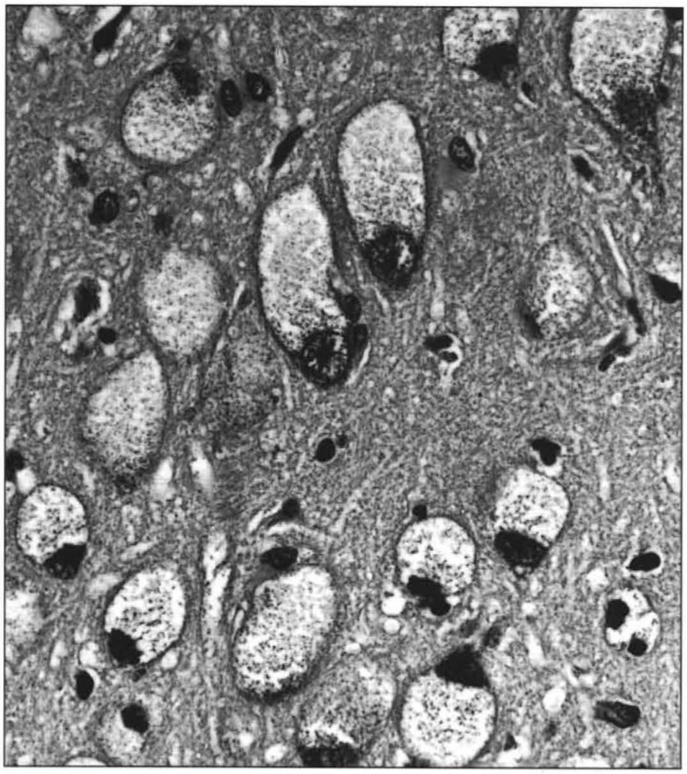

Figure 3.41 Swollen neurons in a **lysosomal storage disease** (GM_1 gangliosidosis) in a sheep. (Reprinted with permission from Murnane RD, et al. Vet Pathol 1991;28:332.)

In several ganglioside storage diseases, certain populations of neurons, particularly in the pyramidal system of the cerebral cortex and thalamic relay nuclei, undergo a form of *focal hypertrophy* in order to generate more "storage space." These cells develop large swollen compartments between the axon hillock and the initial axonal segment, dubbed "*meganeurites*." In addition, cells in these regions may sprout *aberrant dendritic spines*, whether or not they have meganeurites. The spines arise from the axon hillock and from meganeurites and form synaptic contacts. The origin of the presynaptic elements of these contacts has not been determined, but such abnormal neuronal connections could well contribute to malfunction. They may be permanent in the induced storage diseases in which otherwise the stored material may be catabolized and removed if the toxic inhibition of the enzymes is removed. These changes, dramatic as they are, cannot be appreciated without the use of special techniques, most notably the Golgi impregnation method. In addition, focal swellings may develop along the course of axons, appearing as eosinophilic spheroids, similar to those described for axonal dystrophy (see Fig. 3.9). They are often very prominent in some nuclear groups, exhibiting a tendency to form in the terminal presynaptic regions of axons, but they can be seen anywhere in the white matter and also in the peripheral nerves. They do not contain specific storage material, but are crowded with degenerate organelles and/or abnormal tubules and vesicles. They probably reflect a secondary effect of the storage process on retrograde axonal transport. The functional significance of this secondary axonal dystrophy is not resolved, but it is a prominent pathologic feature in many storage diseases.

Inherited storage diseases

Virtually all the inherited storage diseases of animals are proven or assumed to be lysosomal in nature. This applies to all those to be described below with the exceptions of the canine glycogenoses analogous to types 3 and 7 glycogenoses in humans. They are classified into broad groups, according to the class of macromolecule whose degradation is defective. As many of these diseases were first described in humans, the catalog is replete with eponyms, mostly derived from the names of the eminent people who provided those first descriptions. Within the broad groups, individual entities are defined by the nature of the dominant storage material, which reflects the specific enzymic deficit. Not all the storage diseases documented in humans have been found to have analogs in domestic animals, but the list is growing and the prevalence of inbreeding makes it likely that this will continue. *The general clinical characteristic is the onset of progressive neurologic impairment at a young age.*

In the descriptions of pathology that follow, variations in the patterns of lesions are likely to surface as more cases are described. A useful practical distinction can be made between those diseases in which the vacuoles appear empty in both paraffin and resin sections (Fig. 3.42A), and those in which they contain residual material (Fig. 3.42B). The former reflect water-soluble substrates leached out during processing, and point to certain diseases as described below.

Sphingolipidoses

Sphingolipidoses are lysosomal storage diseases caused by a genetic defect in catabolism of *glycosphingolipids*, which are important normal components of cell membranes.

In general, **gangliosidoses** are characterized clinically by the *onset at an early age of discrete head and limb tremors and dysmetria.* Worsening locomotor deficits and mentation terminate eventually

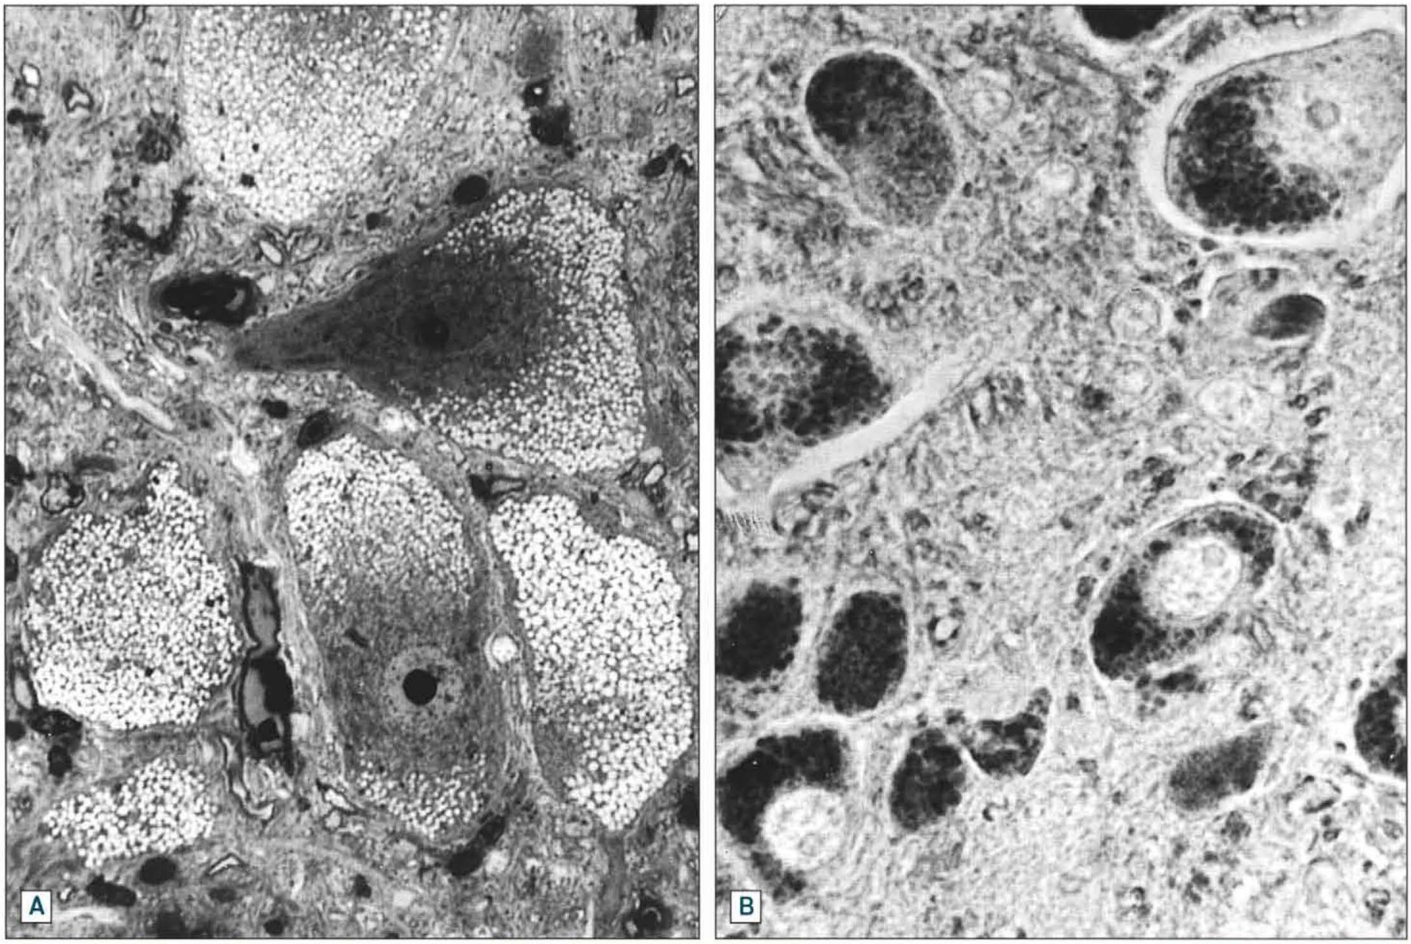

Figure 3.42 Neuronal **lysosomal storage disease**. **A.** Resin section showing "empty" vacuoles in bovine mannosidosis. (Courtesy of RD Jolly.) **B.** Dense granules, Sudan black positive, in gangliosidosis in a German Shorthaired Pointer dog. (Courtesy of E Karbe.)

in blindness, somnolence, seizures, and quadriplegia. Data indicate *autosomal recessive inheritance.*

In **GM_1 gangliosidosis** (generalized gangliosidosis), deficiency of *β-galactosidase* leads to accumulation of GM_1 ganglioside and some oligosaccharides. GM_1 gangliosidosis has been documented in cats (domestic shorthair, Korat, Siamese), dogs (Alaskan Husky, Beagle, English Springer Spaniel, Portuguese Water Dog, Shiba), Friesian cattle, and sheep (Coopworth-Romney, Romney, Suffolk).

In **GM_2 gangliosidosis**, GM_2 ganglioside accumulates due to deficient lysosomal degradative activity of *hexosaminidase*, which exists as a dimer in two forms, αβ (hexosaminidase A) or ββ (hexosaminidase B), or of an *activator protein*. Globoside may also accumulate. GM_2 gangliosidosis has been documented in domestic shorthair and Korat cats (β subunit deficiency), German Shorthaired Pointer dog, Golden Retriever (β subunit deficiency), Japanese Spaniel dog (GM_2 activator protein deficiency), and Yorkshire pigs. Variants of GM_2 gangliosidosis in humans are Tay–Sachs and Sandhoff diseases, and activator deficiency.

Neuronal storage in gangliosidoses is manifested in routine paraffin sections as marked distension of the soma, with *foamy, faintly eosinophilic cytoplasm* (Figs 3.41, 3.43A). The stored material is strongly PAS-positive in frozen sections, and is evident in plastic sections as 1–3 μm osmiophilic granules. Ultrastructurally, these are seen as *characteristic membranous cytoplasmic bodies*, consisting of concentric membranous whorls with a periodicity of about 5 nm (Fig. 3.43B). Vacuolated macrophages may also be found around blood vessels in the CNS, and storage also occurs in glial cells. Axonal spheroids may be reasonably numerous. Gliosis, demyelination and neuronal loss are not apparent until end stage. In those instances where hepatic storage occurs, hepatocytes and Kupffer cells contain large, empty vacuoles, the site of storage of a water-soluble glycopeptide.

GM_1 gangliosidosis in Suffolk sheep is associated with a dual enzyme deficiency, with βl-galactosidase deficiency being profound (5% residual activity), and α-neuraminidase deficiency less so (20% residual activity). Progressive ataxia in affected lambs first becomes evident at 4–6 months of age. Histologically, there is intense storage in most central and peripheral ganglionic neurons (Fig. 3.41), and in the kidney, liver, and lymph nodes, and cardiac Purkinje fibers. Stored material in neurons stains PAS and Luxol fast blue positive, but Sudan black negative. Axonal spheroids are frequent in cerebral and cerebellar white matter.

Glucocerebrosidosis (glucosylceramidosis) has been described in the Sydney Silky Terrier, and is the counterpart to *Gaucher disease* of humans. It results from deficient activity of *glucocerebrosidase*, which

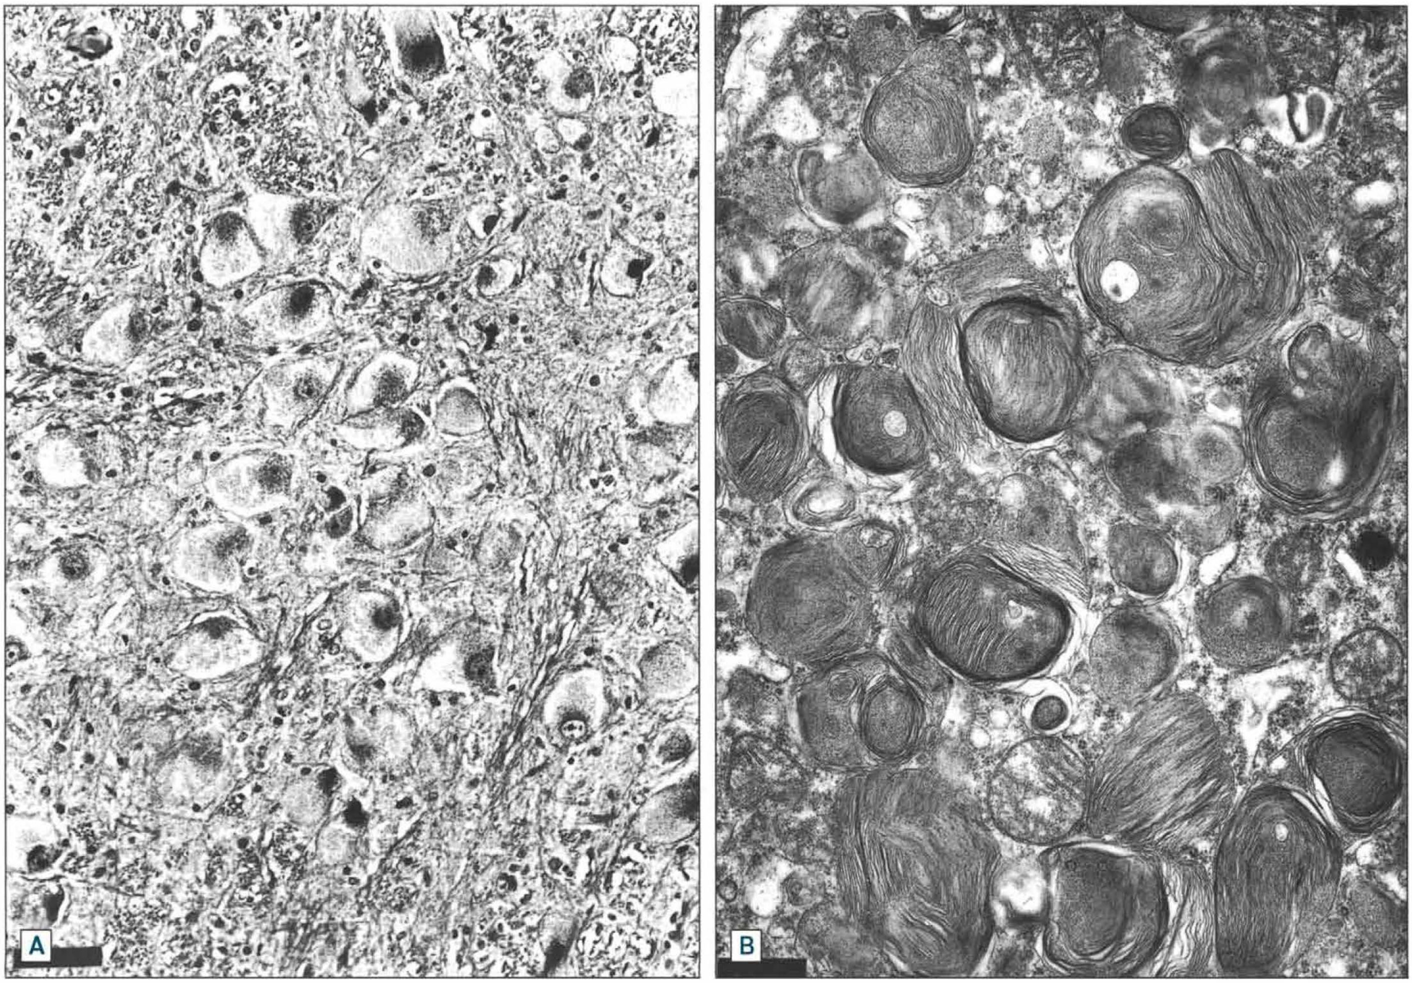

Figure 3.43 GM_1 gangliosidosis in a Portuguese Waterdog. **A.** Pale swollen neurons. Bar = 63 μm. **B.** Storage bodies showing concentric lamellae or parallel stacks of membranes. Bar = 0.6 μm. (Reprinted with permission from Saunders GK, et al. Vet Pathol 1988;25:265.)

catalyzes the conversion of glucocerebroside to ceramide. The former is derived from the catabolism of gangliosides.

Storage in the dog is expressed in macrophages in the hepatic sinusoids and lymph nodes, and in neurons in some parts of the brain but, interestingly, not in Purkinje cells and not in the spinal cord. Swollen cells have weakly eosinophilic cytoplasmic vacuoles, which are PAS-positive in the macrophages but PAS-negative in neurons. Degenerating neurons occur in the cerebral and cerebellar cortices, and Wallerian degeneration in related white matter.

Ultrastructurally, the macrophage storage material has a *characteristic twisted branching tubular structure*, and the cells in the human disease are known as *Gaucher cells*. In neurons, the storage granules are either lamellated membranous cytoplasmic bodies, resembling the Zebra bodies of mucopolysaccharidoses, or bilamellar wisps. In Gaucher variants in humans, storage may not occur in neurons.

Sphingomyelinosis has been recognized in Siamese, domestic shorthair and Balinese cats, and Poodle and Boxer dogs, and is regarded as the counterpart of *Niemann–Pick disease* in people, of which there are several variants. In types A and B, deficient activity of *sphingomyelinase* results in storage of sphingomyelin, cholesterol, and gangliosides in most neurons, and in macrophages in the liver, spleen, lymph nodes, adrenals, bone marrow, and lungs. The type C variant is caused by defective activity of a cholesterol transporter, NPC1 protein, or in the soluble lysosomal cholesterol-binding NPC2 protein. In animals, most cases are analogous to human type A; type C is described in cats and Boxer dogs.

At necropsy there is enlargement and pallor of the liver, splenomegaly, and gray nodules in the lungs. Microscopically, the visceral organs mentioned are packed with foamy macrophages, and the neurons are distended by masses of light gray, 1–2 μm autofluorescent granules. In frozen sections, the reactivity of vacuoles to oil-red-O and PAS stains is variable.

Type C Niemann–Pick disease is also characterized by numerous axonal spheroids in many areas of the neuraxis. Ultrastructurally, neuronal storage granules are concentric multilamellar structures or dense bodies.

Galactosialidosis, which results from combined deficiency of β-galactosidase and α-neuraminidase enzyme activity, is reported in a Schipperke dog. A similar combined enzyme deficiency in inbred Suffolk sheep resembled GM1 gangliosidosis phenotypically.

Galactocerebrosidosis (*galactosylceramide lipidosis, globoid cell leukodystrophy; Krabbe disease*), due to deficiency of *galactocerebrosidase*, is a member of this group, but involves storage in macrophages rather than neurons. It is discussed later under myelinopathies.

Glycoproteinoses

This group includes diseases in which there is *defective degradation of the carbohydrate component of N-linked glycoproteins*. These carbohydrate moieties are rich in mannose, N-acetyl glucosamine and fucose, and in particular diseases this is reflected in the storage residues that are detectable in the urine.

α-Mannosidosis has been the most economically important of the inherited storage diseases of animals, as it once occurred at high frequency in some populations of Angus cattle and the derivative Murray Grey breed. It is also recorded in the Galloway breed. The characterization and study of the disease in New Zealand led to effective carrier detection and certification schemes for its elimination and the incidence declined significantly. Inheritance is autosomal recessive, and affected calves have retarded growth, increasingly severe ataxia, and behavioral changes. The disease reaches end-stage by about 18 months of age.

Due to the synthesis of a defective enzyme protein, such individuals have *deficient lysosomal α-mannosidase* activity in virtually all cells except hepatocytes. All but the final mannose molecule of the glycans destined for digestion by this enzyme are alpha-linked. As a result, mannose/N-acetylglucosamine oligosaccharides accumulate in storage vacuoles that appear empty by light microscopy (Fig. 3.42A), as the material is extracted during tissue processing. Ultrastructurally, the vacuoles are seen to contain sparse membranous fragments and some floccular material (Fig. 3.44).

Neuronal storage is widespread and severe, but neuronal loss is not conspicuous until the terminal stages. Axonal spheroids are numerous in both gray and white matter, but especially in the cerebellar roof nuclei, the caudal brain stem proprioceptive nuclei, and on the proximal parts of Purkinje cell axons. The striking extent of storage in secretory epithelia, such as in pancreas and kidney, endothelia, fixed macrophages and fibrocytes is best appreciated in plastic-embedded sections.

α-mannosidosis has also been described in Persian and domestic shorthair and longhair cats. In the first two breeds, kittens are clinically affected very early in life, having retarded growth, facial dysmorphism, ataxia, tremor, and hepatomegaly. Intense and universal neuronal storage is accompanied by hypomyelination in the cerebrum, and widespread occurrence of axonal spheroids. Extensive storage in other tissues is as described for the bovine disease.

In the domestic longhair cat, nervous signs are reported to be milder and more slowly progressive, and there are no ocular abnormalities, hepatomegaly, myelin deficiency, or pancreatic acinar cell involvement. However, intense loss of Purkinje cells is evident and there is great diversity in the morphology of the storage cytosomes, with many membranous cytoplasmic bodies in caudal brain stem nuclei.

β-Mannosidosis has been described in the Anglo-Nubian goat, and in Salers cattle. The final mannose residue of the glycoprotein glycans is beta-linked to N-acetylglucosamine; its hydrolysis normally follows that of the alpha linkages described above. Deficiency of *β-mannosidase* leads therefore to the storage of di- or trisaccharides containing one molecule of mannose.

The disease has been most comprehensively documented in Nubian goats; inheritance is autosomal recessive. Clinical signs are severe at birth, affected kids having small palpebral fissures, facial dysmorphisms, domed skulls, joint contractures, intention tremors, and deafness. They are generally unable to stand and, even with intensive care, will survive for only a few months.

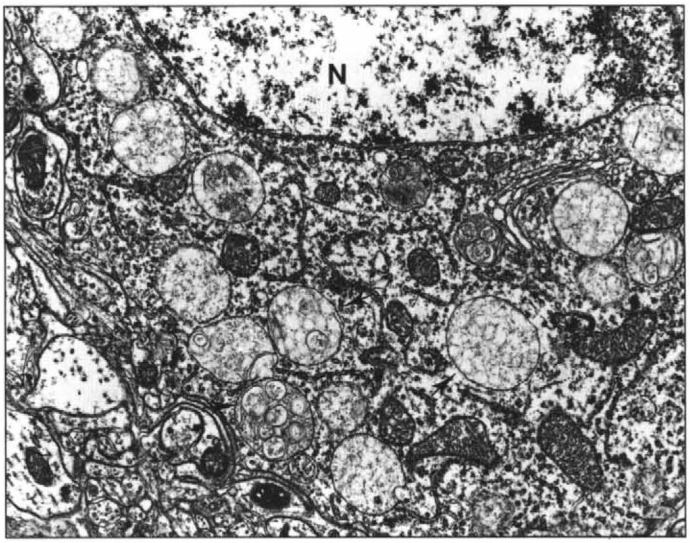

Figure 3.44 Cortical neuron in **feline mannosidosis**; storage vacuoles (arrows) contain either sparse floccular material or membranous arrays. Nucleus (N). (Courtesy of SU Walkley.)

Grossly, there is dilation of the ventricles and hypomyelination of the cerebrum and cerebellum. The latter may be the result of congenital hypothyroidism, due to storage-mediated interference with thyroid function, and it accounts for the congenital syndrome. Microscopically, neuronal vacuolation is ubiquitous and axonal spheroids numerous, especially in the internal capsule, cerebellar white matter, and basal ganglia. Vacuolated macrophages occur around some blood vessels in the brain, and there may be focal mineralization in the cerebellum and cerebrum. Large focal swellings filled with neurofilaments are sometimes present in the proximal axons of spinal motor neurons, and spheroids are numerous in sensory endings in mucous membranes and conjunctivae. Intense storage in most other tissues is similar to that described for α-mannosidosis, as is the ultrastructure of the storage vacuoles.

α-L-fucosidosis occurs in the English Springer Spaniel. As the result of deficient activity of *α-L-fucosidase*, water-soluble, fucose-containing compounds are stored as glycosylasparagines. Autosomal recessive inheritance is established, and the disease has a somewhat delayed clinical onset, with wasting, ataxia and proprioceptive deficits beginning at about 6 months of age, and becoming severe by about 2 years. A striking gross lesion is marked swelling, up to 10 mm diameter, of the cervical portion of the vagus nerves, the cervical nerves, and dorsal root ganglia.

As in mannosidosis, storage is intense in most tissues, cells becoming distended with apparently empty vacuoles. In the CNS, it is present in all neurons and in astrocytes and microglial cells; there are numerous perivascular accumulations of vacuolated macrophages. Axonal spheroids are present in the cerebellar white matter. In the thickened nerves, there is heavy infiltration of macrophages and the accumulation of myxoid perineurial ground substance.

Mucopolysaccharidoses

This group of diseases is defined by *defective catabolism of glycosaminoglycans (GAG, mucopolysaccharides)* and has major expression in the skeleton and connective tissues. These diseases are therefore also discussed with Bones and joints. Glycosaminoglycans – dermatan sulfate, heparan sulfate, keratan sulfate, chondroitan sulfate – are extremely large and complex molecules, and many enzymes are involved in their degradation. As a result, 11 are entities defined in humans; four have been reported in domestic animals, and in three of these there is major involvement of neurons. General features include facial and skeletal dysmorphisms, degenerative joint disease, corneal clouding, thickening and distortion of heart valves, and thickening of the leptomeninges. Large quantities of heparan and dermatan sulfates are excreted, and are detectable, in the urine.

In animals, deficiency of **α-L-iduronidase** has been observed in the domestic shorthair cat and the Plott Hound, and is regarded as the counterpart of *mucopolysaccharidosis type I* (**MPS I**) *in man*, variants of which include the *Hurler and Scheie syndromes*. The macroscopic features described above are subtended by intense storage in fibroblasts, fixed macrophages, chondrocytes, myocytes, and pericytes in most organ systems. Glandular epithelial cells are consistently less affected than mesoderm-derived cells. The involvement of chondrocytes is associated with dysplasias of endochondral ossification, and with degeneration of articular cartilage.

Neuronal storage is universal, but neuronal loss is not conspicuous. Storage vacuoles are ultrastructurally pleomorphic; they may appear largely empty, or to contain sparse floccular to granular amorphous material, or lamellar membranous structures termed *Zebra bodies*. The latter appear to be lipid in nature, and probably represent induced secondary storage of sphingolipids. There is thus a somewhat variable reaction to tissue staining for GAG and lipid. There is some suggestion that affected cats may have a high incidence of cranial meningiomas.

In the Nubian goat, **N-acetylglucosamine-6-sulfatase deficiency** gives rise to a counterpart of human **MPS III**, *Sanfilippo disease*. Clinical features encompass delayed ability of the neonate to stand and walk, persistently ataxic gait, marked bowing of the forelimbs, and corneal clouding. Gross changes include dwarfism, kyphoscoliosis, scapular hypermobility, and cartilaginous and bony abnormalities. Two main types of lysosomal storage bodies occur microscopically. The primary storage material is *heparan sulfate*, which appears as lucent floccular material in lysosomes in arterial smooth muscle and cardiac myocytes, fibroblasts, macrophages, hepatocytes, Kupffer cells, and chondrocytes. Neurons, in contrast, are packed with PAS-positive multilamellar bodies representing secondary storage of *gangliosides* induced by interference with neuraminidase activity. Mucopolysaccharidoses IIIA and IIIB are reported in several dog breeds.

In Siamese and domestic shorthair cats, **arylsulfatase-B deficiency** produces a counterpart to human **MPS VI** (*Maroteaux–Lamy syndrome*). The disease has the same general features as described above, but neuronal storage does not occur. Storage in peripheral blood neutrophils is detected as metachromatic cytoplasmic granules.

A **β-glucuronidase-deficient MPS** has been described in dogs and cats, and is considered analogous to human **MPS VII** (*Sly disease*). The general features of the clinical disease are as described above, and there is excessive urinary excretion of chondroitin-4-sulfate and chondroitin-6-sulfate. There is *widespread neurovisceral storage*, with cytoplasmic inclusions appearing largely empty or containing sparse granular or lamellar material.

Glycogenoses

A number of enzymes are involved in the catabolism of glycogen, but only one of these, *α-1,4-glucosidase*, is a lysosomal enzyme. The lysosomal pathway degrades any glycogen that finds its way into autophagic vacuoles, while the other pathways are more related to metabolic mobilization of glycogen. In humans, eight different glycogen storage diseases have been identified, with the lysosomal type being classified as **type II**, *Pompe disease*. As the storage process is very widespread in this disease, it is also referred to as *generalized glycogenosis*. In most other types, storage is concentrated in liver and muscle.

α-1,4-glucosidase deficiency has been well documented in Shorthorn and Brahman beef cattle. The disease has autosomal recessive inheritance, and affected calves have severe clinical signs by about a year of age. The most damaging effects are produced in the skeletal and cardiac muscle; weakness and congestive cardiac failure are clinically dominant, and cardiomegaly and hepatomegaly evident at necropsy. There is *widespread glycogen storage*, much of which occurs in typical lysosomal storage vacuoles, but some of which is intracytoplasmic. Swollen, vacuolated cells contain diastase-sensitive, PAS-positive material, which is ultrastructurally typical of glycogen. Vacuolar myopathy and cardiomyopathy are prominent (Fig. 3.45); *neuronal storage is universal and severe* and is accompanied by glial storage, with numerous axonal spheroids in the vestibular and cuneate nuclei, terminal fasciculus gracilis, and throughout the spinal cord gray matter (see Fig. 3.8). Mild Wallerian degeneration may be present in the lateral and ventral columns of the spinal cord and in some peripheral nerves.

Type II glycogenosis has also been documented in the Lapland dog, and suspected on morphologic grounds in the domestic cat and Corriedale sheep.

Amylo-1,6-glucosidase deficiency is recorded in the German Shepherd Dog, as a counterpart of glycogenosis **type III** (Cori disease). Cytoplasmic glycogen storage occurs in liver, muscle, and myocardium, and in neurons and glia in the brain and spinal cord.

Polyglucosan body disease (glycogen storage disease **type IV**) is reported in a mixed-breed dog as the result of an inherited metabolic defect associated with a deficiency of glycogen-branching enzyme. Periodic acid Schiff (PAS)-positive polyglucosan bodies (abnormal glycogen) were present in neurons, liver, and myocardium.

Mucolipidoses

Mucolipidosis describes a disease with the features of both sphingolipidoses and mucopolysaccharidoses. **Mucolipidosis II** (ML II), also called *I-cell (inclusion-cell) disease*, is a lysosomal storage disease caused by deficient activity of *N-acetylglucosamine-1-phosphotransferase*. The condition is inherited as an autosomal recessive in domestic shorthair cats. Affected kittens fail to thrive and have behavioral dullness, facial dysmorphia, and ataxia. Diffuse retinal degeneration leads to blindness. Storage lysosomes containing oligosaccharides, mucopolysaccharides, and lipids are most common in bone, cartilage, skin, and other connective tissues; a few cerebral cortical neurons have lipid inclusions, and some sciatic nerve axons are affected.

Ceroid-lipofuscinoses

With advancing age and senility, intracytoplasmic granules of the autofluorescent lipopigment, **lipofuscin**, accumulate in neurons, fixed phagocytes, macrophages and muscle cells. This *"wear and tear" pigment* is familiar to all pathologists, and has a characteristic histochemical profile and ultrastructure; the irregularly shaped granules have a high-density component punctuated with vacuoles of low density. For many years, in the group of diseases known as the "ceroid-lipofuscinoses," it has been assumed that a similar pigment is stored in lysosomes. However, other compounds, such as the hydrophobic lipid-binding protein subunit c of mitochondrial ATP synthase are also complexed with lipid and may predominate; hence at least some of these conditions might better be termed **proteinoses**.

In animals, neuronal ceroid-lipofuscinoses (NCL, Batten disease) of proven or presumptive **inherited** nature have been described in Siamese cats, South Hampshire sheep, Devon cattle, Nubian goats, and many breeds of dog including English Setter, Chihuahua, Dachshund, Saluki, Dalmatian, Blue Heeler, Border Collie, Tibetan Terrier, and crossbred. In general, *although storage may be widespread in several organs, it is most damaging in neurons of the cerebral cortex, retina, and cerebellar Purkinje system.* Thus there is frequently extensive cellular loss and atrophy in these regions, and correlating dementia, blindness, and ataxia. Macroscopically, atrophied areas may have a distinctly brown tinge. Microscopically, the storage granules are brightly autofluorescent under ultraviolet light, pale brown-red or colorless with hematoxylin and eosin, weakly acid-fast, magenta with PAS, and intensely positive with Luxol fast blue. Ultrastructurally, they appear as *membrane-bound cytosomes* up to 15 nm in diameter, irregular in outline, and with a variety of forms (Fig. 3.46). Some have membranous material arranged as *"curvilinear bodies" and "fingerprint bodies,"* which are considered characteristic. Others may have *laminated stacks of membranes* akin to zebra bodies, membranous stacks, or dense granular deposits.

The variation in features of NCL is illustrated by comparing the disease in various species and breeds. In Devon cattle, the major clinical deficit is profound blindness at about 14 months of age, with death usually due to misadventure by about 2 years. There is severe retinal atrophy but only mild loss of neurons from the cerebral and cerebellar cortices. In Tibetan Terriers, blindness is again the dominant sign, but the onset is delayed to middle life and is accompanied terminally by stupor. In the Border Collie and some other dog breeds, there are gait and visual deficits by 18–24 months of age, accompanied by increasing aggression and dementia. Retinal lesions are mild and blindness is central in origin. Neuronal loss and gliosis are particularly severe in the cerebellar Purkinje cell layer, and significant in the limbic system.

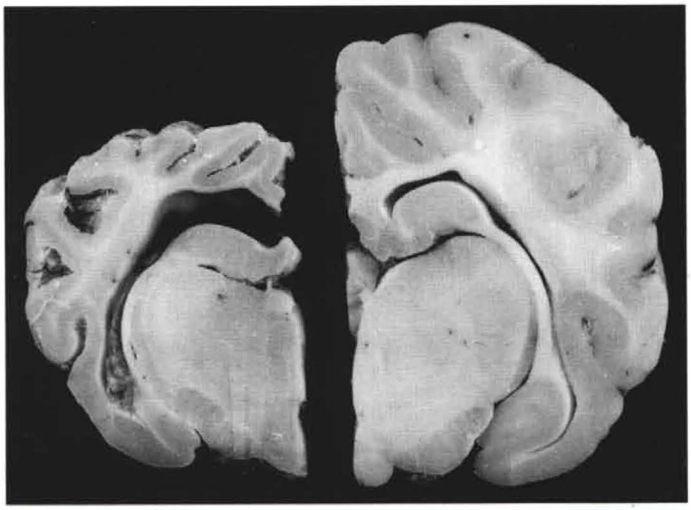

Figure 3.47 Ceroid lipofuscinosis in a South Hampshire lamb. Marked cerebral atrophy at 4 months; control right. (Courtesy of RD Jolly.)

The pathogenesis of at least some forms of NCL may involve a defect in mitochondria rather than a defect in lysosomal catabolism, and may involve accumulation of hydrophobic protein. The NCL in South Hampshire sheep has been thoroughly studied. The brains of affected lambs grow normally until 4 months of age, and then undergo atrophy (Fig. 3.47). Half of the material stored in lysosomes is the lipid-binding protein subunit c of mitochondrial ATP synthase. NCL in Merino sheep is also a subunit c-storing disease, clinically and pathologically similar to NCL in South Hampshire sheep. The NCL in both breeds (OCL6 form) apparently results from a mutation at the same gene locus in chromosomal region OAR7q13-15, and both breeds are potential animal models for the human late infantile variant CLN6. CLN proteins are coded by *NCL* genes.

Miscellaneous genetic storage diseases

The apparent lysosomal storage of lipid material in spinal motor neurons is described in English Pointer dogs, and is discussed under motor neuron diseases.

A counterpart to the autosomal recessive human **Lafora disease** has been recorded in Basset Hound, Poodle and Beagle dogs. Progressive myoclonus epilepsy is associated with *widespread intraneuronal storage of a complex polyglucosan*, which appears as characteristic *Lafora bodies* (see Fig. 3.5). They are most numerous in Purkinje cells, and neurons of the caudate, thalamic, and periventricular nuclei. They are non-membrane-bound spherical structures with a central basophilic core and a peripheral halo of radiating filaments. They are strongly PAS-positive and are found in both perikaryon and dendrites; they vary greatly in size, ranging up to 15–20 μm. Human LD is caused by mutation in the *EPM2A* gene that encodes for laforin and the *EPM2B* gene that encodes for malin. Lafora bodies are occasionally found incidentally in otherwise normal brains and spinal cords, especially in older dogs.

Induced storage diseases

Numerous types of storage process have been successfully produced experimentally, and there is a group of naturally occurring disorders related to the ingestion of plants, in which induced storage disease is proven or suspected.

Swainsonine toxicosis

Swainsonine, *an indolizidine alkaloid*, is the active principle of several species of toxic plants that have caused considerable problems for all classes of grazing livestock. These include poison pea (*Swainsona* sp.) of Australia, locoweeds (*Astragalus, Oxytropis* sp.) of North America, broomweed (*Sida carpinifolia*) of Brazil, and shrubby morning glory (*Ipomoea carnea*) of Mozambique. Endophytic fungi, such as *Embellisia,* that grow on locoweed can induce the same toxicity. As a *potent inhibitor of lysosomal* α*-mannosidase*, swainsonine induces a form of **α-mannosidosis** that is a close copy of the genetic disease of cattle and cats. Continued ingestion of toxic material over a period of 4–6 weeks and more results in failure to thrive and, ultimately, ataxia, proprioceptive deficits and behavioral abnormalities ("locoism" in North America, "pea-struck" in Australia). Necropsy examination during, or within a short time after, exposure to the plant reveals microscopic and ultrastructural lesions identical to those of genetic α-mannosidosis. Within 2 weeks of last exposure, much of the storage disease resolves, but axonal spheroids may persist in large numbers in areas such as the cerebellar roof nuclei and caudal brain stem. Swainsonine-induced mannosidosis has been experimentally compared in the cat with genetic mannosidosis in order to determine the reversibility of changes such as meganeurite and aberrant synapse formation in higher neurons (see introductory section). Clinical recovery may or may not occur following cessation of exposure, and the persistence of secondary neuronal changes suggests that they, rather than the storage process, may underlie neuronal malfunction. Exposure of young growing animals is more likely to produce irreversible disease than exposure of adults.

The induced disease is, however, biochemically distinct from the genetic, as *the alkaloid also inhibits Golgi mannosidase II*, an enzyme involved in the post-translational trimming modifications of the glycan moiety of glycoproteins. As a result, abnormal proportions of different types of glycoproteins are produced, and the storage oligosaccharides are larger than those in the genetic disease. No modification of the storage disease appears to result from this difference.

In swainsonine intoxication of pregnant animals, both dam and fetus are affected, and *abortion and terata are well recognized in ovine locoweed toxicosis.* Suppressive effects on fertility are also recognized.

Trachyandra poisoning

Ingestion of *Trachyandra divaricata* or *T. laxa* for several weeks has been associated with severe neurologic disease and **lipofuscinosis** in sheep, horses, goats, and pigs in South Africa and Australia. The clinical syndrome is one of weakness, suggesting a neuromuscular disorder, and is often accompanied by *intense lipofuscin storage in all central and peripheral neurons* and, to a lesser extent, in macrophages of the intestinal lamina propria, hepatocytes, Kupffer cells, and renal tubular epithelium. Pigment storage may be sufficiently intense to cause macroscopic rusty-brown discoloration of central gray nuclei and peripheral ganglia. The pigment granules have all the histochemical and ultrastructural features of lipofuscin. The clinical signs appear to be irreversible and their relationship to the storage process is obscure; the basis of the storage process is unknown.

Phalaris poisoning

Extensive losses in sheep and cattle in Australia, New Zealand, South Africa, California, and Argentina have been due to grazing *Phalaris* sp., principally *P. aquatica* and *P. arundinacea*, but also *P. minor, P. caroliniana*, and *P. angusta*. Several syndromes of *Phalaris* toxicosis affect principally ruminants but occasionally horses – dramatic large-scale sudden mortalities occur in sheep, sudden deaths have been associated in horses, staggers syndromes of acute onset and recoverable or of chronic onset and not recoverable occur in sheep and occasionally in cattle. Onset of staggers syndromes may be rapid on exposure to immature plants or delayed for up to several months. It is probable that resistance to the toxicosis may be produced by catabolism of toxins by adapted ruminal microflora.

There are two acute neurological syndromes. *Sudden death* in sheep and horses without observable tissue changes is probably caused by cardiotoxic compounds, a mix of *methyl tryptamine* and β*-carboline indoleamines* chemically related to 5-hydroxytryptamine (serotonin). The second acute syndrome is in sheep and is referred to as a polioencephalomalacia-like syndrome, the result of edema of deep cortical gray matter laminae. Severe astrocytic edema in the cortex is similar to that seen in citrullinemia, and suggests peracute ammonia toxicity due to toxic impairment of urea-cycle enzymes.

The clinical onset of the staggers syndrome may be delayed for several months after exposure to toxic pasture has ceased. It is characterized by generalized muscle tremors progressing to stiffness, collapse on forced exercise, and tetanic seizures. In most cases, recovery does not occur and apparent recovery is followed by relapses.

In cases examined early in the course of the disease, there may be no gross or microscopic lesions but, in general, pathologic changes are present. Most characteristically, there is *storage of granular pigment within neurons* of the brain stem nuclei, spinal gray matter and dorsal root ganglia, and in macrophages of the cerebrospinal fluid. A similar pigment is also present within renal tubular epithelial cells. When storage is intense, the affected gray matter and kidneys may have distinct green discoloration on gross inspection (Fig. 3.48A). Histologically, the pigment granules are green-brown and present in a perinuclear distribution in neurons (Fig. 3.48B), although some granules may accumulate in dendrites. Ultrastructurally, the storage granules are composed of concentric membranous lamellae, sometimes interspersed with fine granular material. They are membrane bound and are considered to be lysosomal in nature. In most cases, there is also Wallerian degeneration concentrated in ventral, ventromedial, and lateral funiculi throughout the spinal cord, and in the medial longitudinal fasciculus. This distribution suggests selective damage to long descending motor tracts. Severely affected areas may also have intense diffuse astrogliosis. Intense reactive astrogliosis may also be seen in ventral spinal cord gray matter, along with mild neuronal loss.

Solanum poisoning

Ingestion of *Solanum kwebense* or *S. fastigiatum* is associated with neuronal degeneration and loss in the cerebellum, as discussed elsewhere.

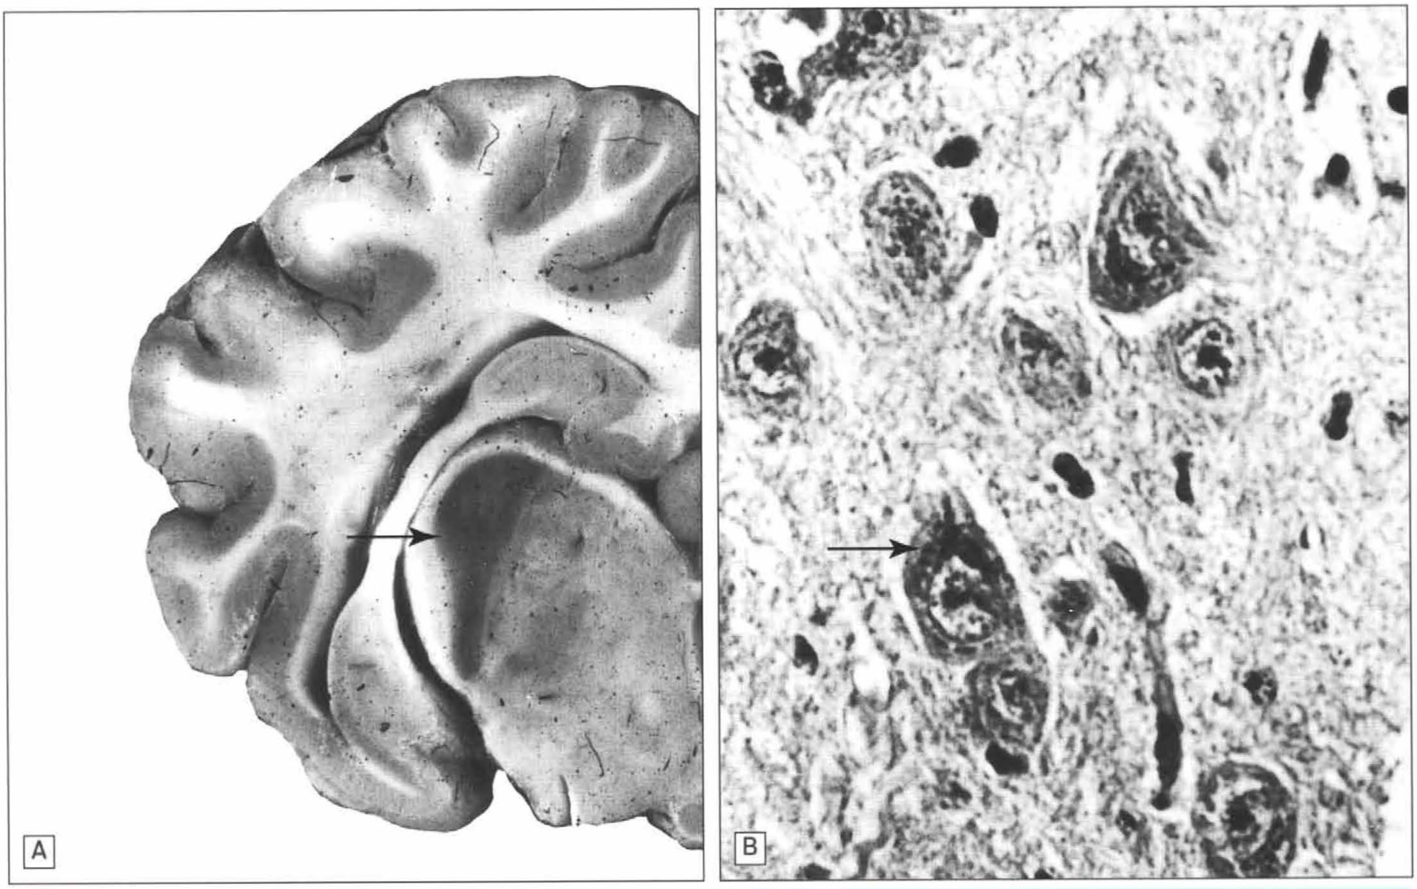

Figure 3.48 ***Phalaris* sp. poisoning** of a cow. **A.** Pigmentation in lateral geniculate body (arrow). **B.** Pigment granules in neuronal cytoplasm (arrows).

Purkinje cells and some other neurons are vacuolated, and lamellated lipid material is stored in endoplasmic reticulum or lysosomes. The lectin-binding pattern is consistent with a glycolipid storage disease.

Gomen disease

As discussed elsewhere, this is a suspected toxicosis of horses in New Caledonia, in which there is cerebellar neuronal degeneration, and associated lipofuscin storage in neurons and phagocytic cells.

INCREASED INTRACRANIAL PRESSURE, CEREBRAL SWELLING, AND EDEMA

Normally only a narrow space separates the brain from the dura mater. Both the dura and skull are unyielding so that only a relatively small increase in the volume of the intracranial contents is permissible without increasing intracranial pressure. When the pressure is increased, something has to yield. The following refers particularly to the brain, but the principles apply equally to the spinal cord, especially in cases of trauma.

The causes of increased intracranial pressure are many and varied. One component of almost all of them is edema. **Brain edema** is an increase in water content of brain tissue. Brain tissue is about 75% water, a little more for gray matter and a little less for white matter. The edema may be more or less localized and geographically related to local lesions, or it may be diffuse. In addition to the pathogenetic mechanisms to be discussed here, acquired hydrocephalus and vitamin A deficiency in young animals can be responsible for increased intracranial pressure. In vitamin A deficiency, there is increased secretion of cerebrospinal fluid by the choroid plexus and decreased absorption by arachnoid villi, effects that may be quickly repaired by administered vitamin. Also important in domestic animals is impaired growth and remodeling of cranium and vertebrae that leads to disproportion between the volume of the growing nervous system and volume of the cranial cavity and spinal canal.

The local lesions that may result in **local edema** of the brain or spinal cord include: neoplasms, inflammations, parasitic cysts, focal necrosis of various causes, trauma, hemorrhages of parenchyma and meninges, and space-occupying lesions of the meninges that cause pressure on the brain. In each example, the edema may be mild or extensive and may contribute more than the primary or inciting lesion to the clinical signs, and to the swelling of the brain or spinal cord and increase of intracranial pressure.

Generalized cerebral edema and swelling of the brain also occurs in relation to a variety of *systemic conditions*. Some degree of swelling can be anticipated as a *postmortem change*, especially in the brain of young animals, and is probably to be related to the imbibition of fluid in autolysis. Cerebral edema with swelling occurs with diffuse *meningitis*, moderately so in the diffuse *viral encephalitides*, *acute bacterial toxemias* such as clostridial enterotoxemia, and *chemical intoxications* such as lead and organomercurial poisoning, and quite severely in the pathologic syndrome of sheep and cattle known as *polioencephalomalacia*. Generalized edema of moderate degree is expected in the many metabolic and toxic conditions which are characterized by disturbances of cellular osmoregulation, in particular disturbances which interfere with intracellular and extracellular concentrations of sodium and potassium; the acute-onset neurologic disease which occurs in *salt poisoning* of pigs and in *water intoxication* in young ruminants given water *ad libitum* after a period of deprivation would be in this category.

There are differences between gray and white matter in their susceptibility to edema, and different areas of gray substance or of white differ in their vulnerability. The considerations of edema here recognize several types of edema but are limited for descriptive purposes to the cytotoxic and vasogenic varieties. **Congestive brain swelling** is an increase in volume, especially in capillaries and post-capillary venules, as a result of loss of autoregulation of arterial input. In vivo imaging techniques can identify this edematous pattern but it is not easily evaluated at postmortem because of the valveless character of intracerebral veins. **Interstitial edema** that affects the central white matter in hydrocephalus and the spinal cord in hydromyelia and syringomyelia is considered with those diseases, the edema is a result of acutely raised intraventricular pressure. Hypo-osmotic edema follows a reduction of serum osmolality, usually as a result of fluid administration or ingestion.

A distinction is maintained here between **cytotoxic edema** and **vasogenic edema**, notwithstanding that the endothelial barrier between blood and brain may be functionally deranged in each type. *Intracellular* or **cytotoxic edema** depends on direct or indirect noxious injury to cells and interference with the mechanisms that control cell volume. For cells in non-nervous tissues, the swelling would represent hydropic change, the movement of water from interstitial tissues into cell cytoplasm. There is, however, in nervous tissue no significant interstitial tissue or intercellular space. The intercellular space in the brain is not more than 10–20 nm. There is a layer of material that stains as glycoprotein or glycosaminoglycan on cell membranes, but there is doubt as to whether it is the counterpart of other interstitial gels. The net increase in water in the brain in cytotoxic edema must represent a movement from plasma, and the regulatory mechanisms must therefore reside in the capillary endothelium and the brain cells. The basic disturbance is in osmoregulation, which depends mainly on the efficiency of the sodium/potassium pump and adenosine triphosphate as an energy source.

In cytotoxic edema, the swelling is in neurons but mainly in the astrocytes. Simple swelling of astrocytes is the most obvious structural change in gray matter. Swelling of the astrocytes involves the nucleus and processes. Glycogen granules accumulate in the watery protoplasm. If mild edema persists, the astrocytes react as described in an earlier section. If the edema is severe, the astrocyte nucleus is much enlarged, the chromatin is dispersed against the nuclear membrane, and the processes are voluminous. Death of acutely swollen astrocytes may not be accompanied by changes in the adjacent neuropil. Neurons may swell as a brief prelude to lysis. Satellite oligodendroglia are generally spared.

However, in cytotoxic edema, oligodendrocytes in white matter degenerate. The nucleus is swollen and less dense than normal; the nucleolus is hypertrophied, and the cytoplasm is enlarged and often visible in routine material. Changes in oligodendroglial processes that are wrapped as myelin are difficult to evaluate histologically except in those instances of specific cytotoxic edema in which there is splitting of the intraperiod line and the accumulation of water in intermyelinic clefts.

Vasogenic edema *is the term used to distinguish the extracellular accumulation of fluid from cytotoxic edema.* The basis of vasogenic edema is injury to vascular endothelium of sufficient severity to allow leakage or permeation of plasma constituents including, if the injury is sufficient, plasma proteins. The fluid spreads between cells in response to hydrostatic pressures in the cerebral circulation and those in the tissue. Vasogenic edema is a common complication of traumatic, inflammatory, and hemorrhagic lesions of the nervous system. It is not a conspicuous change in gray matter, because the dense tangle of neuropil resists the passage of fluid. There are exceptions such as in the periventricular nuclei where vasogenic edema occurs rather selectively in thiamine deficiency. The structure of white matter offers less resistance to the passage of edema fluid of this origin, and the comparison between the susceptibility of gray and white matter can be seen readily with local lesions near their junction in the cortex. The long fiber tracts such as the spinal cord, internal capsules, and optic tracts tend to be spared. The density and disposition of these tracts probably exert a considerable influence on the spread of edema about local lesions as, for example, the corpus callosum seems effectively to prevent spread from one hemisphere to the other.

The histological appearances are similar to those in cytotoxic edema with the addition of dissecting changes along fiber tracts. The white matter is loosely textured, the myelinated fibers being spread apart. The spaces created may be clear or they may, depending on the degree of permeability, contain homogeneous proteinaceous fluid (Fig. 3.49). Plasma droplets that stain brightly with periodic acid-Schiff are frequently present in perivascular clefts (Fig. 3.50).

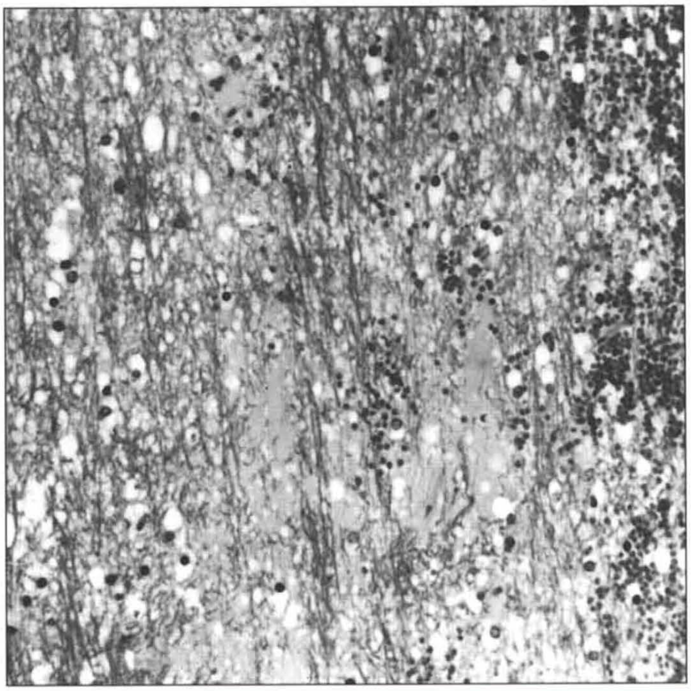

Figure 3.49 Vasogenic edema and hemorrhage with degeneration of white matter.

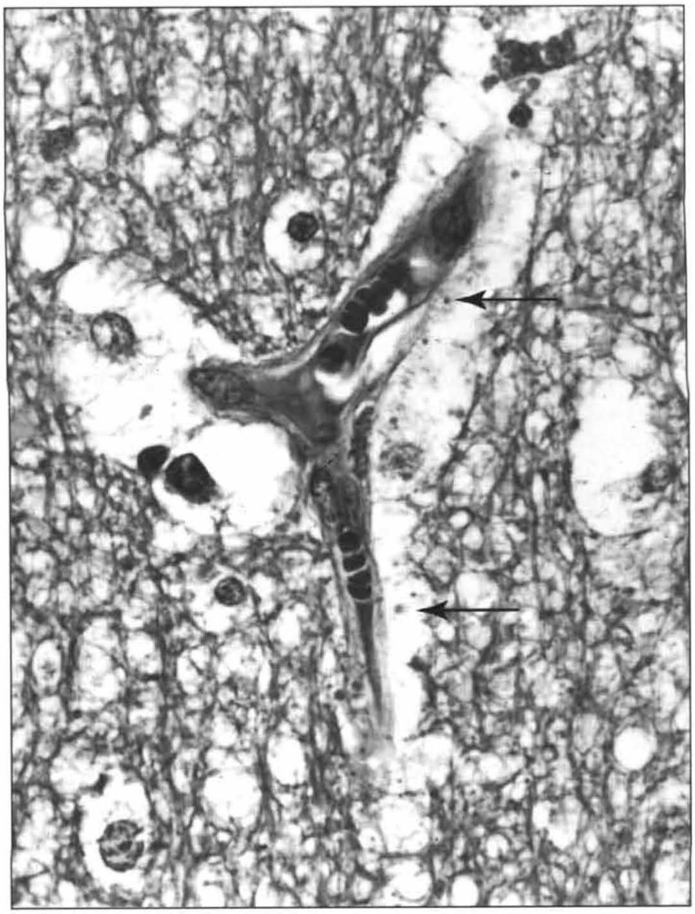

Figure 3.50 Accumulation of clear **edema** with protein droplets (arrows) around a vessel in a pig with mulberry heart disease.

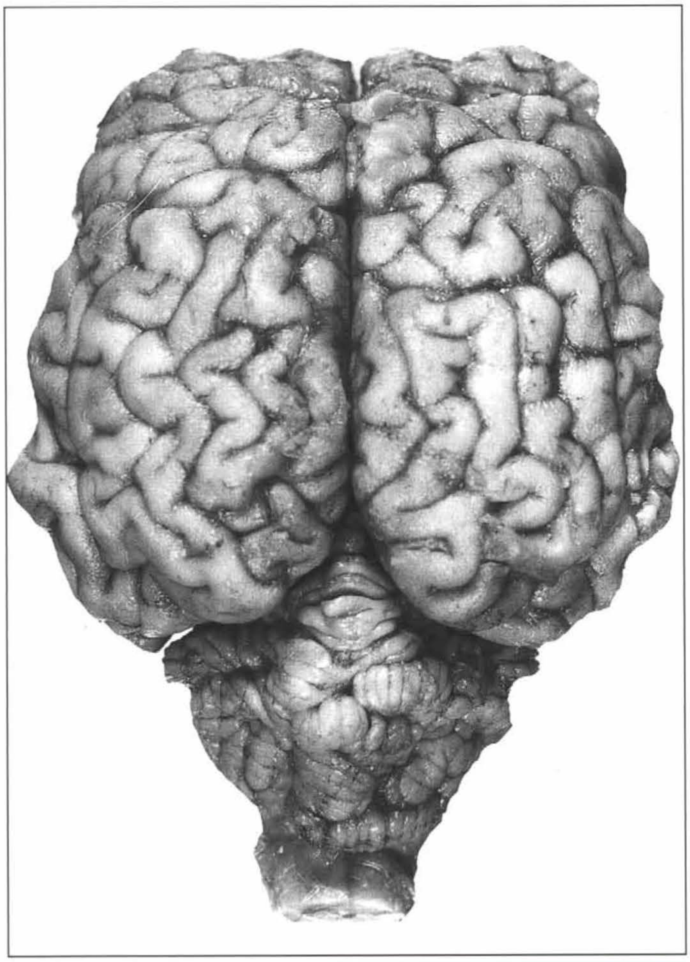

Figure 3.51 Cerebral edema with displacement and coning of cerebellum in a calf.

Diffuse cerebral edema that is mild or moderate may be difficult to recognize grossly. More severe degrees are readily recognized although easily overlooked. *The brain is swollen, pale, soft, and wet* and, because of its softness, the cerebral hemispheres tend to droop over the edges of the parietal bones when the calvaria is removed. With these severe and rapid swellings, the course is short, and there may not be signs of displacement or flattening of the gyri. When the swelling is less severe, and of longer duration, the brain may be relatively firm and dry, the gyri are pale or a faint-yellow color, and the brain is displaced caudally so that it appears unusually elongate. The displacement is most obvious where it involves the cerebellum and medulla (Fig. 3.51). With moderate displacement, the caudal surfaces of the cerebellar hemispheres are depressed by contact with the occipital bones. When the displacement is of greater degree, the *medulla and caudal portion of the vermis are herniated through the foramen magnum.* The displaced vermis is flattened and lies like a tongue over the medulla (so-called lipping of the cerebellum). The rhomboid fossa is flattened. The rostral portion of the vermis is pressed against the rostral medullary velum and may occlude the opening of the cerebral aqueduct to cause internal hydrocephalus. The brain stem is displaced caudally, and this is especially evident in the displacement of the corpora quadrigemina well into the caudal fossa. Perhaps because the tentorium rather closely embraces the brain stem in animals, herniation of the occipital lobes through the tentorial space into the caudal fossa is seldom observed. It may, however, be observed in cerebral edema of long standing in horses and cattle, especially if the brain is fixed in situ so that the pressure grooves produced by the free edge of the tentorium are retained. Impaction of tissue in the tentorial space interferes with the flow of cerebrospinal fluid from the caudal to the rostral fossa and contributes to hydrocephalus.

Displacements in the rostral fossa in diffuse cerebral swelling are of lesser degree and significance. The nerves may be stretched and flattened, but pareses are seldom observed. The vasculature must be compromised in all cases. Occasionally there is thrombosis of the superior sagittal sinus with venous infarction in the dorsal cortex, ischemic necrosis in the caudomedial surface of the occipital lobe referable to compression of the caudal cerebral arteries, and pontine hemorrhage referable probably to occlusion of small veins in this area.

Localized edematous changes reach their most extensive development in the centrum semiovale of the cerebrum and in the deep white matter of the cerebellum surrounding local lesions in these areas. The edematous area may be recognized by the swelling, which may be greater in volume than that produced by the primary lesion and have a soft, depressed and damp or watery appearance on the cut surface. The extent of the edema cannot be appreciated on gross inspection because the margins are indefinite, and the same difficulty in delineating the edematous area is experienced at microscopy. When the lesion is of prolonged duration, the extent of the edematous areas can be appreciated a little better by yellow discoloration that develops.

The combination of edema with a local lesion may displace the brain in one or more directions. Caudal displacement through the caudal fossa may occur as it does in diffuse swelling. The displacements may be more local, involving lateral shifts of the base of the brain or medial displacement of one hemisphere so that the falx cerebri is displaced laterally or the cingulate gyrus is herniated beneath the free margin of the falx and the lateral and third ventricles are depressed.

LESIONS OF BLOOD VESSELS AND CIRCULATORY DISTURBANCES

Diseases of blood vessels are considered in detail with the Cardiovascular system. This section deals with some special features of cerebrospinal circulation and the lesions, usually ischemic or hemorrhagic, which result from vascular injury.

The blood supply to the brain is derived from the *internal carotid and vertebral arteries*, these sources anastomosing under the brain stem and at the *circle of Willis*. The major cerebral vessels, derived from the carotid and vertebral arteries, anastomose quite freely in the pia-arachnoid, but once an artery or arteriole penetrates the substance of the brain, it becomes an *end artery* although there are some anastomoses at the capillary level. Although these anastomoses can be demonstrated readily, even those of arteriolar size in the meninges are probably of little value. Under normal circumstances, the cerebral arteries have rather set fields of supply. If one vessel is occluded, some collateral circulation develops, but it does not take over more than the periphery of the area of supply of the occluded vessel. In the brain, there may be influences governing collateral circulation in addition to those operating in other tissues, but the basic considerations still apply.

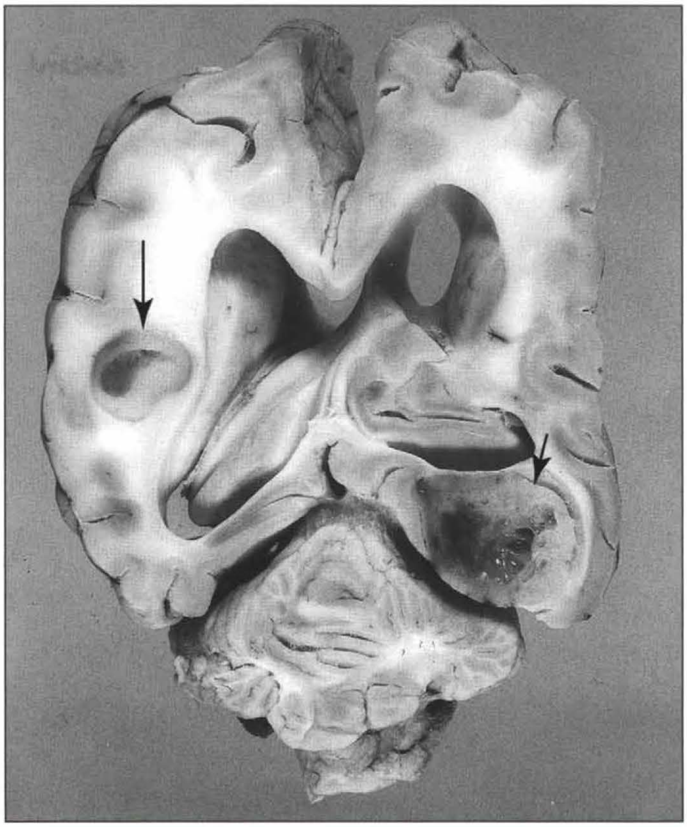

Figure 3.52 Tumor metastases (arrows) at the junction of gray and white matter in a dog.

The development of collateral circulation will be influenced by the anatomic arrangements of vessels, the volume of ischemic tissue, the rate at which the vascular occlusion develops, the size of the occluded vessel, and, importantly, the quantity of blood flow, which is referable to the state of the systemic circulation, and the quality of blood flow, which is referable to such matters as the oxygen tension and viscosity of plasma. For complete cessation of blood flow in an area of brain, it is probably not necessary that there be complete occlusion of the corresponding artery because flow is expected to cease, especially in peripheral twigs, while the intravascular pressure is still above zero. For this reason, ischemic injury in the brain localized to the field of distribution of one or other major cerebral artery may result from occlusion of a carotid vessel. Extracranial anastomoses between the major arterial vessels are, however, effective in the event of vascular occlusion occurring proximal to the circle of Willis.

Arteries entering the substance of the brain are relatively small and arise at right angles from the parent vessels in the pia-arachnoid. There are abrupt changes in caliber when the meningeal vessels divide and this provides an entrapment mechanism for large emboli. The vessels that enter the brain are progressively attenuated to capillaries in both gray and white matter, but many capillaries loop back into the cortex from near the gray–white junction. Many small emboli lodge at the gray–white junction, although expansion of the embolic or metastatic lesions is predominantly in the white matter (Fig. 3.52).

The *arterial supply to the spinal cord* is derived from the vertebral artery in the cervical region and from radicular arteries in the lumbar region anastomosing as the ventral spinal artery. There is some doubt as to the direction of flow in cervical, thoracic, and lumbar portions of the spinal artery and it is possible that there is a border zone in the caudal cervical and cranial thoracic region that is particularly vulnerable to ischemia if flow is impaired in the vertebral artery or the caudal portions of the ventral spinal artery.

In the spinal cord, the central gray matter is supplied by branches of the ventral spinal artery that enter the ventral sulcus, and lesions of these branches affect the gray matter of the cord rather selectively. The white matter is supplied by an anastomotic complex in the meninges that produces many small vessels that penetrate directly as end-vessels and are susceptible to compression or hypotension.

Cerebral veins have abundant and useful anastomoses. Untoward effects are not expected to follow occlusion of single veins because absence of valves permits reflex flow. The venous sinuses of the dura mater empty into the jugular veins, but they also communicate freely through the bones with extracranial veins. Because of these communications, the effects of obstruction of a dural sinus may be relatively slight, unless there is venous stagnation of the head or venous stagnation within the cranium produced by cerebral swelling or occlusion of more than one major sinus. The venous system of the spinal cord is freely anastomotic and drains via the radicular vessels to the paravertebral plexuses. These vessels are also valveless and allow very free communication up and down the spinal canal such that an embolus arising in caudal veins may bypass the caudal vena cava in passing to the lungs. These arrangements of veins may assist in temperature and pressure control in spinal and cerebral vessels. The arrangements have disadvantages. Infiltrating neoplasms may extend from extradural positions to the cord along the venules. In the cranial cavity, infections may extend from the face to the basal meninges. In cattle, sheep, and dogs, pyogranulomatous processes that are occasionally found in the hypothalamic–hypophyseal region are introduced in migrating intravenous foreign bodies that enter the cranial cavity in veins passing through the ophthalmic foramen.

Disturbances in the cerebrospinal vasculature with impaired blood flow may be composed of obstructive and hemorrhagic lesions, or they may be part of global cerebral ischemia with failure of adequate total perfusion. Diseases associated with abnormality of the circulating blood, such as the anoxias, hypoglycemia, and hyperviscosity, are discussed later with neurodegenerative diseases.

Ischemic lesions

The outcome of vascular obstructions depends on the type and size of the vessel obstructed, the degree and duration of ischemia, and the relative vulnerability of the tissues to anoxia. The injury may vary in severity from a temporary functional disturbance to the other extreme of infarction and necrosis. *Neurons and oligodendroglia are the most sensitive of the neural structures to ischemia, astrocytes are moderately resistant, and microglia and the blood vessels are quite resistant and may survive in small areas in which all else dies.* Gray matter, with its high metabolic rate and dependence on oxygen, is more sensitive than is white matter, but there are regional differences in the sensitivity of gray matter.

Obstructive lesions of cerebrospinal vessels are not commonly observed in animals, and ischemic changes may be absent even when the vessels are profoundly altered. On the other hand, lesions which are regarded as being of ischemic type are quite commonly observed in the absence of demonstrable vascular occlusion. These cases tend to be individual in their occurrence and without particular pattern.

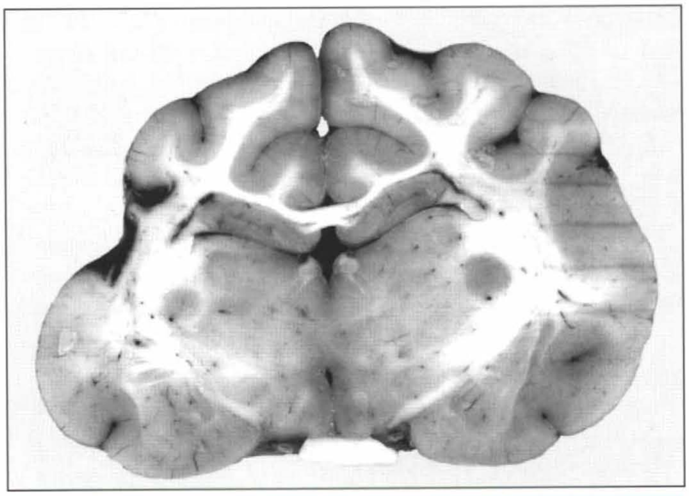

Figure 3.53 Focal loss of gray matter from left parietal cerebral cortex, in **feline ischemic encephalopathy.** (Courtesy of RF Slocombe.)

Global ischemia is occasionally observed in animals suffering cardiac arrest under anesthesia, and in neonatal "barking foals and piglets." Purkinje cells, the hippocampal cortex, and neurons of the cerebral cortex are the most sensitive of all, and, within the cerebral cortex, the deeper laminae are more sensitive than the superficial laminae. Necrosis is accentuated over boundary zones at the margins of distribution of the rostral, middle, and caudal cerebral arteries. Similar regional susceptibility can be demonstrated in the cerebellar cortex. The deeper laminae of the cortex may be selectively destroyed in ischemia, producing a distribution of necrosis that is known as **laminar cortical necrosis**. Lesions are expected to be symmetrical but may not be. In severe and prolonged global ischemia, necrosis may involve all of the cortex and other nuclei such as globus pallidus and lateral thalamus. The sensitivity to necrosis parallels that in severe hypoglycemia except that hypoglycemic injury spares the cerebellar Purkinje cells. The assumption that the injury is a result of anoxia and energy deficit does not recognize the complex biochemical perturbations set in train by cellular anoxia.

Feline ischemic encephalopathy is recognized in mature cats, and results from aberrant migration of *Cuterebra* larvae in the brain. While larval migration tracks may be present, the ischemic lesions may be the result of toxin-induced vasospasm. The extent and distribution of degeneration vary from case to case. Milder lesions occur in superficial cortical laminae as multiple foci. More severe or extensive lesions tend to be in the distribution area of the middle cerebral artery and may be bilateral but asymmetrical (Fig 3.53). In some cases, there may be ischemic lesions in the brain stem.

Ischemic and hemorrhagic cerebral lesions occur in the **neonatal maladjustment syndrome of foals**, also known as the "barker" or "convulsive foal" syndrome, which is discussed with congenital atelectasis in Vol. 2, Respiratory system. The nature of the circulatory derangement is not understood but the lesions are presumed to reflect cerebral ischemia and variably delayed reflow. There is ischemic laminar necrosis of the cerebral cortex (Fig. 3.54), sometimes accompanied by necrosis in the paired gray nuclei of the midbrain and brain stem, and by multiple small hemorrhages. In some foals affected by

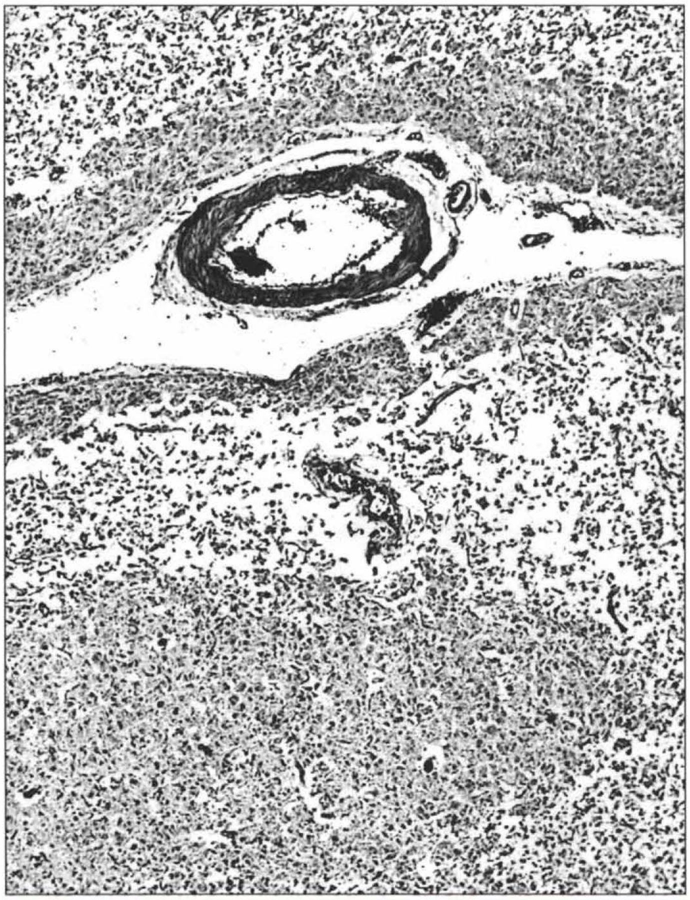

Figure 3.54 Polioencephalomalacia of cerebral cortex in a foal with neonatal maladjustment syndrome.

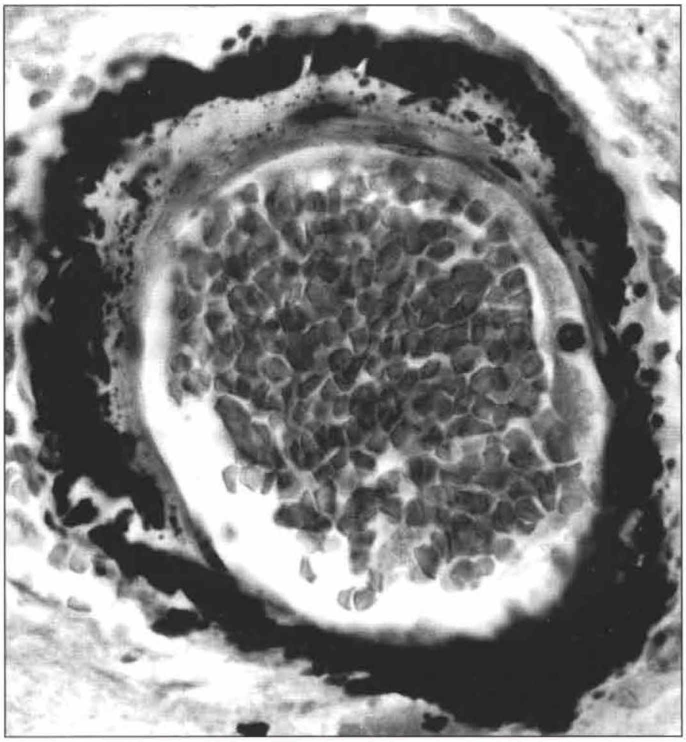

Figure 3.55 Siderosis of cerebral vessel in a horse.

this neonatal syndrome, there is minimal ischemic necrosis but instead a profuse distribution of small perivascular and petechial hemorrhages in the cerebrum, cerebellum, and brain stem.

Degenerative vascular disease of arteriosclerotic type is not important in animal disease. *Atheroma* occurs in some hypothyroid dogs. *Siderosis* of the walls of the arterioles occurs commonly as a change associated with advancing age in horses. The calcium and iron salts may be deposited in amounts capable of converting the vessels to rigid pipes (Fig. 3.55). The patency of the vessels is well maintained. There is no thrombosis, and vascular stenosis probably proceeds slowly enough for adaptive circulatory changes to occur because small areas of softening, presumably ischemic, are unusual.

Hyaline necrosis in meningeal vessels, which is observed in swine with hepatosis dietetica, is not usually associated with secondary lesions. The hyaline necrosis in meningeal vessels in pigs with organomercurial poisoning is associated with severe cerebral injury that may be, in part, due to reduced perfusion (Fig. 3.56). *Amyloid degeneration* of meningeal and intracerebral vessels occurs in aged dogs and the thickenings of the meningeal arteries may be visible grossly. Senile argyrophilic plaques that contain amyloid deposits may be associated with the vascular lesions. The systemic distribution of amyloid is minimal. Petechial hemorrhages occur in relation to the diseased vessels in about 50% of cases and, exceptionally, there is massive hemorrhage.

Cerebrospinal angiopathy is an important cause of neurological disease in pigs. It occurs in the alimentary enterotoxemia known

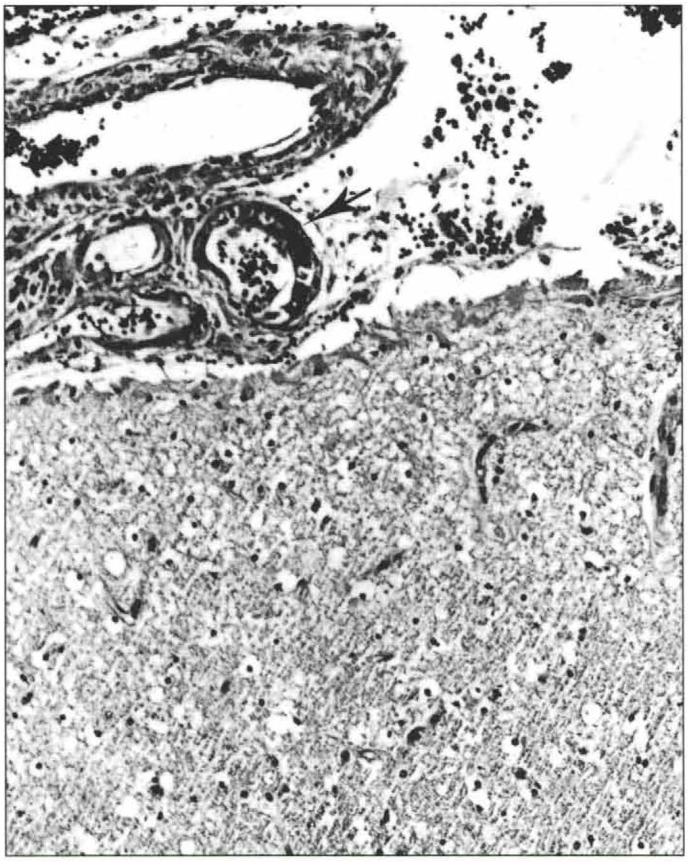

Figure 3.56 Necrosis of meningeal arterioles (arrow) due to organomercurial poisoning in a pig.

as **edema disease** of pigs with similar lesions in vessels of brain and other tissues (Fig. 3.57). The lesions are described in detail in Vol. 2, Alimentary system. In groups of older pigs, arteritis or periarteritis can develop and may represent a chronic or persistent expression of the acute angiopathy.

Vascular permeability changes provide a basis for **annual ryegrass toxicosis** of sheep and cattle in Australia, South Africa, and formerly in the USA. The distribution of the disease is governed in part by the distribution of annual ryegrasses, *Lolium rigidum* and hybrids, in winter rainfall areas, although the disease can occur in other areas by the use of transported fodder. The distribution is also governed by the distribution of toxin-producing *Clavibacter toxicus* (*Corynebacterium rathayi*) and infection by the bacterium of galls produced in the seed head by the nematode *Anguina agrostis*. In addition to *Lolium* spp., known host plants include *Polypogon monspeliensis* (annual beardgrass), *Festuca nigrescens* (chewings fescue), and *Agrostis avenacea* (blowngrass).

The nematode *Anguina agrostis* emerges from fallen galls following first autumn rains, migrates into the growing points of the ryegrass seedlings, and later penetrates the florets to produce galls. The nematodes are harmless to animals but may carry on the cuticle the bacterium that will proliferate in the gall, forming a yellow slime. The active principle, *corynetoxin*, is closely related to the tunicamycin antibiotics produced by some strains of *Streptomyces*. Indeed, tunicamycin-like metabolites have been detected in mycotoxicosis in pigs. Corynetoxins and tunicamycins inhibit lipid-linked N-glycosylation of glycoproteins, which compromises cell membrane integrity.

The toxicosis is characterized clinically by neurologic signs and high mortality. Pregnant ewes may abort. The pathogenesis of abortion has not been examined but the occurrence of hemorrhages in various organs, pulmonary edema and swelling of endoplasmic reticulum of hepatocytes indicates systemic intoxication, notwithstanding the prominence of neurologic signs.

The clinical signs, which are severe, include excitability, aggression in cattle, disturbances of gait and convulsions. The clinical course may be less than 12 hours. Gross changes include pulmonary edema and a pale swollen liver, and occasionally there are hemorrhages in various organs.

Microscopic changes in nervous tissue are subtle, especially following routine fixation by immersion, which may not preserve transudates. Tracer injections show widespread alterations to cerebrovascular permeability in the brain and meninges, indicating endothelial damage and disruption of the blood–brain barrier. The perivascular transudate resembles plasma (Fig. 3.58) in staining properties, and may be present as perivascular lakes or droplets that stain strongly with PAS stain. Only occasionally can fibrin be demonstrated, but extravasation of red cells from capillaries may be present in neuropil. Astrocytes are

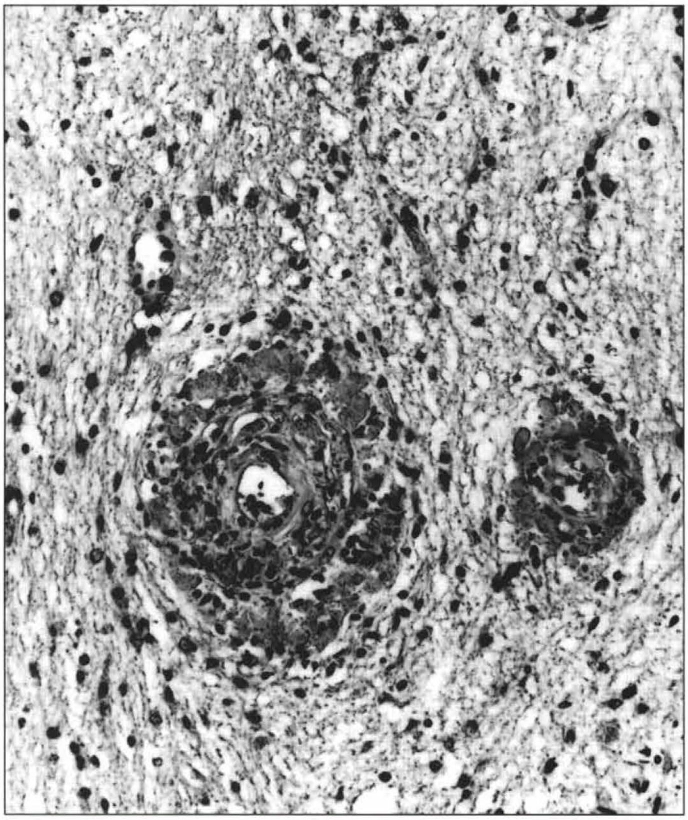

Figure 3.57 Necrosis and inflammation of vessels in brain stem in a pig with **edema disease**.

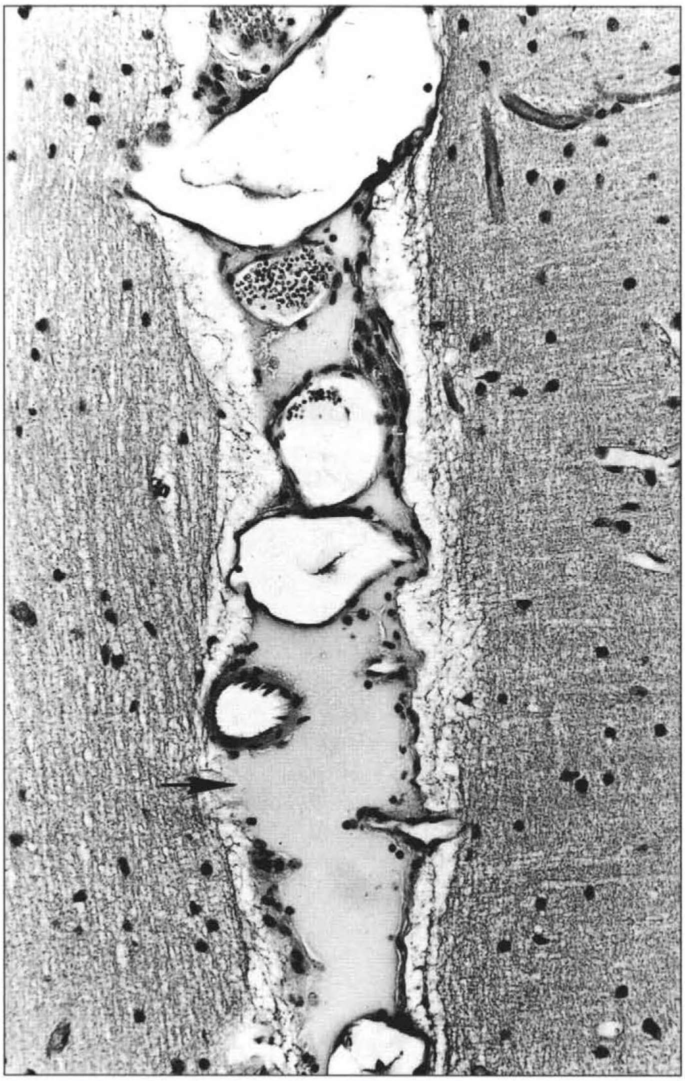

Figure 3.58 **Vascular leakage** (arrow) in the leptomeninges of the cerebellum of a sheep with annual ryegrass toxicity. (Courtesy of J McC Howell.)

swollen with acidophilic cytoplasm, and there may be widespread necrobiosis of oligodendroglia in the cerebral gray matter.

The capillary endothelium shows ultrastructural evidence of injury. Endothelial cells are swollen and electron-lucent, the cisternae of rough endoplasmic reticulum are distended, mitochondria are swollen with disorganization of cristae, and capillary lumina sometimes contain platelet aggregations. The changes are best seen in cerebellar cortex and meninges. Neuronal change is minimal but there may be patchy loss of Purkinje cells and scattered small foci of malacia.

Cerebrospinal vasculitis, affecting both arterioles and veins, occurs in a number of specific diseases. *Polyarteritis* (periarteritis nodosa) appears to have some predilection for the cerebral arteries, especially in the pig, and for the spinal arteries in the dog in which it is cited as **steroid-responsive meningo-arteritis**. Vasculitis is a rather specific feature of classical swine fever (Fig. 3.59), sporadic bovine encephalomyelitis (Fig. 3.60), and malignant catarrhal fever; the agents of these diseases have no predilection for neural tissue, and parenchymal degeneration, which is sometimes observed, is secondary to occlusion of vessels; this occlusion, in turn, is secondary to inflammatory lesions of the vascular adventitia. Adventitial proliferations and perivascular infiltrates are common to many of the encephalitides, both bacterial and viral, and focal softenings of the brain and cord in these inflammatory diseases can frequently be related to occlusive vasculitis. The occlusive lesions are not solely related to the acute phase of inflammation, but adventitial fibrosis and vascular stenosis may be prominent in the healed phase of encephalitis and may lead eventually to ischemic damage and softenings.

Thrombosis and embolism in the cerebrospinal arterioles is very seldom observed in animals. Thrombosis of an internal carotid vessel or ventral spinal artery may accompany atrial and aortic thrombosis, especially in cats (Fig. 3.61). Bone marrow emboli form after trauma and fractures, most commonly in dogs (Fig. 3.62). *Emboli composed of fibrocartilage or nucleus pulposus* occur in spinal arteries and veins in most species, and cause hemorrhagic and ischemic infarcts of sudden onset (Fig. 3.63). The cervical or lumbar segments may be affected. The pathogenesis is discussed with Diseases of bones and joints. *Bacterial thrombi* may develop in a variety of bacteremic diseases such as erysipelas, shigellosis, pasteurellosis, and the septicemias caused by *Histophilus, Streptococcus*, and the coliforms. Abscessation develops rapidly about these bacterial colonies, but in the early stages perivascular zones of softening may be observed.

Perhaps the least morphological expression of arteriolar obstruction is death of neurons in a narrow zone of cortex representing the central portion of a field of distribution of a single arteriole. In the early stage, there is acute ischemic necrosis of neurons and oligodendroglia. There is no softening in these minimal lesions, but they are readily visible at low power as narrow zones of pallor. At higher magnification, the affected zone is seen to be unusually cellular, this being due in the early stages to microgliosis and later to astrogliosis.

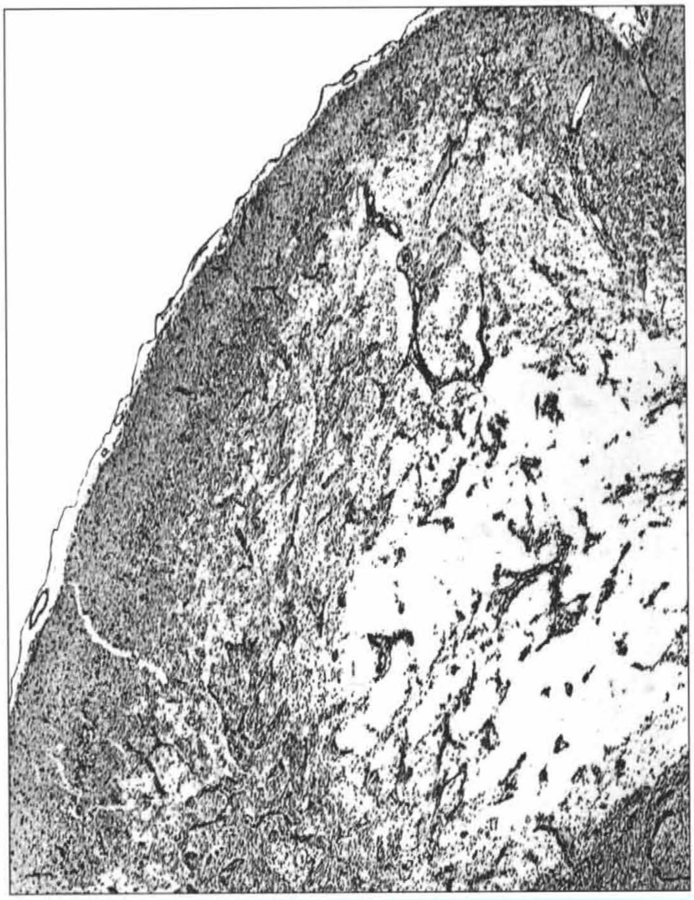

Figure 3.61 Residual cyst in cerebral cortex, the result of carotid thrombosis and ischemic infarction in a cat.

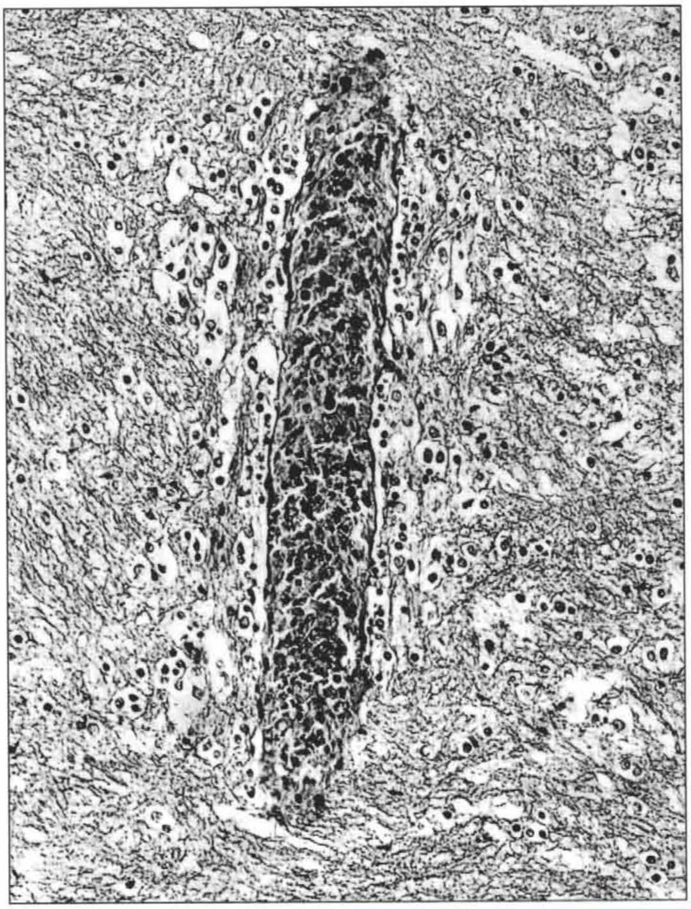

Figure 3.62 Marrow embolus and surrounding intracellular edema following trauma and femoral fracture in a dog.

Obstruction of an artery or arteriole results typically in *infarction*, and infarcts involve both gray and white matter. In the early stages, affected areas swell, and the involved gray matter may be hemorrhagic (Fig. 3.64). At the center of an infarct, there is coagulative and liquefactive necrosis and around the periphery there is a zone of minimal ischemic injury with the characters mentioned above. Many capillary vessels survive, partly because of their relative insensitivity to anoxia and partly because they benefit first from the collateral circulation that develops. Surviving vessels show endothelial and adventitial proliferation, and the astrocytes around the margin of the lesion react. The necrotic tissues are removed from the periphery by liquefaction and microglial phagocytosis, and a cyst remains (Fig. 3.61). The cyst contains fluid, and distended microglia, so-called *compound granular corpuscles*, may be found in it for very long periods. The wall of the cyst is ragged and irregular and is formed by reactive astrocytes. When the defect extends to the meninges, it may be partially filled in by proliferated leptomeningeal tissue.

Obstruction of cerebrospinal veins is the result either of pressure or inflammation with thrombosis, although rarely it may be due to neoplastic invasion and permeation of the dural sinuses. *Thrombophlebitis* is usually bacterial and the associated meningitis is more conspicuous and important than the venous thromboses; isolated venous obstructions are not of much significance.

Intracranial thrombophlebitis can be due chiefly to retrograde spread of inflammation from an extracranial primary focus, but thrombophlebitis of this type is uncommon. Such primary foci may occur in the orbital or nasal cavities, the paranasal sinuses, or the middle ear. Intracranial inflammations have little tendency to cause thrombosis of the dural sinuses. In verminous infestations of the brain, especially those caused by *Strongylus* larvae in horses, there is some tendency for the larvae to migrate to the superior sagittal and transverse sinuses and to cause thrombosis of these. Spinal thrombophlebitis results from ascending infections from docking wounds in lambs and from bite wounds of the tails of pigs.

Noninflammatory thrombosis of the cranial dural sinuses occurs chiefly in the superior sagittal sinus. It occurs in polioencephalomalacia of cattle, in which it is probably secondary to severe and prolonged swelling of the brain. Sinus thrombosis may also be observed following head injuries, even those not accompanied by lacerations (Fig. 3.65).

Venous infarcts differ from arterial infarcts by the more extensive hemorrhage in the affected areas and by the diffusion of blood into the adjacent subarachnoid space. The superficial veins are engorged and the congested area is edematous and swollen. The hemorrhages are perivenular and petechial or larger, and are present in the gray matter and to a lesser extent in the white matter. The subsequent course and reaction are similar to those following arterial obstruction, and the residual lesion is a depressed and shrunken or cystic area that is dark brown-yellow.

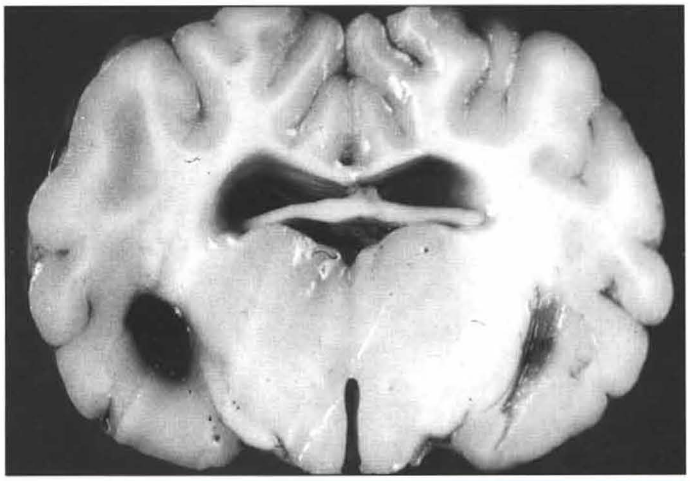

Figure 3.64 Hemorrhage (left) and malacia (right) in cerebrum of a pig with **mulberry heart disease**.

Hemorrhagic lesions

Hemorrhages in the CNS may be *traumatic or spontaneous* and may be restricted to the meninges or the parenchyma or involve both. Hemorrhages accompanying periventricular leukomalacia in neonates are discussed earlier. The causes are, in general, the same and are of much variety. They can be broadly grouped into those affecting the integrity of the vessel wall and those that reduce the coagulability of the blood. Care is necessary in deciding whether observed extravasations are significant because they can be produced readily as *artifacts at postmortem.* Quite extensive spread of blood into the basal meninges commonly occurs from the venous sinuses when the head is removed at the atlanto-occipital junction, and into the spinal meninges when the spinal column is transected. Hemorrhages of petechial size in the parenchyma can be largely avoided as artifacts if the brain or cord is fixed before slicing. The microscopic distinction of antemortem from postmortem hemorrhages can also be difficult because, apart from minor degenerative changes of the parenchyma, terminal hemorrhages provoke very little reaction, even on the part of the microglia.

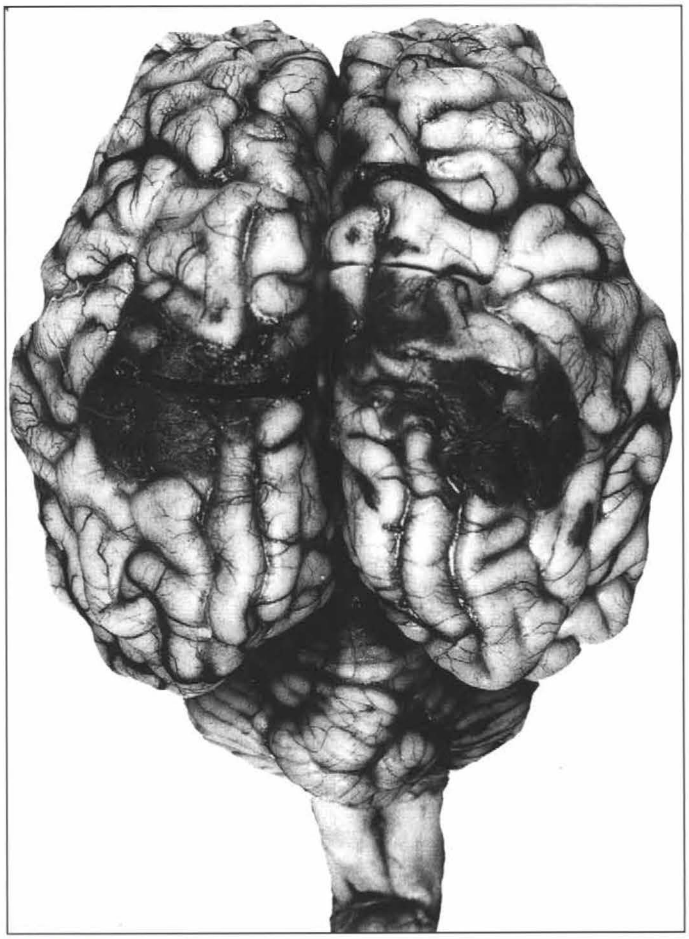

Figure 3.65 Venous infarcts in cortex secondary to thrombosis of sagittal sinus in a calf.

Spontaneous hemorrhages in the brains of animals are almost invariably of petechial or slightly larger size occurring in the hemorrhagic diatheses, especially the symptomatic purpura of septicemic infections (see Vol. 3, Hematopoietic system). Such hemorrhages occur typically from capillaries as well as small venules and are found in meninges and brain. There is no specificity in the geographic distribution of purpuric hemorrhages except in infectious canine hepatitis in which intracranial hemorrhage, although not consistently present, has a predilection for the midbrain and medulla. In "focal symmetrical encephalomalacia" (see Vol. 2, Alimentary system) the lesions are grossly visible only when hemorrhagic; they are regularly bilateral and symmetrical and have a rather specific pattern in which the internal capsules, dorsolateral thalamus, cerebral aqueduct, and pons may all be involved. Hemorrhages also characterize thiamine deficiency in dogs and cats and have a specific distribution and symmetry, being regularly present in the inferior colliculi and less consistently present in the mammillary bodies and other periventricular nuclei.

Isolated hemorrhages or hematomas are quite rare in animals. The hemorrhages may extend to the ventricles and induce hydrocephalus, or involve the central canal of the cord to produce hematomyelia.

Meningeal hemorrhages, both epidural and subdural, are common in lambs and calves that have required obstetric assistance and probably reflect hemodynamic disturbances in dystocia. Hemorrhages of similar distribution occur in calves born unassisted from cows exposed to the coumarins of moldy sweet clover.

Microcirculatory lesions

A range of changes affecting the microcirculation in the nervous system may not produce ischemia or hemorrhage. They are associated with extravasation of formed or fluid elements, are not disease-specific in their character although their distribution may be specific, and result from degenerative changes especially in capillaries and venules. Sludging of leukocytes is frequently observed in venules of cerebral and cerebellar hemispheres in diseases causing leukocytosis, including a range of infectious diseases with neutrophil leukocytosis and the rather rare endotheliotropic lymphoma. Sludging of white cells is frequent in East Coast fever caused by *Theileria parva*, and sludging of red cells infected by *Babesia bovis* and possibly other protozoa; the pathogenesis of sludging may not be the same as for falciform malaria in which adhesion seems to be important in pathogenesis. Viral infections, such as classical swine fever and canine adenovirus, are frequent causes of capillary hemorrhage.

Diapedesis of red cells is a common event in sudden death of many causes and is frequently mimicked in postmortem trauma. The interval between diapedesis and death may be too short for reactive changes, visible by light microscopy, to develop in the vessels. With some delay, swelling of endothelial cells and their nuclei develops. The hemorrhages may be from arterioles, with the red cells remaining in the perivascular space. Diapedesis from capillaries and small venules depends on disruption of endothelium and astrocytic processes and, depending on relative pressures, the red cells may spread in the intercellular spaces.

Diapedesis of red cells occurs in periventricular nuclei in thiamine-deficiency encephalopathy, and in the brain stem in concussion, contrecoup injury, and in hypomagnesemia in sheep and cattle (Fig. 3.66). The white matter of the cerebral and cerebellar hemispheres is susceptible to diapedesis. The hemorrhages are sometimes large enough to be visible as petechiae in diverse conditions including infectious purpuras, anoxia, fat and other microembolism, in diseases associated with erythrocyte sludging, and in disseminated intravascular coagulation.

Leakage of plasma, usually from small venules, may occur in any part of the CNS. It is seen most frequently surrounding areas of traumatic injury or in the conditions noted above that lead to erythrocyte diapedesis. The plasma will contain some fibrinogen, and polymerized fibrin in its usual form may be demonstrated around the vessels. It is more usual, however, for the fibrin to be in its unpolymerized or molecular form, and the plasma both within and outside the vessels to be transformed into a homogeneous gel that stains brightly by the PAS technique. The plasma gel may appear as capillary plugs or as perivascular droplets that appear to incite very little reaction.

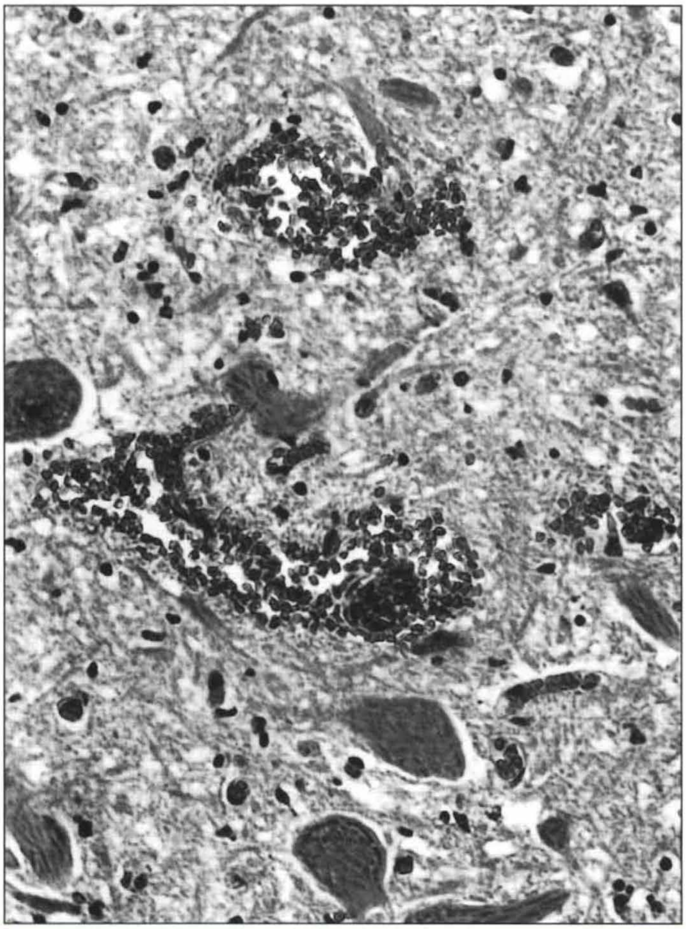

Figure 3.66 Perivascular hemorrhage in a cow with hypomagnesemia.

Vascular injury that allows diapedesis of plasma will also allow passage of serum or protein filtrate (Fig. 3.67). In fields of injury, the differences in levels of permeability change may be evident from the protein content of transudate. While plasma will routinely stain because of its fibrinogen content, the amount of protein in serum may be too low for preservation and staining (see Fig. 3.50). The perivascular changes occur especially about capillaries and venules in the white matter and have the characteristics described earlier for vasogenic edema. Prolonged survival or recovery may leave *focal glial scars* as residue (see Fig. 3.15).

TRAUMATIC INJURIES

Trauma to the head and vertebral column are of importance because of the effects that such injuries have on the contained brain and spinal cord. Both the brain and spinal cord are well protected from external injurious forces by the bony encasements. The more or less rounded shape of the skull favors glancing blows and the lateral diffusion of lines of force; the diploe and sutures are capable of absorbing considerable amounts of shock; and the internal system of bony ridges directs lines of force to the base of the skull. The spinal column is well protected by the surrounding soft tissues, by its own highly cancellous structure, system of ligaments, and intervertebral disks. The nature of acquired injuries is quite varied and is determined by many factors including: the relative vulnerability of the soft tissues, the direction in which the injurious force is applied, the physical rigidity of the bones, the ability of the part to move in response to the applied force, and the mass and velocity of the force.

Concussion

Concussion is a transient loss of consciousness and reflex activity following a sudden injury to the head. Full recovery is expected, and it is assumed that in mild cases there is no morphological injury. In experimental animals, however, degenerative changes are found in the nuclear masses of the brain stem, and these are probably responsible for the clinical features. Following single injuries, chromatolysis develops in many of the larger neurons of the brain stem, and in a proportion of affected cells the degeneration is progressive. With repeated episodes of concussion, affected neurons have a wider distribution that includes the cerebral cortex, and the proportion of cells irreversibly injured is increased. These changes in the brain stem and reticular formation occur if the impact forces are substantial and the brain is subject to rapid acceleration/deceleration; in these cases direct injury in the hemispheres is to be expected. The mildest degrees of concussion produce no visible structural damage when examined with the light microscope, but there is some experimental evidence that plasma substances including proteins may be transported in vesicles through the endothelial cells, and the brain and cord may lose their capacity for autoregulation of blood flow in local areas of static injury.

While the dynamics of the disturbances in neurons that are responsible for the concussion are unclear, some of the physical qualities of the reaction between the head and the applied force have been elucidated. The vibrations that travel back and forth in the brain from the point of impact appear not to be important. If the head is firmly immobilized, quite a considerable force may be suddenly applied to it with relatively minor effect, the force of the blow (**coup**) being absorbed by the skull. Force of much lesser magnitude will cause concussion if the head is capable of moving in response to the blow. The principle to be obtained from these observations is that *a degree of acceleration or deceleration is necessary to produce concussion,* neural injury being due to displacement of the cranium relative to its contents. The brain of an adult animal is normally a little smaller than the cranial cavity and being suspended in the cavity, is capable of slight independent movement. If the head is freely movable and struck a heavy blow, it moves away from the point of impact and collides at the area of impact (coup) with the brain that is momentarily static. As the brain moves suddenly within the skull toward the point of impact, leptomeningeal blood vessels may be torn as the brain pulls away from the skull (**contrecoup**), and *the contrecoup injury may be greater than the coup injury*. In young animals, the brain closely fits the cranial cavity, so relative displacement of the whole brain is expected to be minimal. However, the brain is plastic, so sudden acceleration or deceleration leads to internal deformation. Displacements and transient deformations of the brain result in neuronal changes and unconsciousness probably through the effect of shearing strains on neurons, axons, dendrites, synapses, and blood vessels, as well as direct pressure effects when the brain is displaced across bony ridges.

Contusion

In contusion, the architecture of the nervous tissue is retained but there is hemorrhage into the meninges and about the blood vessels in the parenchyma. Contusions may be diffuse or focal injuries, although often those coexist.

The pathogenetic factors in diffuse contusions are generally the same as those operating in causing concussion, but the applied force, the displacements, and the induced shearing and direct forces are all of greater magnitude. Typically in diffuse injuries, *some of the most severe hemorrhages occur on the surface of the brain opposite the point of impact*. Hemorrhages of this distribution are known as *contrecoup*, and their development depends on the sudden movement of the brain to the point of impact (*coup*) with tension and tearing of pial and cortical vessels opposite the point of impact, and with direct or rotational displacement of brain over bony prominences, where the vessels become exposed to tensile and shear forces.

Focal contused injuries develop typically at the point of impact, and the mechanism of development is somewhat different from that of the diffuse injuries. In focal injuries, movement of the head is not sufficient to cause significant displacement of the brain. Instead, the applied force, usually with relatively high velocity and relatively low mass, causes fracture or deformation of the skull at the point of impact. The deformation of the skull may only be transient but sufficient to cause bruising of the tissue immediately beneath.

Laceration

Laceration is a traumatic injury in which there is disruption of the architecture of the tissue. The mechanics of lacerations are in general the same as those of contusion. Penetrating injuries are analogous to, but more severe than, those that result in focal contusions. Lacerations may also occur with blunt injuries of the type that cause displacement of the brain. In such cases, contrecoup lacerations occur typically on the surfaces of gyri where these are displaced over bony prominences. Shear forces developed during deformation or molding of the brain may be adequate to cause deep hemorrhages and even the cleavage of the gray from the white matter over small areas of the cortex.

Lacerations caused by penetrating injuries are always liable to *secondary infections*, especially when fragments of skin and soft tissue and spicules of bone from the internal plates are displaced into the brain. In the absence of infection, repair takes place in the manner that is usual for defects of nervous tissue. The detritus of blood and nervous tissue is removed by microglia and meningothelial macrophages. If the defect is small, an astrocytic scar forms, but usually a cyst remains, lined by proliferated astrocytes. Adhesions between the glial tissue and pia mater produce meningocerebral scars that are notably epileptogenic.

Fracture of the skull

Fractures of the skull can be important in terms of the concurrent injuries to the underlying meninges and brain and because they can provide a pathway of infection to the sinuses, meninges, and brain. They are indicative of injuries produced by considerable force and, when the inner plates are fractured, of contusion or laceration of the underlying brain. Fractures of the base of the skull may involve the middle ear and allow the escape of cerebrospinal fluid and the entrance of infection. Frontal fractures involving the cribriform plate may allow cerebrospinal fluid to escape into the nasal cavity.

Fractures of the skull are usually quite easy to detect by virtue of the displacement of bone and meningeal hemorrhage. Some, however, may be difficult to detect. This applies especially to fissures that develop during transient deformation of the skull and to impacted basilar fractures, such as occur in horses that rear backward and strike the nape of the neck and occiput. With these fractures, hemorrhages may be scant and basilar fractures are revealed only when the dura is carefully dissected away.

Injuries to the spinal cord

It is possible for direct injuries to the spinal cord to occur without obvious injury to the vertebrae. Such spinal injuries are necessarily lacerations caused by penetrating foreign bodies. Wandering parasites as causes of traumatic injury are discussed later. Much more common are indirect injuries to the cord acquired in the course of vertebral luxations or fractures with dislocation. *The most common of indirect injuries to the cord are produced by extruded nucleus pulposus in dogs, and by compression of the cervical cord in the syndrome known as "wobbler"* (see Vol. 1, Bones and joints).

Vertebral subluxations are the result of trauma, but *fracture dislocation* may be pathological as well as traumatic, and frequently is in swine and ruminants when the fracture occurs through an area of vertebral osteomyelitis or osteochondrosis. The injuries to the cord occur chiefly at the time of accident and are due mainly to the stresses to which the cord is subjected and partly to impediment to the blood supply. Cumulative injury may occur, especially in dislocations when continued pressure on the cord or stretching of the cord over bony prominences causes intermittent ischemia.

Subluxations are largely restricted to the cervical column, where there is relative mobility of the ligaments. In the thoracic and lumbar spine, comparable forces are more likely to cause fracture because of the brevity of the ligaments. The fractures may involve only a lamina, the odontoid process, or an articular process, and therefore be difficult to detect. *Fracture dislocations of the vertebral column occur chiefly in the caudal cervical region and about the thoracolumbar junction*. Most injurious are those fractures that involve the vertebral body because there is usually displacement of a fragment caudodorsally into the spinal canal. Both in luxation and fracture displacement, pressure may be exerted over several segments of cord by epidural and endodural blood clots (Fig 3.68).

Traumatic injuries to the spinal cord may be slight enough to be satisfactorily recoverable, or they may, at the other extreme, cause transection and an extensive length of necrosis. Early contused

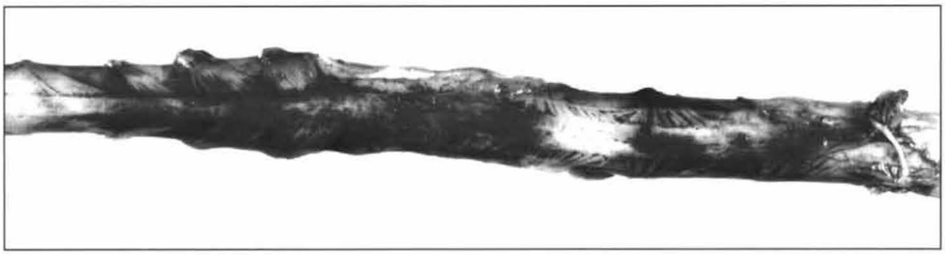

Figure 3.68 Extensive **subdural hemorrhage** of the spinal cord in a dog, caused by physical trauma. (Courtesy of RF Slocombe.)

lesions cause swelling of the cord over one or two vertebral segments. The swelling may be easier to palpate by gently stroking the cord than to appreciate by inspection. Later, the cord is shrunken at the level of injury, and this also may be best detected by palpation. In the swollen zone, dark points of hemorrhage may be detected on section, and these occur usually in the central gray matter and at its junction with the white. If the demarcation of gray from white matter is obscured, it can be expected that softening of some degree is present. Cores of softening may be recognizable grossly, and the fact that they are extending up and down the cord from the point of injury is explained as tracking of exudate, especially serum or edema fluid, along the fiber tracts and the path of least resistance since, because the meninges are usually intact, the amount of local swelling is limited.

With severe compression, the cord may be entirely necrotic at the point of injury and over several segments. *Necrosis is probably due to vascular injury*, and, for the same reason, isolated segments of necrosis may occur apart from the main injury. When the cord is necrotic, it is initially swollen, but after a lapse of some weeks the dura forms a narrowed, collapsible tube containing debris.

Microscopically, in the mildest injuries there is swelling of axons and myelin sheaths. The injured axons become beaded, but they are possibly not irreversibly injured unless fragmentation follows the beading, because functional recovery can follow minor and transient paralytic injuries. Where the axons are severed, there is bulbous swelling of the retracted ends. Degenerative neuronal changes consisting of the clumping of Nissl substance and central chromatolysis are constantly present. Ultimately, there is some loss of neurons. When softening occurs, the sequence of changes is the same as occurs in any neural lesion with loss of substance. The hemorrhage is usually slight and perivascular, but it may enter the central canal and pass along it for a considerable distance.

In long-standing spinal injuries, adhesions may be found between the meninges and between the dura mater and periosteum. In the injured zone of cord, there may be loss of fibers and myelin sheaths with astrogliosis or, in the more severe injuries with loss of substance, there may be cysts, pial-glial or collagenous scars, or the cord may be converted to a thin sclerotic band.

DEGENERATION IN THE NERVOUS SYSTEM

Foregoing sections dealing with cytopathology and the effects of circulatory disturbances and trauma are discussions of changes that are largely degenerative. The same will be true of many sections in later parts of this chapter because neural injury, regardless of cause or severity, is characterized chiefly by degeneration. Discussed in this section are those lesions and diseases of the CNS that are expressed as degenerations of nervous tissue.

Meninges

Age changes in the meninges may advance to such a degree as to be pathological. *Collagenous and osseous metaplasia* occurs commonly in the cranial dura mater of dogs and cats. The process begins in the frontal region and extends to the temporal and occipital areas. The plaque-like thickenings of the surface meninges tend not to extend to the basal or cerebellar meninges. Ossification, which is detectable as small intradural plaques, follows hyalinization of the connective tissues and may or may not be preceded by mineralization. The dura adheres firmly to the periosteum. Perhaps by an independent process, *spherical mineralized nodules* form in the basal dura beneath the medulla in some aging dogs. Histologically, these nodules show a whorled pattern of fibroblastic cells often enclosing small concretions known as **psammoma bodies**.

Hyalinization of dural collagen occurs also in the spinal dura mater with aging and may be preliminary to the osseous metaplasia of the dura observed frequently in large breeds of dogs. The latter condition is referred to as **ossifying pachymeningitis** but, in spite of the frequency of the dural change, little is known of its pathogenesis or effects. *Dural ossification* is found in older age groups of some large breeds and varies in its expression from multiple separate plaques to rigid ossification over several segments of the cord. The changes are best developed in the lumbar region but may involve much of the spinal dura. The basic change appears to be degenerative and metaplastic rather than inflammatory. Locomotor dysfunction in affected animals is more likely to be attributable to concurrent spondylosis and degenerative/reactive changes in joints. The plaques consist of lamellar bone that is mature in appearance and that from the earliest stages contains cancellous spaces and active bone marrow.

Degenerative changes in leptomeninges are less well identified than those in the dura and are limited to collagenization and hyalinization. They are not functionally significant, but the opacities produced, especially the focal thickening in arachnoid granulations in old animals, can be misinterpreted as inflammatory change.

Choroid plexuses

With advancing age, there is *hyaline degeneration of the connective tissues of the choroid plexuses*, especially those of the lateral ventricles (Fig. 3.69). The basement membranes of the capillaries are also involved. The hyaline tissues may become mineralized.

Cholesteatosis of the choroid plexuses in the form of tumor-like nodules, usually termed *cholesteatomas* or *cholesterol granulomas*, occurs in 15–20% of old horses. They are more frequent in the plexuses of the fourth ventricle than in the lateral ventricles, but those in the lateral ventricles are the more important because they may attain large size and, by obstructing the interventricular foramen,

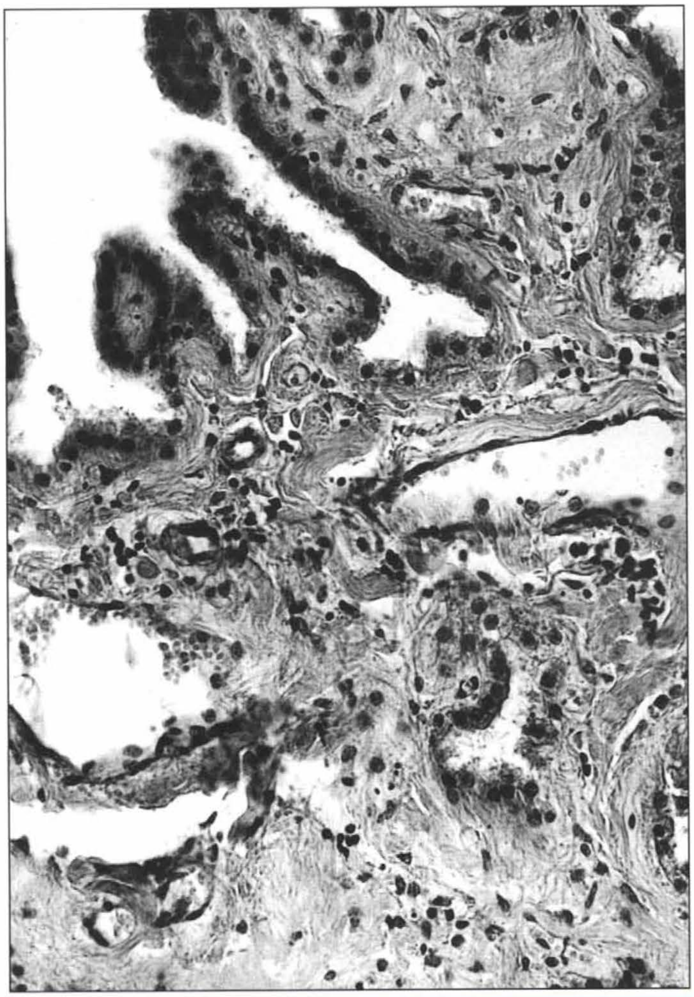

Figure 3.69 **Senile hyalinization** in the choroid plexus of a horse.

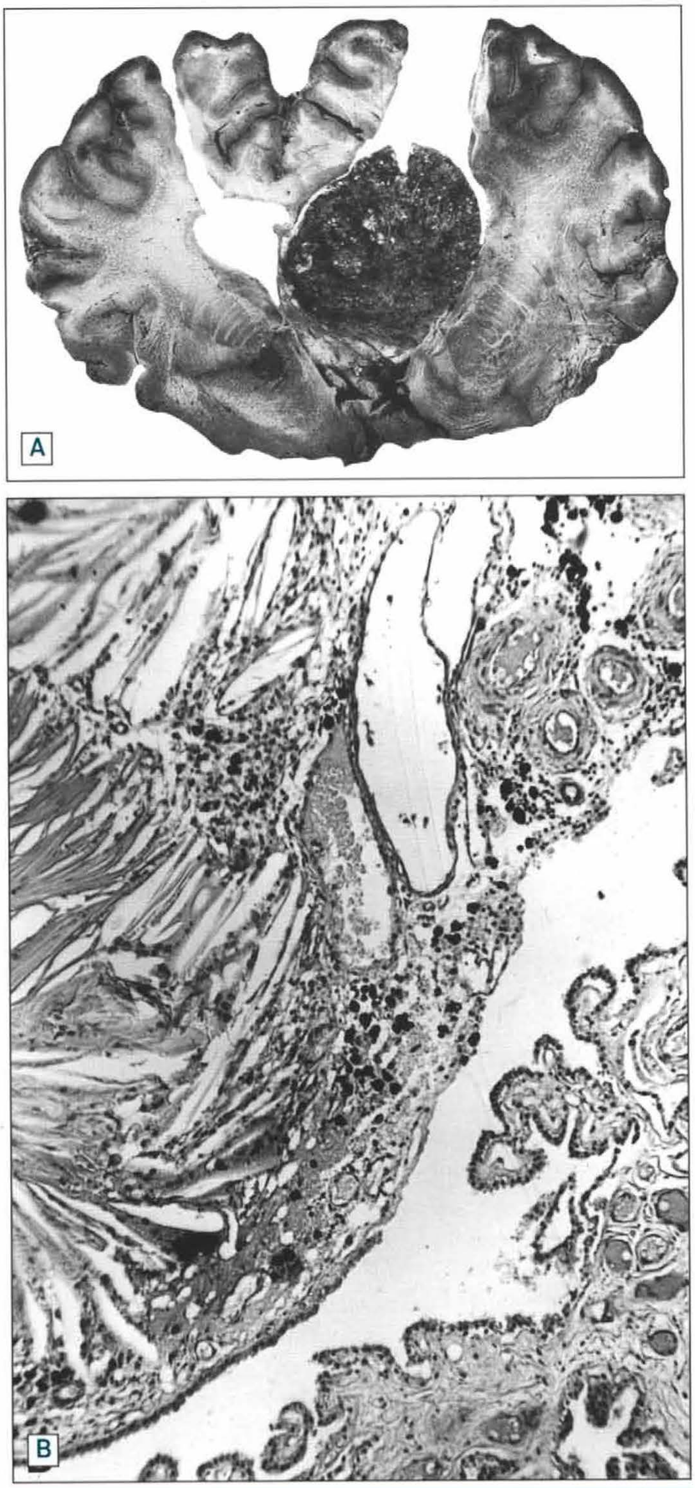

Figure 3.70 **A. Cholesterol granuloma** in the choroid plexus of the right lateral ventricle of a horse. (Courtesy of P Olafson.) **B. Cholesterol granuloma** in the choroid plexus of a horse.

cause hydrocephalus leading to dilation and pressure atrophy of the walls of the ventricles (Fig. 3.70A).

The development of cholesteatosis appears to be related in some manner to chronic or intermittent congestion and edema with congestive hemorrhages in the choroid plexuses. During an edematous episode, the plexuses are slightly swollen, yellow, and soft. The interstitial tissues are edematous and infiltrated lightly by macrophages containing lipid and hemosiderin. The crystals of cholesterol are deposited in the tissue spaces and apparently act as foreign bodies to stimulate low-grade productive inflammation (Fig. 3.70B).

The affected plexus is swollen, and small areas or the whole of it may be occupied by the cholesterol granulomas. These are firm but crumbly, gray nodules with a gleaming, pearly appearance on cut surface. The crystals can be expressed from the cut surface by slight pressure.

Atrophy in the brain and spinal cord

The most spectacular atrophy of the cerebrum occurs in cases of congenital lipofuscinosis and of progressive internal hydrocephalus. **Senile atrophy** of the brain and cord is frequently obvious but seldom severe in animals. The atrophy is most marked when it is associated with the combined influences of senility and marasmus, and it occurs more frequently in sheep than in other species. The pachymeninges are thickened and those of the cranium are partially adherent to the periosteum. The leptomeninges are thickened, tough, and granular. The brain is reduced in volume and weight and may be discolored a darker gray-yellow. The convolutions are narrowed and wrinkled and the sulci are shallow and widened. Both brain and cord are much firmer than is normal. The ventricles are moderately dilated. Histologically, the neurons, especially of the cortex, are shrunken, distorted, and dark staining and their numbers are depleted. The amount of Nissl substance is reduced and the neuronal nuclei stain diffusely. Lipochromes are increased in amount and satellitosis is prominent; macrophages laden with lipochrome are present in the perivascular spaces. There is a diffuse increase in glial fibers, which is responsible for the increased firmness of the tissue. The gliosis is most prominent about Virchow–Robin spaces, and there is a general tendency for protoplasmic astrocytes to transform into fibrous ones. The Virchow–Robin spaces are dilated, and some may be visible to the naked eye. The media of the vessels contain increased amounts of collagen.

Focal atrophy of the brain and cord is the result of slight but long-continued pressure. The loss of function is often disproportionately large as the result of acute pressure lesions compared with the extent of pathologic change. The reverse is often true in chronic pressure, and function may be retained to a surprising degree. Hydrocephalus is common as a cause of chronic pressure, and other sources of pressure are space-occupying lesions of the meninges or bony vault.

The pathogenesis of the changes produced by chronic pressure is unclarified. Because the immediate effects of pressure are more likely to be felt by veins than by arteries or solid tissue, the atrophic changes are usually attributed to venous stasis and edema. More acute pressure effects grade into circumstances and consequences discussed under trauma. Whatever the mechanism, myelin is the most vulnerable component of the tissue and undergoes slow progressive degeneration. There is also slow progressive atrophy and loss of neurons, especially of the Purkinje cells when pressure is exerted on the cerebellum, the neurons of the deeper laminae when pressure is exerted on the cerebrum, and of the ventral horn cells in the spinal cord. The degenerating myelin is replaced by glial fibers.

Segmental cerebellar atrophy is common in pigs following a variety of nervous diseases. The rostral vermis and adjacent portions of the lateral lobes are affected, these being within the distribution of the rostral cerebellar artery. There is no acute change but, instead, a gradual loss of granule and Purkinje cells with secondary changes in the white matter and reactive gliosis. The lesion is asymptomatic.

Anoxia and anoxic poisons

The neuropathological effects of anoxia are seldom observed in animals or perhaps seldom looked for. Since most cases die acutely, there may be very little to see. The pathological effects of anoxia, not only in the CNS, but in general, are expressions of "vulnerability," a property which differs from organ to organ and between parts and cells of one organ. *The components of the nervous system are vulnerable in a rather fixed order,* which is neuron, oligodendroglia, astroglia, microglia, and blood vessels in that diminishing order of sensitivity. The neurons are not a uniform population, and there are regional differences in their susceptibility to anoxia, those of the cerebral cortex and the Purkinje cells being the most sensitive. Within the cerebral cortex, the neurons of the deeper laminae are more sensitive than those in the superficial laminae. Beneath these levels, there is a gradient of susceptibility through the geniculate bodies, hypothalamus, thalamus, paleocortex, and caudate nucleus. The various patterns of vulnerability are relative; they are established largely by experiments in animals and are subject to some variation depending in part on the experimental species and on the type of anoxia induced. They do nevertheless emphasize the problem of selective vulnerability at the cellular level. There are, in addition, broader regional differences in vulnerability to anoxia such as those that allow parts of the cerebral cortex to be necrotic while adjacent parts survive intact and that allow the same agent or anoxic insult to cause, leukomalacia on some occasions, and poliomalacia on other occasions. The basis of these regional differences in vulnerability, and the apparent differences in the patterns of degeneration following different types of anoxia, is still to be established.

The pathological effects of anoxia on nervous tissue are of two types, which are to some extent differences in degree. The least clear morphological expression is *selective neuronal necrosis*. The neuronal necrosis is typically of the ischemic type, and it is followed by glial repair. Greater degrees of anoxia, sufficient to kill astroglia as well as neurons, result in *softening*. These are the expected changes in anoxic anoxias such as might occur with cardiac arrest or periods of apnea in grand mal epilepsy.

As a response in some episodes of anoxia, such as may be induced, for example, in the histotoxic variety of cyanide poisoning, the degeneration and necrosis may affect the white matter with only minimal changes in the gray. The reason for this is not known. The malacic changes in the white matter of the cerebral hemispheres are preceded by edema, which suggests that local circulatory disturbances contribute to its development. Clearly the attribution of selective vulnerability on the basis of local metabolic demand for oxygen is inadequate, and a fuller explanation will probably require, in addition, consideration of vascular architecture, the autoregulation of blood pressure and flow, and local metabolic factors in the maintenance of myelin and axons.

Cyanide poisoning

The anoxia produced by cyanide is classified as *histotoxic* because the action of the poison is to *inhibit intracellular respiratory enzymes*. The cyanides are particularly rapid in their action, and death usually occurs from a few minutes to an hour after the onset of clinical signs. In the most acute cases, the clinical course occupies only a few minutes and is characterized by dyspnea, drooling, trembling, and recumbency; it terminates in convulsions. The *blood is bright red* owing to its high degree of oxygen saturation. In cases that survive for an hour, the clinical signs are the same with, in addition, vomiting, especially in pigs, nystagmus and cyanosis. In these cases, the blood is often dark owing to anoxemia.

The morbid changes are those associated with anoxia. Because most cases survive for half an hour to one hour, the blood is dark and does not clot and the tissues are dark. There is congestion in the lungs and hemorrhages of dyspneic type in the tracheal mucosa. Ecchymoses of the epicardium are usual. In pigs, there is pulmonary edema and hydropericardium, and there may be capillary hemorrhages deep in the myocardium by the coronary grooves. Severe pulmonary edema is present in some dogs.

Descriptions of lesions in the nervous system of animals in cyanide poisoning are largely limited to experimental observations in dogs and cats. In many natural cases of the poisoning, there is no significant alteration in the brain. The degenerative lesions in the brain in experimental poisoning may involve predominantly the gray matter or the white. When in gray matter, there is patchy necrosis and laminar loss of cells in the cerebral cortex, and necrosis in the head of the caudate nucleus, paleocortex, substantia nigra, and thalamus. There is edema in the cerebral white matter, sometimes in the absence of cortical change. On the other hand, single graded exposures of rats may produce the principal lesions in white matter, especially in the corpus callosum. In this species, there are gradients of injury in the callosum reflecting gradients of susceptibility, the most severe degeneration occurring in the caudal core of the callosum. The gradients are attributed to regional differences of blood supply, which are expected to reinforce the histotoxic anoxia of cytochrome oxidase inhibition by cyanide. The earliest change described in the callosal lesion is axonal swelling producing a spongy appearance by light microscopy; alterations of myelin, and oligodendrocytes are second in time.

Plants containing toxic levels of hydrocyanic acid bound as glucosides are common and widespread and are the usual source of cyanide poisoning. The compounds are in general the β-glycosides of α-hydroxynitriles and are activated by endogenous glucosidases in the plant, or in other plants, or by ruminal microorganisms. For these reasons, cyanide poisoning occurs chiefly in ruminants. Toxin generation of this type does not occur at the low pH of the monogastric stomach, but a lethal amount may be absorbed from the large bowel if there has been a large intake of toxigenic material.

Both sheep and cattle are capable of detoxifying cyanide in the liver to form *thiocyanate*. Thiocyanate itself is toxic but in a manner different from that of cyanide; if thiocyanate is present in low concentrations over prolonged periods, it is goitrogenic. The cyanide concentration in a stated species of plant varies considerably with stage and rate of growth and with the fertility of the soil. Plants that are growing rapidly contain the highest concentrations of the glucosides, especially if the growth phase follows one of retardation caused, for example, by wilting, frostbite, or close grazing. The glucosides are regarded as being metabolic by-products.

Plants of many species contain cyanogenetic glucosides but only a few are important in this regard. The majority of cyanogenetic plants are usually harmless either because of low palatability or low concentration of the glucosides. The important cultivated toxic plants are the sorghums (*Sorghum* spp.), and the star grasses (*Cynodon* spp.). Those of the cherry family are also potently cyanogenetic. Linseed concentrates can be dangerous, especially if eaten in large quantities.

Chronic cyanide intoxication is not recorded, but extended periods of grazing the cyanogenetic sorghum and sudan grass may lead to ataxia in cattle and horses, cystitis and urinary incontinence, and abortion in mares. Attempts to link the clinical syndrome to cyanogenetic compounds in the plants are inconclusive, and a causal association with cyanides seems unlikely. There is axonal degeneration and demyelination at all levels of the cord but most prominent caudally in ventral and lateral funiculi. Ataxic syndromes occur in sheep grazing *Sorghum* sp. may involve large numbers of animals in syndromes that differ from those in horses and cattle. Urinary incontinence does not occur. There is limb paresis with knuckling, incoordination and disturbance of equilibrium, and head and body tremors. Pregnant ewes may produce stillborn, weak, or arthrogrypotic lambs. While the lesions in horses and cattle are of Wallerian type in the spinal cord, those in sheep are of an axonopathy with proximal spheroids in the major nuclei of the brain stem and ventral horns of the cord.

Nitrate/nitrite poisoning

Ruminants are also vulnerable to *phytogenous nitrates*, when intraruminal microbial conversion of nitrates to nitrites exceeds the rate of conversion of the latter to ammonia. The nitrate sources again include many crop plants as well as weeds; plant nitrate concentrations are influenced by soil nitrogen level, and physiologic stresses on the plants, such as water stress and herbicide damage. Occasionally, high nitrate concentration in drinking water is the problem. *Absorbed nitrites convert hemoglobin to methemoglobin*, which imparts a *dark "chocolate" color* to the blood, and causes dyspnea, cyanosis, weakness, tremors, collapse, and coma. There are no gross or histological brain lesions. The condition is discussed more fully in Vol. 3, Hematopoietic system.

Fluoroacetate poisoning

Fluoroacetate is toxic by virtue of its ability to form fluoracetyl-CoA, which potently inhibits the Kreb's cycle enzymes *cis*-aconitase and succinate dehydrogenase, thereby paralyzing cellular respiration. Herbivores are usually poisoned by ingesting *fluoroacetate-containing plants*, while other animals may be affected by accident or design by being exposed to sodium fluoroacetate formulated as a *pesticide*. The clinical signs are of the same general character as those described above but, in the dog, frenzied hyperactivity is reported. As with cyanide, the myocardium is highly vulnerable, and multifocal necrosis may be seen. Fluoroacetate poisoning is discussed in Vol. 3, Cardiovascular system.

Carbon monoxide poisoning

This is rarely observed and is discussed in the interests of completeness. Carbon monoxide has an affinity for hemoglobin which is several hundred times the affinity of oxygen for hemoglobin. The carboxyhemoglobin produced prevents oxygen exchange and causes anoxic anoxia. The anoxia is reinforced by a histotoxic component due to the affinity of carbon monoxide for iron-containing respiratory enzymes.

Carboxyhemoglobin and, therefore, the blood and tissues of poisoned animals are *bright pink*. All organs are congested, but especially the brain, in which the veins and capillaries are much dilated. The dilated vessels are observed especially in the white matter and hemorrhages occur from them. Acute fatalities are not expected to be associated with neural lesions. Survival is expected to be followed by complete recovery, but there may be residual lesions of anoxic type, especially neuronal loss.

Carbon monoxide poisoning is reported occasionally in animals in confined quarters that are heated by petroleum fuels. Most of the reported instances are in pigs, and poisoning is associated with a high level of stillbirth and neonatal mortality. Following experimental exposure, patchy or extensive leukomalacia may be present in the hemispheres in the newborn.

Hypoglycemia

It is useful to extend the classification of anoxia to include hypoglycemia, which causes a *disturbance of intracellular respiration*. Oxygen is available to the nervous tissue, but, in the absence or reduction of the amount of substrate, the oxygen is not utilized.

Hypoglycemia may occur as a result of a functioning *tumor of the pancreatic islets* or as a response to insulin overdosage in the treatment of diabetes. It is also part of the metabolic disturbance of *ketosis in cows* and *pregnancy toxemia in ewes*, and arguments have been advanced for regarding the irreversibility of pregnancy toxemia as being due to hypoglycemic encephalopathy. Piglets in the first week of life readily develop hypoglycemia if there is dietary restriction from any cause. Effective gluconeogenesis does not develop in piglets until about the seventh day of life, and during this first week their glycemic levels are rather precise reflections of dietary intake. In spite of the severe convulsions and deep coma that occur in hypoglycemia, conspicuous changes do not occur in the brain. It is probable that biochemical disturbances in the neurons precede histological signs of degeneration by a considerable period. For this reason, acute hypoglycemic death is not expected to produce cerebral lesions. When the period of coma is prolonged, it is probable that all neurons are to some extent altered, but the differentiation of hypoglycemic from autolytic and nonspecific changes can seldom be made with confidence. Although classified with the anoxias, hypoglycemia does not produce the ischemic type of neuronal degeneration characteristic of the usual sorts of anoxia. There is, instead, a tendency for the severe type of neuronal degeneration to occur, characterized by rapid and complete chromatolysis, disappearance of the cytoplasmic margins, and then fading of the cytoplasm, with pyknosis, eccentricity and fading of the nucleus. The regional susceptibility of neurons to hypoglycemia, exclusive of the Purkinje cells, parallels that of susceptibility to anoxia.

Malacia and malacic diseases

Necrosis of individual elements of nervous tissue is described earlier under Cytopathology. **Encephalomalacia** and **myelomalacia** refer to necrosis in the brain and cord respectively. *Malacia means softening*, and is used interchangeably with that term to signify necrosis of tissue in the CNS. It is sometimes, as imprecise practice, used interchangeably with demyelination. There is no sharp line to be drawn between demyelination and malacia, especially in the early stages of development of the degenerative process, but the term demyelination should probably be restricted to those lesions in which the myelin sheath is primarily or selectively injured to leave the axons naked but intact. When neurons and neuroglia degenerate and die as part of the primary response, the term malacia is applicable.

The *sequence of events* in softening or malacia is specific only for the tissue. The morphological changes in necrosis, in the removal of dead tissue, and in healing are the same regardless of the insult. The insults can be varied, and *malacia, alone or as part of another change, is one of the most common lesions in the brain and cord*. It is discussed in the sections dealing with vascular accidents and trauma, it occurs in many instances of encephalomyelitis, is discussed elsewhere in these volumes as a lesion of mulberry heart disease, of antenatal *bluetongue virus* infections in lambs, and of clostridial enterotoxemia in lambs that escape apoplectic death and live for some days. Malacic lesions are probably the basis of most cases of hydranencephaly.

Although the nature of the malacic process is not specific for cause, there is some specificity in the localization of lesions and in their particular pattern of distribution. These features may allow the recognition of known associations or causes, such as the nigropallidal distribution of lesions in horses poisoned by yellow star thistle, and the focal symmetrical lesions of the internal capsule in lambs with clostridial enterotoxemia. Although these and some other associations have been determined, the pathogenesis of the lesions and the problems of selective injury to certain parts of the brain remain to be resolved.

The sequence of changes in malacic foci is approximately the same in all cases and is outlined below. The rapidity of change is quite variable and depends on the species and age of the animal, the location of the necrosis, the volume of tissue affected, and the inciting cause. The speed of resolution is also affected by the quality of vascular perfusion in adjacent nervous tissue, whether the necrosis is ischemic or hemorrhagic and on the time over which the cause acts.

The malacic process, once initiated, appears to proceed very rapidly in the fetal and immature nervous system, and to leave cystic structures and hydranencephaly without much evidence of continuing reaction at the time these animals are available for necropsy examination (see Fig. 3.27). The reasons for the rapidity of change in immature nervous tissue are not clear, but contributing factors may involve the paucity of myelin that is difficult to remove, the paucity of mature mesenchyme in meninges and about vessels, and the plasticity of vascular arrangements in the developing brain. The rapidity of change in gray matter is generally greater than in the white. Autolytic liquefactive changes depend on continued enzymatic activity that, in turn, depends on availability of oxygen either by diffusion from surrounding tissue or by reflow in the local vessels. Small foci of necrosis are expected to resolve more quickly than large. Malacic lesions in the neocortex where diffusion from collateral vessels is available are expected to resolve more rapidly than those in the paleocortex where the vascular supply is more strictly of the end-artery type. Some causes of malacia, such as vascular occlusion, act promptly and the pathological changes are directly consequential. The cause may act continuously over a period, as in leukoencephalomalacia of horses, and the changes may be incremental. The process, once established, may itself initiate progressive change as in traumatic injury to the cord in which swelling within the confines of the meninges assists the spread of edema and vascular response beyond the site of the original injury.

A malacic lesion that develops acutely may not, in the absence of hemorrhage, be demonstrable before about the twelfth hour of onset. The early change is in texture, with the affected part being soft, and in color, with the affected part being gray. Within 2–3 days, the malacic foci begin to disintegrate, the softness is more evident, and the surrounding tissue is swollen by edema, and pale in gray matter or yellow in white matter. Subject to the above qualifications, *the necrotic area eventually liquefies and a cyst remains.* The cyst may be loculated or traversed by vascular strands that have survived the episode.

Histologically there is, in acute episodes, reduced staining affinity by about 12 hours. The cellular elements show the changes described earlier. The early active response involves circulating neutrophils, which may enter in large numbers, but this response is replaced in 3–4 days by macrophages. The first appearance of macrophages is about blood vessels, their peak activity occurs in about 2 weeks, but a few will survive for a very long time. Astrocytic gliosis replaces or surrounds the resolved necrotic area (see Fig. 3.61).

In the specific syndromes to be discussed below, the degenerative changes tend to be restricted to, or to affect principally, either the gray matter or the white matter. Softening of gray matter is known as **poliomalacia** and softening of white matter is known as **leukomalacia**; each may be qualified as to whether cerebral (encephalo-) or spinal (myelo-). The diseases to be described below are specific, but malacia is not exclusive to them. Necrosis of cerebral cortex, is rare in horses except in the neonatal "barker syndrome" (see Fig. 3.54). In ruminants, poliomalacia is, in the early stages, expected to respond to thiamine, but it also occurs in lead poisoning, in water intoxication, and in other, ill-defined, circumstances. Lead also causes poliomalacia in dogs. Convulsive episodes in dogs, some associated with distemper, may leave malacic changes especially in parietal and temporal cortex. Idiopathic necrosis and malacia of the hippocampus and piriform lobe in cats is reported from Europe as a cause of seizures. Metronidazole intoxication of dogs and cats can result in brain stem leukomalacia. In pigs, polioencephalomalacia is usually due to salt poisoning, but individual cases occur in meningitis or without other association. The isolated case of malacia can be difficult to explain.

Focal symmetrical poliomyelomalacia syndromes

This disease, as described from Kenyan **sheep**, is characterized by focal softening of the gray matter of the spinal cord, most consistent and severe in the cervical enlargement. A similar syndrome occurs in parts of West Africa. There is no information on the cause or pathogenesis, although the distribution of necrosis in relation to the cross-section of the cord and the irregular segmental involvement of the gray matter, especially in the cervical region, are consistent with a *vascular component* in the pathogenesis. Lesions of similar distribution and character are occasionally met with in dogs and cats with inflammatory or thrombotic occlusion of the ventral spinal artery. Affected sheep suddenly develop flaccid or spastic paresis that always involves the forelimbs and sometimes the hindlimbs as well. There are no cerebral signs. Affected animals are lambs or up to 18 months old. There are no gross lesions to be observed except in cases of long standing, in which some brown discoloration may be noted in the malacic areas. Microscopically, there are bilateral lesions of remarkable symmetry in the ventral horns of the spinal cord. The dorsal horns are spared, as is a narrow rim of gray substance around the periphery of the ventral horns, and the commissural gray matter. The affected areas undergo dissolution with the usual reaction on the part of the microglia. At a later stage, proliferating capillaries in small numbers criss-cross the microcavitations, and the astrocytes at the margins proliferate. The malacic foci are found in the cervical and lumbar enlargements as "skip" lesions involving a few segments and, when the necrosis is extensive, similar foci may be found in the medulla.

A similar syndrome has been responsible for heavy losses in native sheep in Ghana and Ivory Coast. All ages are affected but mainly adult ewes. Clinical progression is rapid, from initial stumbling to ataxia and recumbency, opisthotonos and nystagmus and ultimately flaccid paralysis. There are microscopic changes of cytotoxic edema, especially affecting oligodendrocytes widely in the nervous system and also perivascular astrocytes and capsule cells of spinal ganglia. Foci of spongy degeneration and malacia, bilateral but not always symmetrical, are of patchy distribution and most frequent in the spinal intumescence, cerebellar roof nuclei, and large nuclei of the brain stem.

Encephalomyelomalacia of similar character is reported in young individual **goats** in California. The lesions are bilaterally symmetrical and affect particularly the lumbar and cervical enlargements and the inferior colliculi. Other brain stem nuclei are inconsistently involved. The similarity of these malacic lesions to those which can be produced experimentally by nicotinamide antagonists has been noted.

Focal symmetrical poliomyelomalacia of pigs is clinically and pathologically similar to the spontaneous poliomalacias of sheep and goats. The presenting signs are spinal with ataxia progressing to forelimb or hindlimb paresis or quadriplegia in a few days. In field cases, malacic foci are found, symmetrically in the ventral horns of the cervical and lumbar enlargements. The malacic foci are visible grossly as yellow-brown areas of softening or gray depressed areas of liquefaction. The histologic changes are typical of malacia (Fig. 3.71). There is heavy loss of neurons, and endothelial and glial proliferation in older lesions. Similar changes may be present in medullary nuclei.

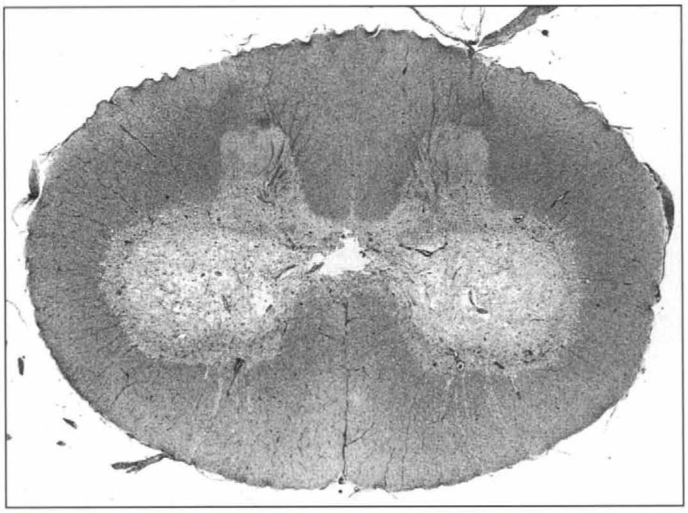

Figure 3.71 Focal symmetrical poliomyelomalacia involving ventral horns of cervical cord in a pig with selenium toxicity. (Courtesy of TM Wilson.)

Affected animals may show changes associated with *selenium toxicoses*, including scurfiness of skin, hair loss and separation of horn at the coronet. Dietary selenium, whether as sodium selenite added to rations or the feeding of selenium-accumulator plants, reproduces the syndrome, although there is some inconsistency in the lesions produced, with degeneration being more frequent in the nuclear masses of the medulla and brain stem. *Astragalus bisulcatus*, a selenium-accumulator plant, will cause concurrent polioencephalomalacia. The mechanism of neurotoxicity of selenium is obscure, but may occur through the generation of reactive oxygen species during reaction of thiols, and is expected to be influenced by other nutritional and metabolic interactions.

Focal symmetrical poliomyelomalacia, the lesion limited to the sacral and lumbar enlargements, is described in **Ayrshire calves**. The malacia affects the ventral horns, sparing the dorsal horns and the central gray matter. The cause is not known.

Aeschynomene indica is a common weed in irrigated rice fields and may be fed with rice and screenings of broken rice. Signs of neurologic disorder develop in a few days. Lesions are restricted to the brain, are symmetrical, involve especially the vestibular and cerebellar roof nuclei, nuclei of the midbrain, and the paleocortex. The toxic factor is unknown, but pathogenesis may depend on primary damage to microvasculature.

Polioencephalomalacia of ruminants

Polioencephalomalacia (PEM) as used in practice applies especially to softenings restricted to the cerebrocortical gray matter of laminar distribution. The lesion may alternatively be designated as "cerebrocortical necrosis" or "laminar cortical necrosis." Necrosis of this distribution is the basis of the well-recognized syndrome of cattle, sheep, and goats known as PEM. It is also the lesion of salt poisoning in swine, is occasionally observed in lead poisoning of cattle, and is described among the residual neurologic lesions of cyanide poisoning. Apart from these known associations or causes, laminar cortical necrosis is observed sporadically in swine, dogs, and cats.

The disease, PEM of sheep, goats, and cattle and other managed ruminants, is similar in its clinical and pathologic aspects in the several species, but the course in sheep and goats is, as a rule, shorter, with fewer survivors from the stage of overt brain swelling. Merino sheep appear to be much more resistant than other breeds.

The incidence is highest in sheep in the age group from weaning to 18 months, but sporadic cases occur in older animals. This general statement of incidence applies to pastured animals as well as to those in feedlots or barns. It is a disease of young cattle, the age incidence depending on the population exposure. As originally described in Colorado, affected animals are mainly 1–2 years of age but, elsewhere, the incidence is highest in younger stock of 3–8 months of age. The severity of the disease is rather less in pastured than in feedlot or housed cattle and sheep. Its least clinical expression, occasionally observed in outbreaks in sheep, is blindness and dullness, a tendency to head press against obstacles, and cessation of feeding. There are no ocular abnormalities in this, or in any other, grade of the disease, and the blindness is cortical. Animals showing these mild signs usually recover completely in the course of several days. If they are killed for examination, malacic changes may be found to be minimal or absent but there is widespread neuronal necrosis of ischemic type in the deeper laminae of the cerebral cortex. Animals affected more severely may remain on their feet and show, in addition to the above signs, muscular tremors especially of the head, and intermittent opisthotonos; if they survive, they become partially decorticate and remain blind and stupid.

In severe cases of PEM, the animals are recumbent. There is twitching of the face, ears, and eyelids, intermittent grinding of teeth, drooling, and bulbar paralysis in some. Opisthotonos is present and some animals are convulsive. In the early stages, the neurologic signs are intermittent, but later they become more constant with persistent opisthotonos and nystagmus. Flaccidity is usual, although there may be transient periods of spasticity, and clonic convulsions are intermittent. Death occurs in coma after a course of one to several days. These signs are entirely referable to the nervous system; other systems are undisturbed except for the very occasional case in which massive hemoglobinuria after excess water intake precedes the onset of neurologic signs.

The **lesions** are qualitatively the same in all cases, but they differ in their degree and in the ease with which they may be detected, this depending on severity and duration. Young animals usually die more rapidly than old ones and may show cerebral edema and swelling only. The swelling affects the cerebral hemispheres, which are pale, slightly soft, and droop over the cut edges of the cranium. In these cases of short course, there may be no obvious displacement of the brain. When the fresh cortex is sectioned, it usually shows a laminar paleness about 0.5–1 mm wide following the contour of the gray matter at the junction between gray and white. This change may be most easily visible in the gyri rather than in the depths of the sulci. Its extensiveness varies considerably from case to case but remains within the boundaries of the supply area of the middle cerebral and caudal cerebral arteries. In the rostral distribution of these vessels, the lesions are patchy but are more extensive caudally towards and

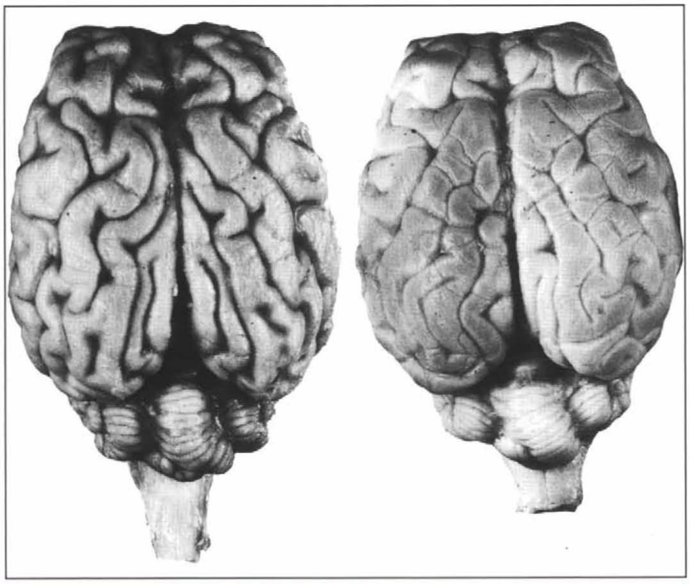

Figure 3.72 Polioencephalomalacia in a sheep. Normal brain (left), and affected brain with flattened gyri (right).

over the caudal poles of the hemispheres. The dorsal surfaces of the hemispheres are involved, and the distribution is approximately symmetrical. In either fresh or formalinized material, the gross lesions of cortical necrosis autofluoresce under ultraviolet light, due to the presence of lipid metabolites in macrophages, or of high-molecular-weight, collagen-like material.

In cases that survive for several days, the necrosis becomes more and more obvious. The brain is grossly swollen (Fig. 3.72), and, almost without exception, it is displaced caudally with herniation of the medulla and cerebellum into the foramen magnum. The dorsum of the hemispheres is palpably quite soft and the normal turgidity of the brain is gone. The surfaces of the gyri are a characteristic yellow-brown and the normal adhesion of leptomeninges to the gyral surfaces may not be present. On the cut surface of the cerebrum, there will be areas of minimal change resembling those described above. The necrotic zones can usually be appreciated to be narrow and pale or yellow instead of gray, and they are friable and shrink away from the cut surface (Fig. 3.73). Lines of cleavage between the gray and the white matter can be discerned. These are present especially over and extending down the sides of the gyri but seldom extend around the depths of the sulci. In some cases, yellow foci of softening can be found in the herniated portion of the cerebellar vermis. Hemorrhage is insignificant and usually not apparent in the cerebrum and cerebellum, but hemorrhagic foci of softening may be found in the collicular region, thalamus, and caudate nuclei. In some cases, there is thrombosis of the dorsal longitudinal sinus.

Animals that survive for 2 weeks or longer are decorticate over more or less extensive areas. The white cores of the gyri are largely intact and project nakedly or with an irregular covering of softened friable gray matter. Over some gyri, the gray matter is intact. The subarachnoid space is widened and the meninges droop over the enlarged sulci. Subpial cysts may be evident where the devastation is not complete and the meninges are adherent. The brain is smaller than normal and not displaced, the lateral and third ventricles are dilated, and there is an excess of cerebrospinal fluid.

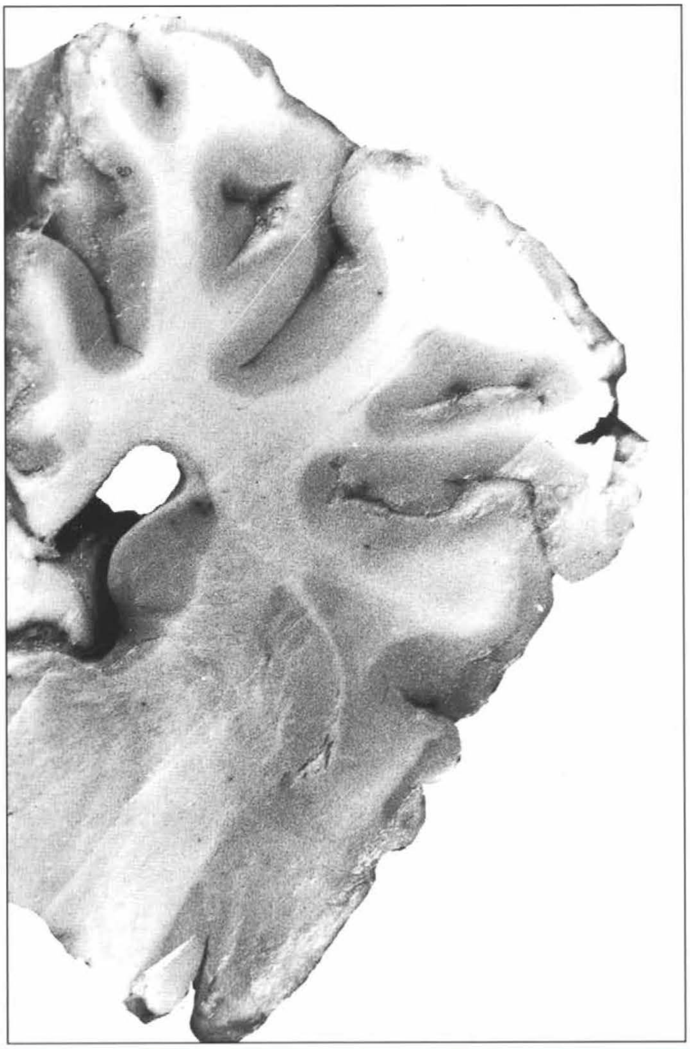

Figure 3.73 Chronic lesion in **polioencephalomalacia** in an ox; note the marked irregular narrowing of cerebral cortex.

The **microscopic changes** are of the same type in all affected parts but vary in distribution and severity. The least change is one of laminar necrosis of neurons affecting especially the deeper laminae. The neurons are shrunken, acidophilic, and surrounded by a clear space; in 2–3 days, many are converted to eosinophilic globules without nuclear remnants. Healing, if it occurs, is with intense astrogliosis.

The malacic areas are laminar (Fig. 3.74). The deepest laminae are consistently involved. Frequently, the superficial lamina is involved. The softened laminae do not necessarily overlie one another although there is usually considerable overlapping. When two distinct laminae of necrosis overlie one another, they frequently merge in the depths of the sulci to produce necrosis of the total width of the gray stratum (Fig. 3.74). Necrosis of the superficial lamina is first recognizable as a rather uniform sponginess. The layer then disintegrates and the middle laminae, if intact, are separated from the pia by a moat of gitter cells in which vessels are very sparse (Fig. 3.75). The leptomeninges are thickened and contain many activated histiocytes.

The middle laminae may remain structurally intact for considerable periods. The neurons therein die acutely, but the glia are rather persistent. The vessels are prominent, with swollen proliferating endothelial and adventitial cells and a perivascular clear space.

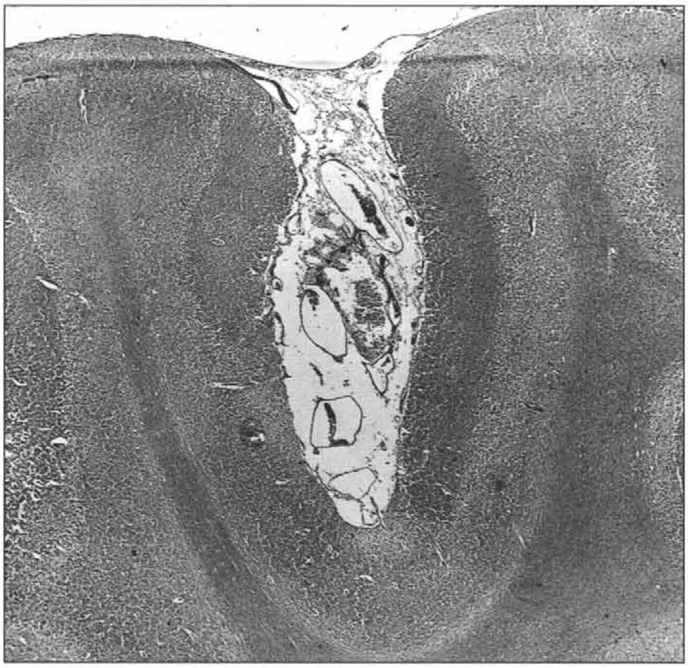

Figure 3.74 **Polioencephalomalacia** in an ox. Pallid areas of degeneration involving full width of cortex in depth of sulcus.

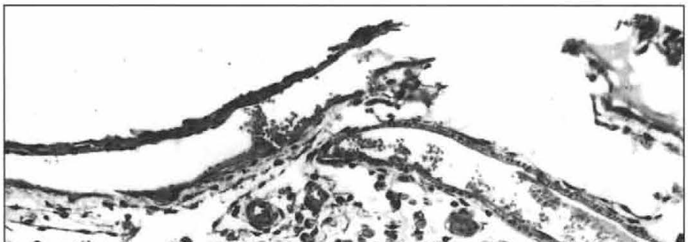

Figure 3.75 Collapse of meninges, with gitter cells replacing necrotic cortex in **polioencephalomalacia** in an ox.

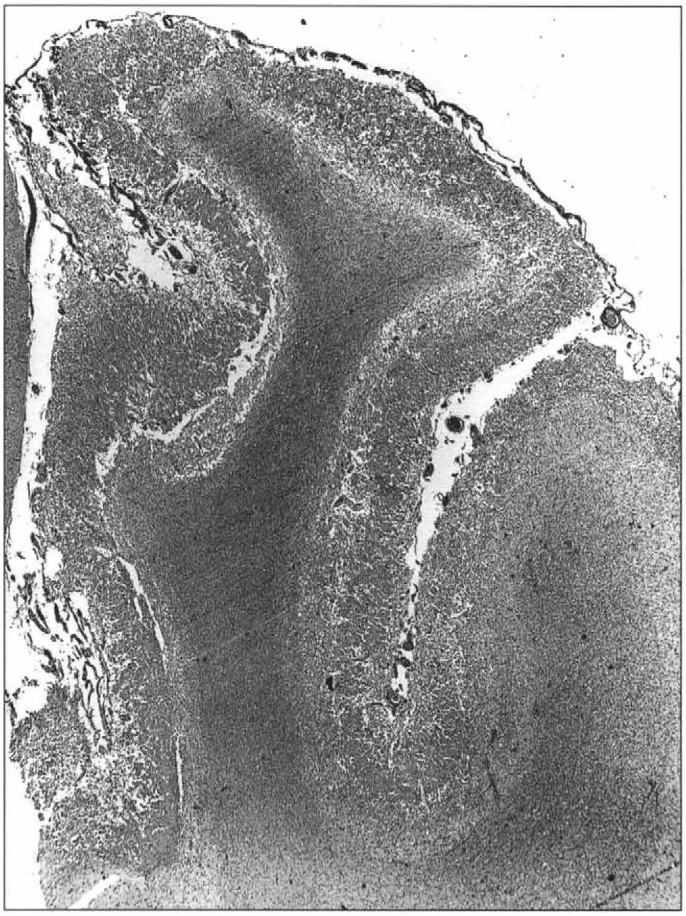

Figure 3.76 Subtotal cortical necrosis with separation in **polioencephalomalacia** in an ox.

There is *early edema and neuronal necrosis in the deepest laminae* and the edema extends to the adjacent white matter, giving the zone a pale washed-out, fibrillary appearance in sections (Fig. 3.74). There is demyelination in the edematous white matter, but the glia survive fairly well, and the astrocytes react and swell. The microglia become active and concentrate in the deep laminae, which disintegrate to cleave overlying cortical remnants from the subjacent white matter (Fig. 3.76).

The macroscopic lesions observed in the cerebellum and subcortical areas are typical foci of softening. Microscopic changes of less severity are more common. They occur in the herniated portion of the vermis and consist of acute degeneration of Purkinje cells with more or less extensive cytolysis in the granular layer.

The chronic lesions of surviving animals resemble those described earlier in ischemic infarcts. The dead tissue is removed by microglia. In zones where the gray matter has been entirely necrotic, the pia may be separated from the white matter by a clear space or be in contact with the white and partially adherent as a glial–pial scar formed by connection with the proliferated astrocytes that line the defect. Where the superficial laminae have remained intact, elongate cystic spaces lined by astrocytes remain where the necrotic parenchyma has been removed.

The areas of softening quite clearly have a distribution related to the field of supply of the middle cerebral artery. When the lesion is of restricted distribution, it is related to the periphery of the field of distribution

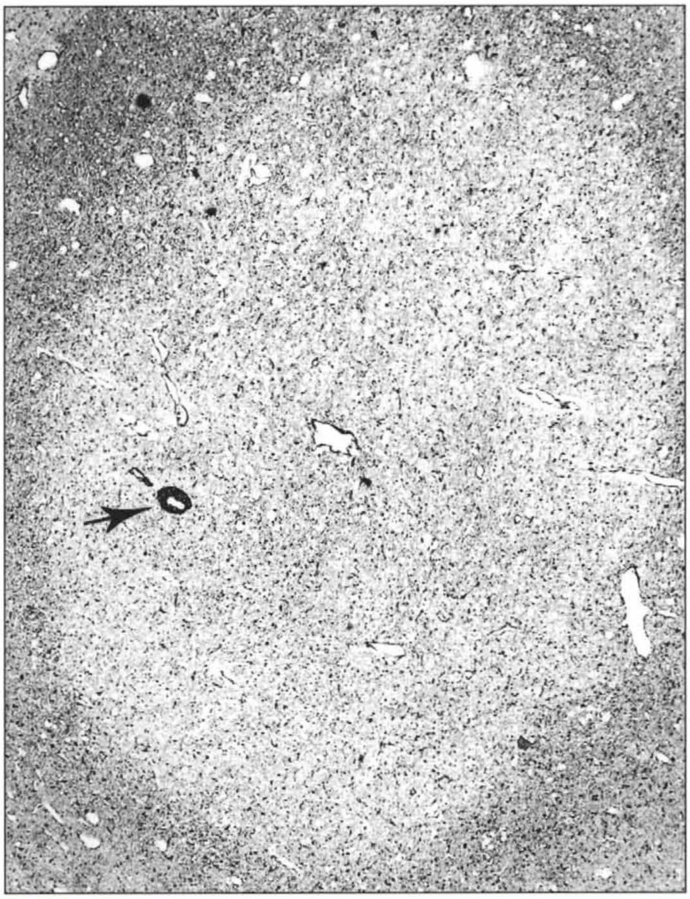

Figure 3.77 Edema in inferior colliculus with ring hemorrhage (arrow) in **polioencephalomalacia** in a sheep.

of this vessel over the dorsal cerebral cortex and, when the lesion is more extensive, it covers more of the field of supply of this vessel, but necrosis is seldom found ventral to the caudal ectosylvian fissure. The cortex rostral to the transverse sulcus and in the field of supply of the rostral cerebral artery escapes significant injury. Necrosis may be observed in the distribution area of the caudal cerebral artery, but only when the swelling and displacement is severe, a fact suggesting that necrosis in this distribution is secondary to tentorial herniation with compression of the caudal vessels against the free edge of the tentorium.

Degenerative changes in periventricular nuclei of type and distribution typical of thiamine deficiency in other species are present in some cases of PEM (Fig. 3.77) and their histologic appearances suggest that their development precedes the cortical necrosis. This observation applies also to the experimental disease produced by amprolium.

The **cause** of PEM in ruminants is often unknown, as the lesion of PEM lacks etiologic specificity. Sporadic cases and outbreaks are observed in animals given access to water after a period of deprivation suggesting that these cases may be expressions of *water deprivation–sodium ion toxicosis* developing in the manner discussed later for salt poisoning in swine. It has been observed in sheep eating the nardoo, *Marsilea drummondi*, and associated with the *thiaminase* present in that fern. The disease has been produced experimentally with analogues of thiamine with impaired activity, and by the feeding of rhizomes of bracken fern, which are known to contain thiaminase.

Deficiency of thiamine or a disturbance in its metabolism is implicated in PEM. Thiamine, if administered early, may lead to prompt clinical recovery. Calves examined early in the course of the disease may have elevated blood pyruvate, reduced blood transketolase, and reduced levels of thiamine in liver and brain. Cerebral edema and laminar necrosis have also developed in lambs and calves given the thiamine antagonist, amprolium. Thiaminolytic enzymes can be found in rumen contents in some cases of PEM, and it is accepted that they are produced as exoenzymes of some rumen microbes. Degradation of thiamine may reduce the amount available and simultaneously produce analogues of the vitamin. The thiamine-responsive disease is sporadic.

Sulfur compounds have emerged as important causes of morbidity. Sulfite, an intermediate in the reduction of sulfate, can cleave thiamine into pyrimidine and thiazole constituents thereby rendering it inactive. Diets and drinking water containing high levels of sulfates can increase the incidence of PEM in cattle, and in sheep fed diets high in sulfur. Sulfur compounds, mainly sulfur dioxide, used to color meat can precipitate a thiamine deficiency syndrome in dogs and cats. The sources of sulfur to ruminants are varied. There is a high incidence of PEM in cattle in feedlots especially when they are fed diets based on molasses, which can be high in sulfur. Inappropriate use of ammonium sulfate for urine acidification in feedlot cattle and sheep is recorded. The high incidence of the disease in animals fed sugarbeet pulp and the occasional outbreak in cattle fed thiocyanate-containing *Brassica* plants may be ascribed to high sulfur content. Groundwater in many areas has a high content of calcium sulfate. The NRC recommended dietary sulfur level for ruminants is less than 0.3%; the maximum tolerated intake is 0.4%; water sulfate concentrations >2000 ppm are associated with the occurrence of PEM. The molecular pathogenesis of sulfur-related PEM is unclear, as is its relationship to thiamine activity and to the malacic lesions in the corpus striatum not seen in thiamine-responsive disease.

Thiamine deficiency

Thiamine (vitamin B1) is a *dietary requirement of carnivores*. Herbivores are capable of synthesizing their own requirements, the synthesis being microbial and taking place in the rumen, and probably in the large intestine of horses. Experimental deficiency can be produced in calves and lambs, but only when they are very young and before they have established a useful ruminal flora; neurologic signs, including ataxia, cerebellar tremors, and convulsions, occur in these experimental deficiencies (see also Polioencephalomalacia of ruminants). Horses are poisoned by eating bracken fern and horsetail (*Equisetum arvense*), both of which plants contain a *thiaminase*. The plants are unpalatable, but poisoning may occur when they are included in pasture hays. The disease in horses is characterized by incoordination, which may be severe and lead to recumbency and bradycardia. Affected animals respond rapidly to thiamine. The nervous system has never been suitably examined for lesions.

Thiamine deficiency has been produced in most domestic species and in others. It has been an important natural disease in foxes and cats and continues to be of some importance in mink. In these carnivorous species, the deficiency is induced by a *thiamine-splitting enzyme naturally present in many species of fish*. Metabolic analogues of thiamine are known and have been used experimentally to produce the deficiency, but there are no known naturally occurring competitive analogues. Processed foods for dogs and cats can easily be made deficient in thiamine as the vitamin is susceptible to heating at 100°C or above in a medium of neutral or alkaline pH. The feeding to cats and dogs of meat that has been exposed to sulfur dioxide to preserve the fresh appearance can lead to thiamine deficiency; *thiamine is destroyed by sulfates.*

The syndrome, originally described as *Chastek paralysis*, produced by thiamine deficiency in foxes and mink is comparable to that in cats and may develop in 2–4 weeks of being fed the deficient diet. The onset of neurological signs is indicative of severe depletion of thiamine; the clinical and pathological consequences of marginal deficiency are not known. Initially, there is reluctance to eat, and drooling and anorexia may be present for up to one week before distinct clinical signs occur. Neurologic signs first consist of ataxia, incoordination, pupillary dilation, and sluggish pupillary reflexes. Convulsions are easily induced and are characterized by strong ventroflexion of the head. At this stage, animals usually respond rapidly and fully to thiamine, but there may be residual mild ataxia. After 2–3 days of neurological signs, animals pass into an irreversible phase of semicoma, opisthotonos, continual crying, and spasticity.

The *lesions of thiamine deficiency in carnivores* pass through the sequence of vacuolation of neuropil, vascular dilation, hemorrhage, and necrosis. These changes are occasionally observed in the middle laminae of the occipital and temporal cortex as poliomalacia, but *the areas of remarkable vulnerability are in the periventricular gray matter.* The periventricular lesions are always bilaterally symmetrical. The only consistency in the pattern of the lesions in the periventricular system is the involvement of the inferior colliculi (Fig. 3.78A). Next to the inferior colliculi, lesions are most commonly found in the medial vestibular, red and lateral geniculate nuclei, but they may be found in any of the periventricular nuclei. In contrast with Wernicke encephalopathy in man, with which the disease in carnivores can be compared, cats and foxes only irregularly develop hemorrhages in the mammillary bodies.

The initial morphological change is *vacuolation in nuclei of special susceptibility*. This is easiest to detect in the lateral geniculate bodies, inferior colliculi, and red nuclei (Fig. 3.78B, C, D). The vacuolation develops in cats at about the time they become susceptible to the induction of convulsions and at about the time that alterations in the permeability of the blood–brain barrier become demonstrable. This altered permeability, which may result from free-radical injury, is limited to those nuclear masses that are known to be vulnerable to injury in this deficiency. The case may not progress beyond this stage but, instead, pass to recovery. In the event of recovery, *intense astrogliosis* develops and remains to indicate the past presence of thiamine deficiency. With the development of vacuolation it is also possible to recognize vascular dilation especially affecting venules and especially in the susceptible nuclei. *Hemorrhage* occurs from both capillaries and venules, consistently in fatal cases. The hemorrhages may be large enough in the colliculi and vestibular nuclei to be visible to the naked eye (Fig. 3.78A, B).

Thiamine deficiency appears to affect most severely the relay systems from the eye and ear, but the histogenesis of the changes is vague. Phosphorylated thiamine is the coenzyme, *cocarboxylase*, and it participates probably in all oxidative decarboxylations as well as in some other metabolic transformations. It is a cofactor for transketolase, α-ketoglutarate dehydrogenase, pyruvate dehydrogenase, and branched-chain α-keto acid dehydrogenase. It may also have a function in axonal conduction and synaptic transmission. In all animals in which thiamine deficiency has been produced, the deficiency is attended by an *elevation of the pyruvate levels of blood*. This is to be anticipated from what is known of the function of the vitamin, but cannot be connected in any way to the nature of the nervous signs or the nature or distribution of the neural lesions. There is decreased glucose utilization by the brain and shortly before the development of lesions the vulnerable areas suffer a burst of metabolic activity with local production of lactate, and it is possible that the focal lesions, initially, are the result of focal lactic acidosis. The bradycardia is explainable on the basis of impaired carbohydrate metabolism because cardiac muscle depends for its energy supplies on carbohydrate, chiefly pyruvate, and in this differs from skeletal muscle. *Myocardial degeneration* is described in the experimental disease in several species and in the spontaneous disease in cats, dogs, and foxes; focal myocardial necroses are more prominent in the right than in the left ventricle.

Although it is not possible to correlate thiamine deficiency and its lesions with the distribution and activity of pyruvate decarboxylase, there is some correlation between thiamine deficiency and the distribution of transketolase activity in the nervous system. Transketolase is a thiamine pyrophosphate-dependent enzyme active in the hexose monophosphate shunt. The enzyme is active in white matter and apparently important in the metabolism of oligodendrocytes. During progressive thiamine depletion, brain transketolase activity declines before signs of the deficiency develop, and the decline is greater than for pyruvate decarboxylase. Moreover, the decline of brain transketolase is greatest in those areas in which lesions develop in rats.

The relation of transketolase deficiency to the evolution of lesions is unclear, as is the sequence of morphological changes. The spongy change appears to be a primary event, and vascular changes secondary. The hemorrhages are a terminal event. Fine-structural studies suggest that changes in vessels in selective areas of injury are secondary to degenerative changes in regional glia. The glia are edematous – swollen with clear cytoplasm – and their rupture leads to increase of extracellular spaces. Additional studies have shown early damage in the neuropil with degenerative and hypertrophic changes and axonal degeneration with preservation of neurons. Increased release of glutamate in vulnerable brain structures may result in N-methyl-D-aspartate receptor-mediated excitotoxicity; apoptotic cell death may result from increased expression of immediate early genes such as *c-fos* and *c-jun*.

Nigropallidal encephalomalacia of horses

Prolonged ingestion of yellow star thistle, *Centaurea solstitialis*, or Russian knapweed, *Centaurea repens*, produces encephalomalacia in horses. It is a disease of dry summer pastures in which the thistle, which remains green, provides most of the forage. The putative neurotoxin is *repin*, a principal sesquiterpene lactone present in aerial parts. Repin appears to cause glutathione depletion, which leads to oxidative damage, mitochondrial dysfunction, and neuronal cell death.

The onset of the disease is sudden and may occur as early as 1 month after initial exposure to star thistle. The syndrome is characterized by idle drowsiness, persistent chewing movements, and difficulty in prehension, the latter apparently related to incoordination of the lips and tongue. Sensation and reflexes are normal. Death is due to starvation, dehydration, or intercurrent disease. *Malacic lesions are consistently present in the brain and affect specifically the pallidus and substantia nigra.* There is some variation of the pattern depending on whether the lesions are symmetrical or not and involve both pallidus and substantia nigra or only one of the structures. Usually both structures are symmetrically involved. The pallidal foci involve the rostral portion of the globus pallidus, are lenticular in form, and 1–1.5 cm in size. The core of necrotic tissue in the substantia nigra is ~0.5 cm in diameter and extends from about the level of the mammillary bodies to the point of emergence of the oculomotor nerve (Fig. 3.79). The affected areas are evident as slightly bulging, yellow, gelatinous foci. The softening progresses rapidly, and in about 3 weeks the lesion is sharply demarcated as a *pseudocystic cavity*. The microscopic changes are those ordinary in malacia and do not give a clue to the immediate pathogenesis.

Salt (NaCl) poisoning

Salt poisoning may be a *direct and immediate* result of excessive ingestion of salt, or it may be *indirect and delayed*, developing only after several days of excessive salt intake and restricted water intake. These two types of salt poisoning are pathogenetically dissimilar, and neither will occur if animals are always provided with free access to water of low saline content.

Direct salt poisoning is largely a problem of salinity of drinking water. Excessive saline content of fodder is not a concern, except in terms of palatability, if an abundance of fresh water is available; for example, sheep may take rations containing up to 13% sodium chloride for prolonged periods without ill effects. This high tolerance for salt in fodder is utilized to restrict food intake during periods of scarcity and also to encourage water intake in the control of urolithiasis.

The salinity of drinking water is important, not only in terms of the concentration of sodium chloride or total salts, but also in terms of what salt and what acid radicals are present. It is difficult to provide figures for acceptable salinity of drinking water for livestock because of the variations in the proportions and concentrations of the various salts present, but the usual recommendation is that the concentration of sodium chloride or total salt should be <1.7% for sheep, <1.0% for cattle, and <0.9% for horses, and preferably not more than one half of these concentrations.

Acute, direct salt poisoning occurs chiefly in cattle, especially if they are very thirsty when first given access to saline water. Poisoning may also occur in cattle if they are given free access to salt supplements after a prolonged period of salt restriction such as occurs in cattle grazing on mountain pastures. *Clinical signs in cattle are referable to the alimentary tract and nervous system*, and include vomiting, polyuria, diarrhea, and abdominal pain with paresis, knuckling of the fetlocks, and blindness. Death may occur in 24 hours.

At autopsy, there is severe congestion of the mucosa of the abomasum and excessive, dark, fluid intestinal content. The alimentary changes are probably in large measure due to osmotic disturbances in the gut, but the neurological signs are unaccounted for. Also unexplained is the development of moderate anasarca in animals that survive for some days.

Indirect salt poisoning is a neurologic disease. There are circumstantial reasons for believing that it occurs in cattle and sheep and that it is occasionally responsible for PEM in these species, but *the disease is proven to occur only in swine*. Toxicity is related to the sodium ion; the clinical and pathological features of this disease are not duplicated in any other.

Apparent blindness and deafness initiate the clinical syndrome in indirect salt poisoning in swine. The animal is oblivious to its environment and cannot be provoked to squeal. There is head pressing suggestive of increased intracranial pressure, arching or pivoting, and these signs usually lead to the convulsive syndrome. The convulsions are very characteristic in their pattern and in the regularity of the time intervals in which they recur. They begin as tremors of the snout and rapidly extend as clonic spasms of the neck muscles with jerky opisthotonos that causes the pig to walk backwards and sit down. The animal passes into lateral recumbency and generalized clonic convulsions.

The lesions of this intoxication are restricted to the brain. There is moderate cerebral edema but no displacement. The basic changes in the brain are laminar loss of cortical neurons and laminar (middle laminae) malacia. These are the changes described earlier for PEM of cattle and sheep. The specificity of the lesion is given by the *abundance of eosinophils that are infiltrated into the meninges and Virchow–Robin spaces*. This particular lesion and its frequent relation to excessive intake of salt have been recognized for many decades, but until the cause was established, the syndrome was designated as "eosinophilic meningoencephalitis" on account of the relatively pure infiltrations of eosinophils that were found. Eosinophils tend to infiltrate in the meninges and perivascular spaces in the brains of pigs with other cerebral lesions, such as the leukomalacia of mulberry-heart disease and various encephalitides, but *the combination of laminar change and cerebral eosinophilia is pathognomonic of salt poisoning*.

The amount of salt in the diets of pigs varies considerably, but toxicity does not occur if plenty of water is available. The critical level of salt in the fodder is approximately 2% when water intake is restricted. Signs of poisoning may occur when the water supply is replenished after a period of restriction.

Although excessive intake of salt over a period of several days sets the stage, which is reflected in elevated plasma levels of sodium and chloride, the disease is precipitated by water so that it may equally well be regarded as a *form of water intoxication*. Beyond this, the pathogenesis of the lesions remains obscure. It is noteworthy that they are anoxic in character and distribution.

Mycotoxic leukoencephalomalacia of horses

A neurological syndrome occurs in horses fed moldy corn for ~1 month or longer. The neurological signs are of fairly sudden onset and consist of drowsiness, impaired vision, partial or complete pharyngeal paralysis, weakness, staggering, and a tendency to circle. The course is from a very few hours to about a month, but death usually occurs on day 2 or 3. Recovery from clinical signs apparently does not occur; chronic cases with static signs are dummies.

The mycotoxin responsible is *fumonisin B1*, a product of *Fusarium verticillioides* (*Fusarium moniliforme*) and *F. proliferatum*, which grow on corn (maize) in warm moist conditions, circumstances in which outbreaks of the disease occur. Sporadic cases occur in circumstances involving moldy fodder. The neurological disease occurs in donkeys and mules as well as in horses.

The neurological signs described in the spontaneous disease are related to the encephalomalacia, which may be due to fumonisin-induced microcirculatory damage as well as impairment of cardiovascular function. In the experimental disease and a small proportion of spontaneous cases, nervous signs may include mania rather than neurological deficit; these dramatic cases may be icteric and the nervous signs are those usual in the horse in acute hepatic failure. In natural and experimental cases, there may be *hepatic lesions* varying greatly in severity. The hepatic lesions when present are similar to those produced in other species by aflatoxin (see Vol. 2, Liver and biliary system).

The lesion usually described is *necrosis of the white matter of the cerebral hemispheres* (Fig. 3.80). The surface of the brain may be unaltered on inspection, but palpable softness may be detected in the cortex overlying large areas of leukomalacia. Grossly, there is no cerebral edema or brain swelling, although the overlying gyri might be slightly flattened and discolored. The foci of softening may be of microscopic dimensions, but usually they are readily visible on the cut surface. The softenings occur at random in the white matter of the cerebral hemispheres. They may be bilateral but are not necessarily symmetrical. The malacic foci are soft, pulpy, gray depressions distinct by virtue of

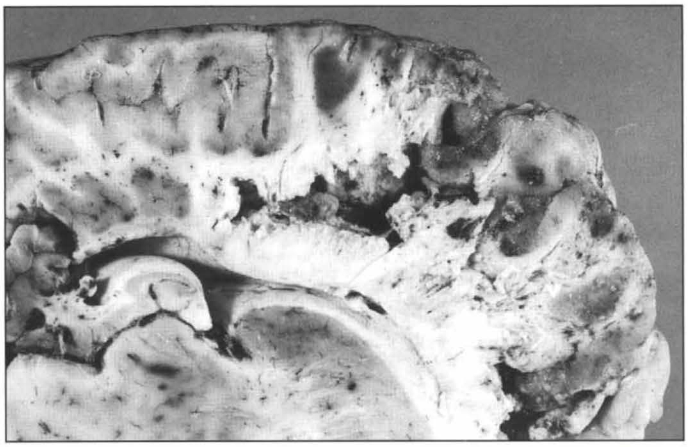

Figure 3.80 Irregular malacia and hemorrhage in cerebral hemisphere in a horse with **mycotoxic leukoencephalomalacia.** (Courtesy of TM Wilson.)

numerous small hemorrhages in a peripheral zone of a few millimeters' breadth. Depending on the duration, there may be diffuse, yellow, edematous swelling of the adjacent white matter.

In small foci, and probably initiating them all, there is severe edema of the white matter. The white matter is spread apart by fluid, and the myelin sheaths, axons, and glia disintegrate to form a structureless, acidophilic, semifluid mass to which the microglia react. The edematous change is not confined to the cerebrum but is reported to occur in all parts of the spinal cord. Foci of softening also occur in the brain stem and spinal cord, but here, in contrast with the brain, the necrosis affects the gray matter chiefly (Fig. 3.81).

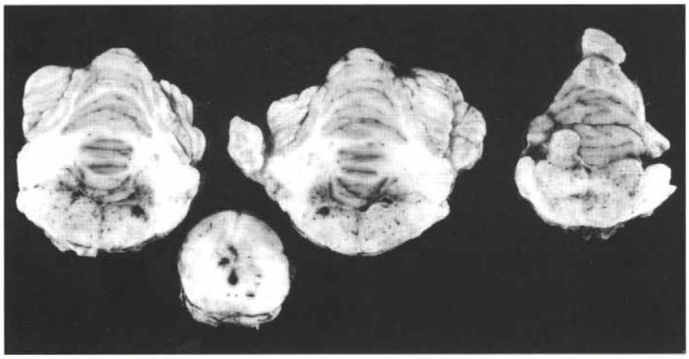

Figure 3.81 Focal hemorrhage and malacia in brain stem of a horse with **mycotoxic leukoencephalomalacia.** (Courtesy of TM Wilson.)

Microscopically, *the areas of malacia are widely distributed and irregular in their form*, mainly in the white matter but a few small foci may be seen in the cortex. The irregular cavitations tend to surround and follow the course of the blood vessels, and there is edematous separation of tissue extending from the periphery of the cavitations (Fig. 3.82A). Cellular infiltrations, mainly of eosinophils but with some plasma cells, are present in the walls of vessels, in the perivascular spaces, and lightly in the edematous parenchyma (Fig. 3.82B). The adventitia of the vessels, especially in the brain stem, may be remarkably thickened. There is abundant lipofuscin pigment in macrophages.

Lead poisoning

Lead is perhaps the most consistently important poison in farm animals. Poisoning is common and fatal in cattle, is less common but fatal in sheep, is occasionally observed in horses, dogs, and cats, and is rare in swine. The disease in cattle is probably always acute whereas that in horses is virtually always chronic. The signs are almost exclusively neurologic even though the amount of lead deposited in nervous tissue is relatively small.

The usual sources of lead for cattle are *paint* and *metallic lead in storage batteries*. Adult cattle are most frequently poisoned at pasture by licking paint or putty cans from rubbish dumps. Calves are usually poisoned when from boredom or allotriophagia they lick painted pens, troughs, etc. Metallic lead does not reliably produce poisoning in ruminants under experimental conditions but frequently does so naturally, perhaps because the metal, when well weathered, contains soluble salts on its surface. Lead, chronically ingested, does accumulate in the tissues of ruminants, but it is not a cumulative poison in these species. Under conditions of chronic assimilation in ruminants, large amounts of lead may be stored in tissues, including the brain, without causing lesions or clinical disease. Cows have been shown to tolerate 2 g of lead daily for as long as 2 years without apparent harm. Sheep may accumulate large amounts of lead in the course of grazing over abandoned lead-mining areas that have been converted to pasture; the severe osteoporosis that may develop cannot be attributed to the accumulated lead, but may be related to copper deficiency.

The situation in horses is largely the reverse of that in ruminants because in horses lead poisoning is usually chronic. This probably represents in part species susceptibility, but is in part due to the manner of exposure in that horses are usually poisoned by prolonged inhalation of fumes from lead smelters or by prolonged ingestion of pastures contaminated by such effluent; such pasture exposure of course also occurs in cattle. Contaminated pastures may contain as much as 100–200 mg Pb/kg foliage.

Lead poisoning may occur in circumstances additional to those cited above. Boiled linseed oil contains lead and it is occasionally mistakenly used as a laxative for animals. Dogs are occasionally poisoned by drinking gasoline that contains tetra-ethyl lead. Lead pipes may yield significant amounts of lead to soft water. Lead arsenate, widely used as an orchard spray, is commonly responsible for poisoning of cattle and sheep, but the signs and lesions refer largely to activity of the arsenate.

Lead is usually obtained by ingestion but only a small proportion of the ingested dose is absorbed, something of the order of 1–2% even of a soluble salt such as lead acetate. The limitation of absorption is due largely to formation of insoluble complexes in the alimentary tract. Absorbed lead is slowly excreted in bile, milk, and urine, and is deposited in tissues, especially in liver and kidneys in acute poisoning and in bones in chronic poisoning. The turnover of deposited lead is slow but continuous with gradual elimination in bile and urine; the half-life of lead in blood can range from months to years.

The *relative neurotropism of lead* is not well explained. Most metals exert their most deleterious effects at the sites of absorption and elimination, but lead largely spares these and affects nervous tissue with a high degree of specificity. Lead exerts toxicity by a number of mechanisms, including binding to calcium- and zinc-binding proteins, by random hydrolysis of nucleic acids, and by inducing RNA catalysis through activation of ribosomal 5S RNA, a natural leadzyme.

The various species differ in their sensitivity to lead, and the **clinical syndromes** produced also differ somewhat, although they are always chiefly neurologic. There seems to be remarkably little correlation between the doses of lead that will produce experimental poisoning and the very small amounts that induce toxicity naturally. Young animals are relatively more susceptible than adults.

The acute poisoning in *cattle* usually leads to death in 12–24 hours. Calves stagger, develop muscle tremors, and rapidly become recumbent. Convulsions are intermittent until death, and between convulsions there is opisthotonos, muscular tremors, champing of the jaws, and hyperesthesia to touch and sound. Adults show less tendency to early recumbency. In these there is frenzy, head pressing, and apparent blindness, with death in convulsions. When the poisoning is less acute, cattle may survive for 4–5 days. They are dull and apathetic, apparently blind, and without appetite. There may be drooling, intermittent grinding of teeth, and hyperesthesia, but dullness and immobility predominate. Ruminal agony is fairly constant and dark fetid feces may be passed terminally. Death occurs quietly or in convulsions or from misadventure. The manifestations of lead poisoning in sheep are similar to those of the subacute syndrome in cattle.

The disease in *horses* is paralytic. When horses ingest large amounts of lead, they develop severe depression and general paralysis, sometimes with clonic convulsions and abdominal pain. In chronic poisoning, usually known as *chronic plumbs*, the characteristic signs are those of specific nerve pareses affecting chiefly the cranial nerves and expressed particularly as laryngeal and pharyngeal paralysis. The clinical manifestations in dogs are also neurologic, but their pattern is not characteristic. There is anorexia, emaciation, mental irritability, muscular tremors, ataxia, and intermittent convulsions.

Specific **lesions** are not observed in lead poisoning in cattle. In cases that survive for 4–5 days, the ruminal contents may be foul because of immotility and the lower gut may contain a small volume of dark fetid feces, the color attributed to lead sulfide. There is no gastroenteritis and any clinical signs of colic are probably related to nervous dysfunction. There may be mild degenerative changes in the parenchymatous organs, but these cannot be attributed to lead.

There is moderate brain swelling, but probably never severe enough to cause displacement and not often severe enough to be appreciated grossly. Even microscopically, the cerebral edema is not easy to appreciate or to distinguish from early autolytic change. The capillaries and venules are congested and there may be petechial hemorrhages. The prominence of capillaries in the gray matter is due largely to congestion, but there may be some endothelial swelling and proliferation to make them more conspicuous. Neuronal changes are equivocal. In some subacute cases in which the course is prolonged for several days, there may be *laminar cortical necrosis*. The best explanations of laminar necrosis are still based on ischemia-anoxia, implying that lead is not directly neurotoxic in terms of neuronal injury. Indeed, lead tends not to accumulate in nervous tissue. The capillary alterations may therefore be of considerable functional importance and probably precede the swelling of glia. The capillary changes are best seen in thick sections stained by a Nissl stain and in the cerebellum better than in the cerebrum. In the cerebellum, the vascular lesion in the molecular and Purkinje layer is often accompanied by astro- and microgliosis.

The histological basis of the paralytic changes in lead poisoning in horses probably has the same basis as the peripheral neuropathy of chronic plumbs in man, in which the paralysis affects those muscles that are used most constantly and is due to segmental degeneration of axons and myelin in the distal parts of motor fibers. In humans, the peripheral neuropathy of lead poisoning is purely motor.

In dogs, there is edema of the white matter of the brain and cord. Degenerative changes in myelin sheaths occur almost universally but are somewhat less severe in heavily myelinated tracts such as the optic tract, corpus callosum, and peduncles than in lightly myelinated areas, such as the deep white matter of the cerebellum and cerebrum. There is spongy degeneration in the subthalamus, head of the caudate nucleus, and deep cortical laminae with extensive loss of neurons in such areas. Reaction on the part of astrocytes and microglia is slight.

Mild degenerative changes occur in the liver and kidneys of dogs chronically poisoned with lead, and can be overlooked in routine examinations. Most conspicuous is enlargement and vesiculation of the nuclei in the convoluted tubules. *Irregular, acid-fast, intranuclear inclusion bodies can be found in the renal tubules in some cases.* These inclusions are irregularly present in cases of lead poisoning, but when present, they have diagnostic value. They may develop in any species poisoned, but in dogs, they must be distinguished from the brick-like, acidophilic inclusions that can be present in the nuclei of renal tubules and hepatic cells. These inclusions are also acid-fast, but have no specificity for lead poisoning and are present in the nuclei of apparently healthy dogs. In cattle, the degree of tubular epithelial degeneration is slight in most cases, but there is often a surprising degree of mitotic activity and there may be severe nephrosis with extensive fibrosis in young calves.

The **diagnosis** of lead poisoning is necessarily chemical because lesions are either absent or nonspecific. Because of the variability of pathogenetic factors and species susceptibility discussed above, precise figures cannot be given for the concentration of lead in tissues that can be regarded as indicating lead poisoning. As little as 4–7 μg lead/g liver has been found in horses dying of chronic intoxication. In cattle, levels of lead (on a wet weight basis) of 40 μg/g or more in the kidney and 10 μg/g or more in the liver are accepted as confirmatory of lead poisoning.

Neurodegenerative diseases

There are some significant neurologic diseases in which dramatic clinical disturbances are not matched by equivalent morphologic alteration in nervous tissue. For instance, *toxins that interfere with synaptic function can have fatal consequences,* yet leave neurons normal in appearance to routine examination. **Botulism, tetanus**, and **strychnine toxicosis** are well-known examples. In the latter two conditions, the release of spinal motor neurons from the inhibitory influence of "Renshaw cells" (inhibitory neurons) leads to the extensor spasms and hyperesthesia that characterize them. The activity of the inhibitory neurotransmitter glycine is blocked – in the case of tetanus by pre-synaptic blockade of its release, in the case of strychnine by post-synaptic blockade of its receptors. An inborn metabolic equivalent of these poisonings is *hereditary myoclonus* of Poll Hereford calves and of Peruvian Paso horses, in which there is an absence of glycine receptors on spinal motor neurons. In the Hereford disease, the calves are born normally, but suffer severe tetanic spasms on stimulation, are unable to stand, and are nonviable.

A distinctive locomotor disturbance in Australian sheep (Coonabarabran staggers, "cathead" staggers) has been associated with grazing of the zygophyllaceous plant *Tribulus terrestris*. The clinical disease is characterized by asymmetric atrophy of pelvic limb extensor muscles, and irreversible asymmetric para- or tetraparesis without ataxia. There are no significant structural lesions in the nervous system. Evidence has been presented to suggest that the syndrome is caused by β-carboline alkaloids acting on dopaminergic upper motor neurons in the nigrostriatum. The long-term nature of the deficits may be the result of the ability of such compounds to form adducts with DNA sequences of genes associated with the synthesis of dopamine. Locomotor disturbances have also been documented in sheep and cattle grazing other zygophyllaceous plants in North America and Africa.

A large number of plant intoxications cause acute neurologic disease without morphologic alterations; **tremorgenic mycotoxicoses** are discussed below.

Inherited **spasticity syndromes** are described in cattle as "spastic paresis" and "spastic syndrome" and in Scottish Terriers as "Scotty cramp." Various inherited **myotonic syndromes** are referred to in Vol. 1, Muscle and tendon. The common **tetanic/paretic syndromes** that accompany hypocalcemia and hypomagnesemia are not associated with significant neural lesions.

This section will deal with noninflammatory diseases in which there is selective neuronal degeneration, involving either neurons in their entirety (**neuronopathies**) or restricted to axons (**axonopathies**). In reality, this division is somewhat arbitrary, as the axon is a wholly dependent part of any neuron, but the concept is useful for the classification of various diseases.

In general, when entire neurons or just their axons are lost in these circumstances, there are reactions by adjacent tissue elements but, as there is often minimal tissue loss overall, the predominant pathologic change is microscopic. At the end-stage of severe chronic diseases, macroscopic atrophy may become evident (see Cytopathology of nervous tissue).

The diseases have been grouped into *three categories of neuronopathies and axonopathies: "central," "peripheral," and "central and peripheral,"* according to the distribution of the lesions in the central and peripheral nervous systems. The choice of category for a particular disease is based on the predominant pattern of morphological change seen in a typical case, and the criteria are not absolute. There will inevitably be some overlap and the naming and lesion topography of each may not necessarily be fully justified or complete. Some of the diseases are rare, and, because they are inherited, are highlighted by research workers aiming to use them as experimental model systems. New entities are progressively being identified. Sampling of the nervous system in diseases such as these should be as comprehensive as possible. The pattern and extent of lesions are important criteria in the diagnosis of known diseases, and in the documentation of new ones.

Central neuronopathies and axonopathies

Compressive optic neuropathy

Compression of optic nerves in the optic foraminae is a well-known manifestation of vitamin A deficiency in the calf and pig due to stenosis of the foraminae. In poisoning by plants of the genera *Stypandra* and *Helichrysum* and by halogenated salicylanilides, the foraminae are of normal size.

These conditions are discussed fully under myelinopathies, but one usual feature of their pathology is *intense Wallerian degeneration of the optic nerves and tracts*, which may be due to swelling and compression of the nerves within the optic canals. The acute phase of the lesion would be expected to show severe ischemic necro-degenerative changes involving all the nervous tissue elements localized within the optic canals, with acute axonal degeneration extending along the optic nerves, through the chiasm and into the optic tracts of the midbrain. Retrobulbar segments of the optic nerves should be minimally affected. With the passage of time, the site of compression should exhibit malacic alterations, gitter-cell infiltration and astrogliosis, while the progression of Wallerian changes in the optic nerves and tracts should lead to extensive loss of myelinated axons and oligodendrocytes, with reactive astrogliosis. In the long term, retrograde degenerative changes lead to the loss of retinal ganglion cells and their axons, retinal atrophy, and gliosis.

Organomercurial poisoning

Mercurial compounds are cumulative poisons. The syndromes produced by the organic and inorganic salts are quite different, but the differences are probably not qualitative.

The toxicity of the organic salts depends on their solubility and the syndrome produced depends on the size and chronicity of dosage. Poisoning by inorganic salts is expected to be by ingestion, but percutaneous absorption is possible. *Poisoning by inorganic mercury is quite rare in animals.* Acute toxicity following ingestion is characterized by severe abdominal pain, vomiting, and diarrhea caused by the coagulative effect of mercury in the lining of the gut. Death may occur in a few hours. If the animal survives the initial episode, death may occur several days later from nephrosis with uremia. There may at this stage be ulcerative colitis due to the concentration of mercury in the colonic mucosa by which route it is in part eliminated. Chronic cumulative poisoning probably does not occur in animals.

Mercurialism in animals is usually caused by the organic salts, such as ethyl mercury phosphate and mercury p-toluene sulfonanilide, which are applied to seed grains for the purpose of controlling fungal diseases of the germinating plants. Toxicity may not be manifested if the treated grain is consumed for a short period only. Chronic mercurialism occurs chiefly in swine and is occasionally observed in cattle, but is most unusual in other domestic species. The manifestations are almost solely neurological. Mechanisms of organomercurial toxicity include inhibition of protein synthesis, disruption of microtubules, disturbance of neurotransmitter function, oxidative stress, and triggering of excitotoxicity mechanisms.

"*Minamata disease*" is a mercurialism of cats, birds, and man in the Minamata Bay area of Japan, associated with the eating of fish and shellfish from the bay. The fish contain large amounts of organomercurials, which probably spilled into the bay with industrial effluent. Similar environmental disease occurs in other countries.

The **clinical syndrome** of mercurialism in cattle closely resembles that of lead poisoning, but the signs, which are of sudden onset, may not occur for several weeks after the first of continuous exposures. Because degeneration of the conducting system of the heart is common, cardiac irregularities are to be expected. Signs may occur in swine as early as 15 days after being fed treated grain. There is loss of appetite, wasting, dullness, blindness, severe weakness, and incoordination, progressing rapidly until the animal can no longer stand. The dullness passes to coma, which may last for several days with intermittent episodes of clonic-tonic convulsions. Both swine and cattle may be moderately uremic.

Gross **lesions** are minimal. In both swine and cattle, the kidneys may be moderately swollen, pale, and wet, and in pigs there is often hydropericardium. Poisoned cattle have mild to moderate cerebral swelling and displacement. The cerebral cortices are soft and pale, and occasionally there is juxtasagittal venous infarction. The pallor of the cortex is visible on the cut surface so that there may be no clear distinction between gray and white matter; this change is irregular in distribution. Where the gray matter is distinct from the white, a narrow pallid band separating them may be visible. In swine, the dead white color of the cortex is often striking, especially when it is emphasized by the ischemia that may be present. The appearance of the two hemispheres may be different, that uppermost being pallid and ischemic and that of the side on which the animal is lying having congested meningeal veins. The brain is swollen and the gyri are flattened, although this is difficult to appreciate in pigs in which swelling is never severe.

Microscopically, there is *nephrosis* of mild to moderate degree usually without clear evidence of significant tubular epithelial necrosis although this is dependent on dosage. The tubular epithelium is swollen to such an extent that it may obliterate the tubular lumen. There is microscopic proteinuria. *Degeneration of the Purkinje network in the heart* is observed fairly consistently in cattle, but it may

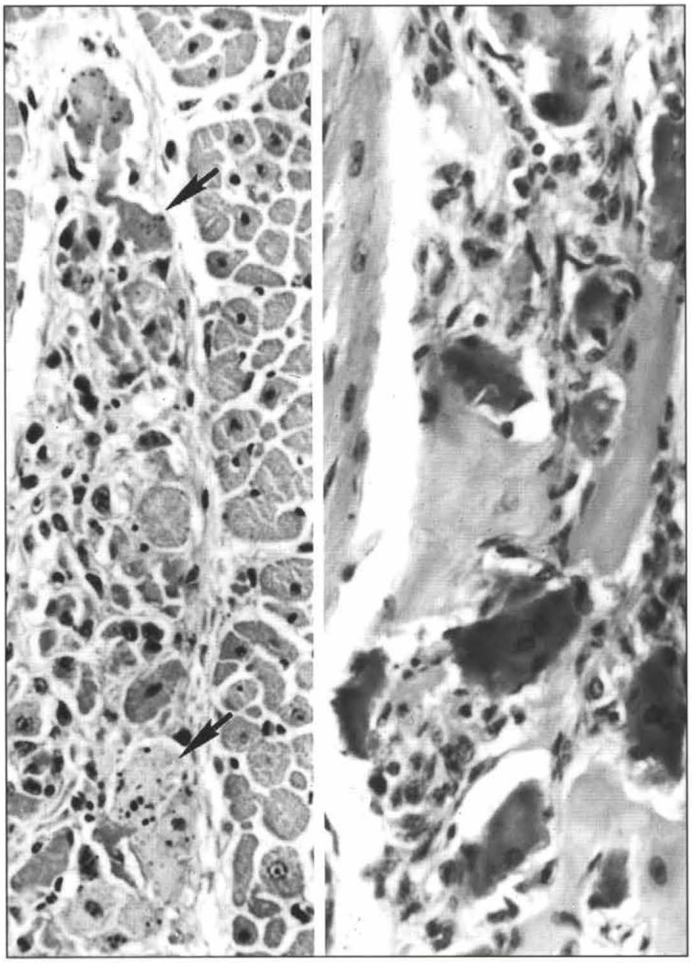

Figure 3.83 Organomercurial poisoning in an ox. Degeneration of Purkinje network in myocardium (left, arrows). Fibrosis and mineralization of Purkinje network (right).

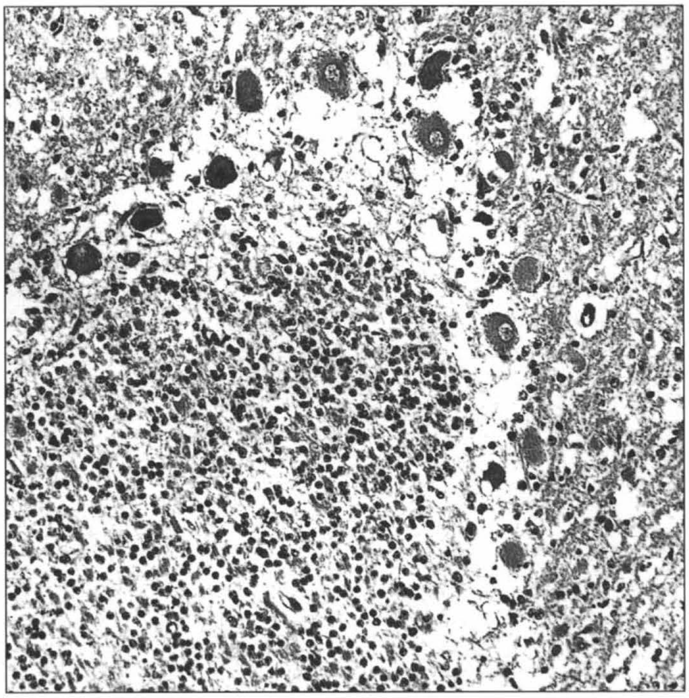

Figure 3.84 Organomercurial poisoning in an ox. Purkinje cell necrosis and degeneration in granular layer of cerebellar cortex.

not be present when the course of the toxicity is short and seems not to occur in swine. There is acidophilic, coagulative necrosis, irregularly but extensively distributed in the Purkinje network (Fig. 3.83A). The degenerate substance fragments and is removed by histiocytes and replaced by connective tissue. Mineralization is common (Fig. 3.83B). There are no clearly demonstrable degenerative changes in the myocardium.

Degenerative changes are consistently present throughout the nervous system in both cattle and swine. They differ quantitatively from case to case but are qualitatively the same. The lesions are rather more rapidly catastrophic in cattle than in swine. There is *acute neuronal degeneration*. This is of ischemic type and largely of ischemic distribution, the neurons of the middle laminae of the cerebral cortex being extensively injured. However, shrunken, acidophilic neurons can be found at all levels of the brain and cord and, with time, there is extensive cell loss from all cortical laminae. Moderate gliosis accompanies the neuronal degeneration and is expected to be most prominent in those areas of the cortical gray matter that, on gross inspection of the cut surface, are pallid. The *gliosis* is in part astrocytic and in part microglial. Compound granular corpuscles are not formed, the reactive microglia being prominently rod-shaped. There is edema in the subjacent white matter. In swine, the edema leads in time to demyelination, but in this species there is no softening. In cattle, the edema of white matter is more severe and, in the multiform layer and middle laminae, frequently produces a spongy degeneration, which may be visible grossly. This occasionally leads to laminar necrosis in cattle.

In both cattle and swine, *fibrinoid necrosis of the media of leptomeningeal arteries* is quite characteristic (see Fig. 3.56). The change probably occurs in all cases, affecting both cerebral and spinal vessels, but it is well marked in a few cases only. Swine are more prone to the vascular lesions than are cattle. Accompanying the vascular lesions, there is an outpouring of much fibrin into the meningeal spaces.

Organomercurials appear rather selectively to damage the *granule cells of the cerebellum* in all species (Fig. 3.84). Cattle are more sensitive to this degeneration than are swine. In swine, the Purkinje cells remain fairly intact, but in cattle they are often lost from about the tips of the folia. The degeneration of Purkinje cells is accompanied by microgliosis in the molecular layer and may be a response to swelling and pressure rather than a direct response to mercury.

Perhaps because the course is usually short in cattle, the spinal neurons are only mildly injured. In swine, there is often extensive ischemic necrosis of individual relay neurons. This, together with peripheral neuropathy, accounts for paralytic phenomena in swine. There is axonal degeneration and demyelination in peripheral nerves, the degenerative changes being more severe when the course is prolonged.

Solanum poisoning

Several of the many hundreds of species of the plant genus *Solanum* (family Solanaceae; nightshade family) are toxic to livestock by a variety of means. The disease of cattle in southern Africa known colloquially as *maldronksiekte* is associated with grazing *Solanum kwebense*. Affected animals show little abnormality at rest, but when moved exhibit head tilt, muscle tremors, incoordination, and convulsions.

The brain at necropsy may show gross evidence of cerebellar atrophy, uniformly affecting all lobes. Histologically there is diffuse loss of Purkinje cells, gliosis in the molecular layer, and atrophy of both molecular and granular layers. Surviving Purkinje cells are swollen, with strongly acidophilic cytoplasm, which contains numerous small "empty" vacuoles. Neurons elsewhere in the brain may show similar but far less intense vacuolation. Morphologically the vacuolation is suggestive of a lysosomal storage process and, ultrastructurally, there are membranous cytoplasmic inclusions similar to those seen in the sphingolipidoses. The nature of any stored material has not been reported to date.

Similar signs and lesions in cattle have been associated with the grazing of *S. bonariensis* in Uruguay, *S. dimidiatum* in the USA, and *S. fastigiatum* in Brazil, and in goats grazing *Solanum cinereum* in Australia.

Cycad poisoning

The primitive palm-like plants of this family (genera *Cycas, Zamia, Bowenia, Macrozamia*) occur in tropical and subtropical environments, and have been associated with the intoxication of both people and animals. Cycad toxicity is proposed as a cause of the amyotrophic lateral sclerosis–parkinsonism–dementia complex in humans. The seeds and young fronds of cycads contain the toxic glycosides, *cycasin* and *macrozamin*, and, following ingestion, the hepatic metabolism of the aglycone, *methylazoxymethane*, may cause neuronal apoptosis and acute zonal hepatic necrosis.

In tropical Australasia, chronic exposure of cattle is associated with a neurological syndrome known as "*Zamia staggers*." The syndrome is characterized by pelvic limb ataxia that may become severe. Pathologically there is distal axonopathy in the spinal cord. The ascending fasciculus gracilis and dorsal spinocerebellar tracts have axonal degeneration most intense in the cervical segments, while the same is true of descending ventrolateral tracts (Fig. 3.85A, B, C). Typical Wallerian changes lead eventually to loss of myelinated axons and reactive fibrous astrogliosis.

Tremorgenic neuromycotoxicoses

Perennial rye-grass staggers is a common mycotoxicosis in parts of Australia, New Zealand, and Europe, and is occasionally reported in the USA and southern Africa. Sheep, cattle, and horses may be affected. It occurs in the summer and autumn on dry, short pastures of *Lolium perenne*, and clinical signs appear 5–10 days following exposure. Animals develop fine head tremors and head nodding and weaving at rest and, if forced to move, have a stiff-legged, incoordinate gait, and are inclined to collapse in tetanic spasms, from which they recover quickly. There is low mortality, and total recovery will take place within 3 weeks of removal from toxic pasture. The disease is a due to indolic *lolitrems* produced by the endophytic fungus *Neotyphodium (Acremonium) lolii*. The toxins are known collectively as *tremorgens*.

There are no gross lesions in lolitrem toxicosis and microscopic change is limited to the occurrence of fusiform enlargement of the proximal axons of some cerebellar Purkinje cells. These axonal swellings are known as *torpedoes* and represent a proximal axonopathy, but their relationship to the clinical signs is unclear, and they have not been reported in any other tremorgenic diseases. The axonal lesions are best demonstrated by the use of silver staining techniques, such as the Holmes method.

Other tremorgenic neuromycotoxicoses are described in which lesions may be absent. *Claviceps paspali*, the ergot of *Paspalum*, produces tremorgenic paspalitrems that cause intoxication in cattle, occasionally in sheep and rarely in horses. Tremorgenic mycotoxin intoxication occurs in dogs from penitrem A or roquefortine produced by *Penicillium* spp. and ingested in moldy food, and in horses consuming mycotoxins in dallis grass.

Equine degenerative myeloencephalopathy

Equine degenerative myeloencephalopathy (EDM) is a *chronically progressive syndrome of symmetrical ataxia of unknown cause in equids* of several breeds and strains, including zebras. Predisposing factors include *vitamin E deficiency, hereditary predisposition*, inadequate exposure to green pasture, and possible exposure to wood preservatives or insecticides. A role for copper deficiency has not been substantiated. A familial hereditary pattern is recognized for Appaloosa, Standardbred, and Paso Fino horses with EDM.

The average age of horses at initial presentation is about 6 months, but may be as much as 24 months. The clinical presentation is

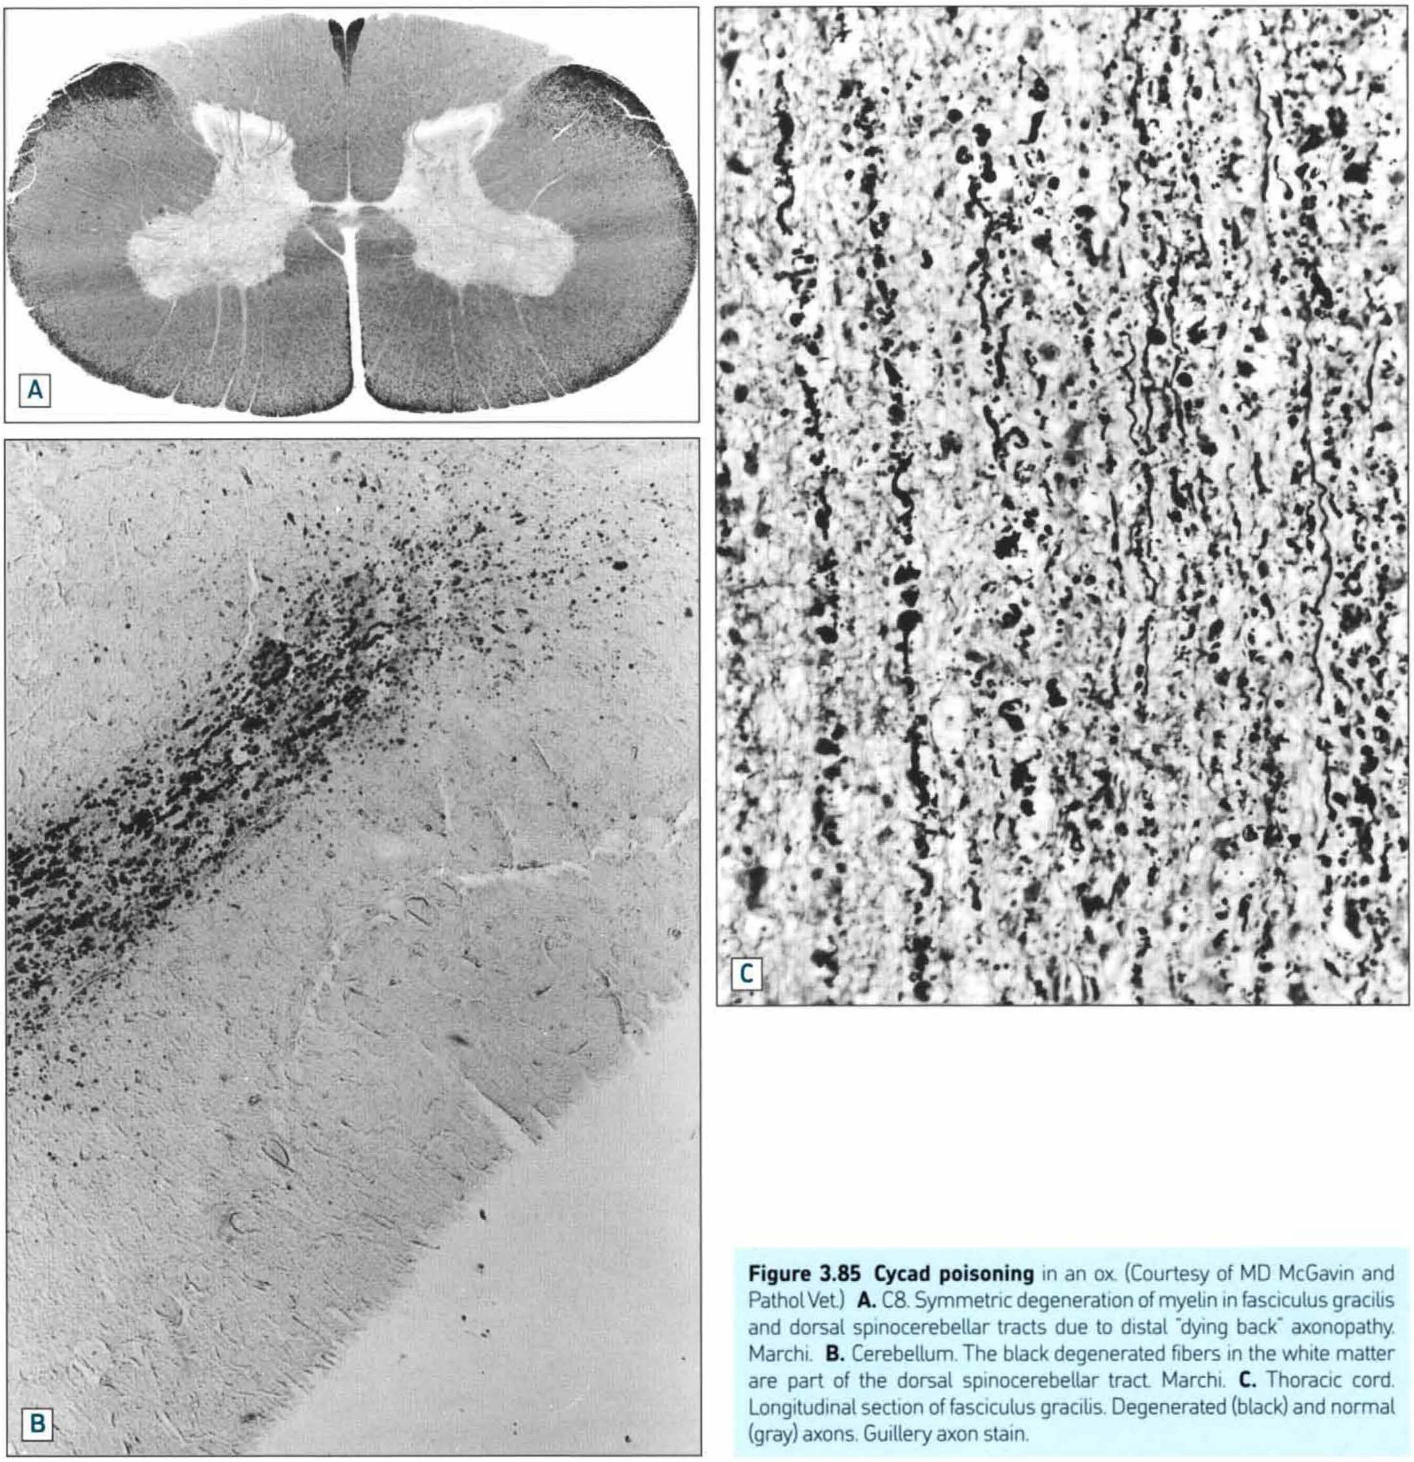

Figure 3.85 Cycad poisoning in an ox. (Courtesy of MD McGavin and Pathol Vet.) **A.** C8. Symmetric degeneration of myelin in fasciculus gracilis and dorsal spinocerebellar tracts due to distal "dying back" axonopathy. Marchi. **B.** Cerebellum. The black degenerated fibers in the white matter are part of the dorsal spinocerebellar tract. Marchi. **C.** Thoracic cord. Longitudinal section of fasciculus gracilis. Degenerated (black) and normal (gray) axons. Guillery axon stain.

dominated by disturbances of general proprioception and upper motor neuron function referable to the spinal cord, and thus closely resembles focal compressive myelopathy of the mid-cervical region. However, no skeletal or other gross lesions can be demonstrated.

Pathologically, there is evidence of *ongoing Wallerian degeneration and post-Wallerian astrogliosis in all funiculi throughout the spinal cord*, but concentrated in the ascending dorsolateral (spinocerebellar) and descending ventromedial (motor) funiculi of the cranial cervical and mid-thoracic segments. The changes are often most severe in the thoracic segments. Similar but mild changes are present in myelinated tracts of the caudal medulla and caudal cerebellar peduncles.

When well established in the thoracic cord segments, the process leads to considerable loss of myelinated axons and dense reactive astrogliosis that also involves the adjacent glia limitans. In some cases, the destructive process seems to reach an endpoint, with dense gliosis but little or no active Wallerian change. Chromatolytic and necrotic neurons, and axonal spheroids, can be found in Clarke's column (the nucleus of the dorsal spinocerebellar tract), which is located just dorsolateral and immediately adjacent to the central canal of the cord between the first thoracic and mid-lumbar segments. The disease involves total destruction of many neurons in this system, and macrophages containing a lipoidal pigment can also be found in this location. Disruption of axonal transport likely plays a crucial role in the pathogenesis of dystrophic axons in EDM.

The origin of the degenerating descending axons in the ventromedial tracts is uncertain, and there have been no reports of neuronal degeneration in the midbrain nuclei likely to be the source of these fibers. It is possible that the descending tract lesion is purely an axonopathy. Axonal spheroids and vacuoles have also been described in the lateral cuneate and gracilis nuclei of the caudal brain stem. These are the relay nuclei receiving the long ascending proprioceptive tracts of the spinal cord. However, even though this disease occurs in young horses, the changes in these nuclei may be nonspecific as they are commonly seen in a variety of situations, including animals with no overt clinical neurologic disease. In contrast to compressive cervical myelopathy (the wobbler syndrome), *there is simultaneous involvement in multiple cord segments of ascending* **and** *descending tracts*. This excludes focal compression of the cord as an etiologic factor. There is no obvious pathogenetic link between the various neuronal systems involved.

Axonal dystrophies

Diseases in which the pathology is characterized by axonal dystrophy, as described under cytopathology (see Figs 3.9, 3.10), have been described in sheep, horses, dogs, and cats.

One of the earliest axonal dystrophies documented occurred in **Suffolk sheep**. In this disease, described in California, lambs normal at birth develop progressive ataxia at 1–6 months of age. The lambs eventually become recumbent after a course of 10–12 weeks. It is virtually certain that the disease is inherited and appears to be a recessive trait. There are no specific gross changes, and *the diagnostic histologic lesion is the presence of numerous axonal spheroids*, in and adjacent to several gray matter areas. The consistently affected areas are as follows: the entire spinal gray matter, with spheroids in greatest numbers at the base of the dorsal horns, in Clarke's column and in the intermediolateral nuclei; the caudal brain-stem nuclei, gracilis, cuneate, accessory cuneate, inferior olivary, lateral reticular and lateral vestibular; the cerebellar roof nuclei with the exception of the dentate; and the rostral colliculi and lateral geniculate nuclei. The spheroids are the focally swollen terminations of sensory axons, and represent a genuine axonal dystrophy. The pattern of lesions indicates the involvement of two sensory systems, one visual and the other proprioceptive and possibly exteroceptive, and the clinical signs could be accounted for by perturbation of the latter.

An identical condition has been described in **Coopworth, Romney, and Perendale sheep** in New Zealand, while in Australia a disease in **Merino sheep** has been reported as an axonopathy, although the lesions described are consistent with axonal dystrophy. In this disease, as reported from localized areas of eastern Australia, sheep aged 1–4 years develop severe caudal gait abnormalities that are progressive and irreversible. Axonal spheroids are present in large numbers, predominantly in myelinated tracts in the mid- and hindbrain and throughout the spinal cord, being more abundant in the dorsal funiculi than the ventral. Wallerian changes are mild. In the brain, areas of predilection are the cerebellar peduncles, transverse pontocerebellar fibers, dorsolateral thalamic tracts, cuneate fasciculus, median longitudinal fasciculus and corticospinal tracts. Rather than being concentrated at terminal regions, the spheroids appear to be multiple along the course of individual axons. The cause remains undefined but seems likely to be a heritable defect.

In horses, neuroaxonal dystrophy is thought by some investigators to be a localized form of equine degenerative myeloencephalopathy. Affected breeds include Morgans, Haflingers, and Quarter Horses. In the **Morgan horse**, a clinical syndrome of pelvic limb dysmetria and incoordination is accompanied by intense axonal dystrophy in the accessory cuneate nuclei. Breeding experiments suggest a familial component, but no definitive inheritance pattern has been demonstrated.

In **Haflinger horses**, a report describes an ataxia syndrome first evident at about 4 months of age, with ataxia in the pelvic limbs more severe by about 2 years of age. A familial hereditary basis is proposed. Neuroaxonal dystrophy was evident as numerous spheroids in the nuclei gracilis, cuneate, solitary tract and intermediomedialis, and in Clarke's column. These changes were accompanied by astrogliosis and lipofuscin pigmentation of neurons and macrophages, and significantly reduced serum tocopherol values.

Canine diseases classified as axonal dystrophies have been described in a growing list of breeds, including Rottweilers, Collie sheepdogs, Chihuahuas, English Cocker Spaniels, Jack Russell Terriers, and Papillons.

In the **Rottweiler**, neuroaxonal dystrophy is a *familial progressive sensory ataxia*, with a pattern of occurrence suggestive of autosomal recessive inheritance. Abnormal expression of various proteins leads to severe disruption of axonal transport in dystrophic axons. Neurologic signs may be expressed before 12 months of age, often being first noticed as abnormal clumsiness. With time, there is steadily progressing ataxia and distinct hypermetria, particularly in the forelimbs, in which there is also toe-dragging and knuckling. Mild head tremor and incoordination may also become evident. By 4–6 years of age, nystagmus, crossed-extensor reflexes, and a positive Babinski sign may be present, but dogs remain alert and responsive. Strength and conscious proprioception are maintained throughout, and the signs are related mainly to a disturbance of unconscious proprioceptive input to the cerebellum.

At necropsy there may be mild patchy cerebellar atrophy, and the optic nerves appear small. The characteristic histologic feature is the presence of *massive numbers of axonal spheroids* (see Fig. 3.9A, B) in the nerve root entry zone of the dorsal horn throughout the spinal cord, in the vestibular, lateral, and medial geniculate, and sensory trigeminal nuclei, and in Rexed's laminae of the spinal cord. Fewer spheroids are present in the inferior olivary, trochlear, and oculomotor nuclei, and in the spinal cord ventral horn. Occasional spheroids are found in the globus pallidus, hippocampus, thalamus, hypothalamus, caudate nucleus, and reticular substance. In the cerebellum, lesions are concentrated in the vermis. Spheroids are present in the granular layer, white matter, and roof nuclei. There is some loss of Purkinje and granule cells.

Affected **Collie sheepdogs** have progressive ataxia and gait abnormalities first apparent at 2–4 months of age. The disease is strongly suspected to be inherited as an autosomal recessive trait. The lesions are purely microscopic and confined to the deep cerebellar and vestibular areas. Many axonal spheroids are present in the central cerebellar white matter and adjacent roof nuclei, and in the lateral vestibular nuclei. Wallerian degeneration is minimal and the cerebellar cortex unaffected.

In the **Chihuahua**, affected animals are normal until about 7 weeks of age, when there is sudden onset of tremor and gait disturbances. The pathogenesis remains undefined. Large numbers of axonal spheroids are present in the white matter of the internal capsule, cerebellum, lateral geniculate nucleus, rostrodorsal thalamus, acoustic tubercle, olivary nuclei, and the corticospinal and spinothalamic tracts.

In the **cat**, several axonal dystrophies have been reported. A GABAergic neuroaxonal dystrophy occurs in *feline Niemann–Pick disease type C*, an autosomal recessive lysosomal storage disease. An *autosomal recessive hereditary condition* has been as described in domestic shorthaired cats in association with an unusual lilac coat color. Clinical signs first become evident at 5–6 weeks of age as head bobbing. In the ensuing 8–10 weeks, there is progressively worsening ataxia, and possibly visual impairment and vestibular deficits. The process may then stabilize, and animals may survive to adulthood, but are poorly grown. Gross neuropathological change is confined to slight cerebellar atrophy, most obvious in the caudal vermis. Histologically there are numerous spheroids in the inferior olivary and lateral cuneate nuclei. Lesser numbers of spheroids are in the lateral mid-brain tegmentum, lateral and rostral ventral thalamic nuclei, and the cerebellar vermis. An additional feature is diffuse swelling of axons in the above locations and in the medial lemniscus, medial longitudinal fasciculus, central tegmental tract, and spinal nerve dorsal roots. Neuronal loss and gliosis can be found in the inferior olivary and lateral thalamic nuclei, and in the Purkinje and granule cell layers in the cerebellar vermis. Spheroids and neuronal loss are also evident in the spiral ganglion and organ of Corti in the inner ear.

Congenital axonopathy in Friesian/Holstein calves

A series of cases is described from Australia in which calves were recumbent from birth, and exhibited spastic paresis and a variety of other neurologic signs. The characteristic microscopic lesion is *active Wallerian degeneration in all funiculi throughout the spinal cord*, especially at the periphery. Similar changes are evident in the cerebellar peduncles, the median longitudinal fasciculus, spinocerebellar and rubrospinal tracts, and in the roots of cranial nerves III, V, VII, and VIII. In a few cases, mild degeneration occurs in the midbrain and some peripheral nerves. The Wallerian changes are accompanied by a very mild glial response and it is likely that the disease begins in utero shortly before birth. The pathogenesis is unknown, and an autosomal recessive trait is suspected.

Myeloencephalopathy in Brown Swiss cattle

The first clinical sign of *bovine progressive degenerative myeloencephalopathy*, known colloquially as *weaver syndrome*, is slight ataxia, appearing at 5–8 months of age and worsening progressively over the ensuing 12–18 months. At the advanced stage, there is severe truncal ataxia and pelvic limb dysmetria, with distinct proprioceptive deficits. This terminates in recumbency with its secondary complications. The condition is inherited as a simple autosomal recessive trait; the weaver gene is closely associated with a microsatellite locus for milk production on bovine synteny group 13.

The major and primary lesion is in the spinal cord white matter. At all stages of the disease, there is *active axonal degeneration, with both axonal lysis and spheroid formation*. Axonolysis imparts an appearance of status spongiosus to affected white matter, and advanced lesions have myelin loss and moderate gliosis. The axonopathy is present in both ascending and descending tracts at all levels of the cord, but is most severe in the thoracic segment. The process may begin in the thoracic segment and extends anterograde and retrograde from this site. Ultrastructural changes indicate disturbed axoplasmic transport and subsequent axonal degeneration. Mild axonal lesions of a similar character occur in the brain stem, but are inconsistent in their location. However, a consistent additional lesion is degeneration and loss of Purkinje cells from the cerebellar cortex.

Multisystem neuronal degeneration of Cocker Spaniel dogs

In this condition, reported from Switzerland, red-haired Cocker Spaniel dogs of both sexes develop slowly progressive neurologic signs from about 6 months of age. The clinical picture is dominated by behavioral changes, disorders of gait and balance, tremors, and sometimes seizures. Ultimately, the severity of signs necessitates euthanasia. The cause remains undefined, but a genetic basis seems likely.

Neuropathologic changes are bilaterally symmetrical and involve loss of neurons, predominantly in the septal nuclei, globus pallidus, subthalamic nuclei, substantia nigra, tectum, medial geniculate nuclei, and cerebellar and vestibular nuclei. The neuronal loss is accompanied by gliosis and axonal spheroids. In addition, the white matter of the fimbriae of the fornix, central cerebellum, corpus callosum, thalamic striae, and subcallosal gyri have intense gliosis, axonal spheroids, loss of myelin, and perivascular macrophages.

Neuronal inclusion-body disease of Japanese Brown cattle

An acute neurologic disease of Japanese Brown cattle is described from the island of Kyushu, in which there is hyperexcitability, fever, profuse sweating, and usually sudden death. The cause is unknown, but cases recorded have all been in females. Neuronal cytoplasmic inclusions have been demonstrated in the CNS of humans dying with multiple system atrophy.

There are no gross lesions of significance, but a large percentage of affected cattle have single, or sometimes multiple, *eosinophilic cytoplasmic inclusion bodies in large neurons of the midbrain, pons and medulla*. The inclusions are mostly in the axon hillock region, are oval in shape and about 18 μm in greatest diameter. Ultrastructurally, they appear as sequestrations of degenerate mitochondria, with associated aggregations of rough endoplasmic reticulum and lipofuscin bodies.

Central and peripheral neuronopathies and axonopathies

Organophosphate poisoning

The toxicity of organophosphates (OPs) is based on their ability to phosphorylate and inactivate a number of esterases for which they can act as substrates. The acute inactivation of acetylcholinesterase is a well-known effect, exploited for pesticidal and anthelmintic purposes. Our concern here is with *delayed neurotoxicity* that follows 2–25 days after exposure and that involves the inactivation of esterases within neurons. Inactivation of esterases tends to be irreversible and recovery depends upon synthesis of new enzyme, and this will vary with the compound and the particular enzyme(s) inactivated. There is also wide individual and species variability in sensitivity to neurointoxication. OPs are derivatives of phosphoric, thiophosphoric, and dithiophosphoric acids, and are used not only as poisons but also in industrial applications in hydraulic systems, as high-temperature lubricants, and as plasticizers. Delayed neurotoxicity, which may be induced by OPs that have no acute effect on acetylcholinesterase, is particularly a property of the *arylphosphates*, the best known being *triorthocresyl phosphate* (TOCP).

The clinical presentation is characterized by the onset of ataxia, weakness and proprioceptive deficits, and ultimately paralysis. Severe dyspnea and loss of vocalization are often present in cattle and pigs, and hypomyelinogenesis is described in piglets and laryngeal nerve degeneration in horses given organophosphate anthelmintics.

The pathology and pathogenesis of delayed OP intoxication have been studied quite thoroughly. OPs are not cumulatively toxic, but a single threshold dose will induce central and peripheral distal axonopathy. *Multifocal degenerative changes develop in distal regions of axons*, with accumulations of organelles in the regions of proximal paranodes producing marked swellings. Axonolysis then follows and there may be cycles of attempted regeneration and further degeneration. In peripheral nerves, these changes are most intense in the intramuscular segments, and involvement of the recurrent laryngeal nerves makes *aphonia* a prominent sign in many cases. In the CNS, axonal degeneration is focused at the distal extremities of the long descending and ascending spinal tracts. The picture is dominated by axonal swellings, microcavitation, and secondary myelin loss.

Coyotillo poisoning

The coyotillo or buckthorn shrub, *Karwinskia humboldtiana*, is indigenous to the southwest USA, Mexico, and Central America, and its fruits are toxic to many species, including humans. The neurotoxin present in the fruit is *tullidinol*. Goats are most commonly affected, and intoxication is first manifested as hyperesthesia, which is followed by ataxia, gait abnormalities, and weakness, with signs developing over a couple of weeks. If the polyneuropathy is mild, recovery may occur.

Pathologically there is a *severe, predominantly motor, distal peripheral axonopathy* that appears to be the major pathological event, although there is significant segmental demyelination as well. Denervation atrophy becomes apparent in skeletal muscle. In the CNS, numerous swellings may develop in the proximal axons of cerebellar Purkinje cells, appearing in the granule cell layer and the folial white matter. Swollen axons may also be found in the lateral and ventral funiculi of the spinal cord.

Mesquite toxicosis in small ruminants

Various species of mesquite (*Prosopis*) are widespread on rangeland in the southwestern USA, Mexico, and Central and South America. Goats are more likely to be exposed given their browsing habits. Ingestion of the leaves, pods, and seeds of *Prosopis glandulosa* (honey mesquite) and *P. juliflora* (velvet mesquite) can cause mandibular tremors, tongue protrusion, drooling, dysphagia, and weight loss due to selective toxicity to cranial nerve nuclei. Histologic lesions consist of fine vacuolation of the perikaryon of neurons in the trigeminal nuclei and occasionally the oculomotor nuclei. Wallerian degeneration occurs in the mandibular and trigeminal nerves, with resultant denervation atrophy of muscles that they innervate.

Aspergillus clavatus toxicosis

An acute clinical syndrome of cattle and sheep has been reported from several countries associated with a mycotoxicosis caused by *Aspergillus clavatus.* Most outbreaks are caused by fungal growth on industrial organic waste or stored products or by plants grown in hydroponics. The fungus is known to produce a variety of toxic metabolites including patulin, kojic acid, cytochalasins, and tremorgenic mycotoxins. The toxic syndromes observed in animals are suggested to result from synergistic action of these toxins. The clinical syndrome is dominated by acute onset of drooling and ataxia that progresses to recumbency and death. The neuropathology is characterized by *acute central chromatolysis of neurons* in the red and vestibular nuclei, and in spinal ventral horn gray matter and ganglia. Wallerian degeneration and myelin edema are evident in all tracts of the spinal white matter.

Arsenic poisoning

Animals may be poisoned by arsenic by ingestion or percutaneous absorption, the toxic dose by the latter route being considerably less than the toxic oral dose. The commonest sources of arsenic are fluids used as insecticides and herbicides. Most arsenical dips and sprays for animals contain sodium arsenite and, after these operations, a considerable but nontoxic amount of arsenic is absorbed through the skin. Percutaneous absorption is increased if the animals are hot at dipping and kept hot afterwards, and if they are not allowed to dry quickly. Absorption is rapid through shear wounds and through hyperemic skin such as of the thighs and scrotum of rams in the breeding season. Local high concentrations of arsenic on the skin also cause local acute dermatitis.

Herbicides of most importance are those containing *sodium arsenite, lead arsenate, and arsenic pentoxide*, and poisoning occurs usually when animals get access to recently contaminated pasture. A variety of mistakes and accidents commonly expose animals to these compounds. Paris green (cupric acetoarsenite), used as poison for grasshoppers and other parasites of plants, is occasionally responsible for poisoning. Ore deposits frequently contain large amounts of arsenic, and chronic arsenical poisoning can occur when pasture and drinking water are contaminated by the exhaust from smelters.

The toxicity of arsenicals varies considerably depending on the solubility of the salt and, in the case of organic arsenicals, on the rate at which the arsenic is released from organic bondage. The syndromes of arsenic poisoning differ according to acuteness or chronicity and also according to whether the arsenic is organic or inorganic, but these latter differences are probably not qualitative. One, and perhaps the main, *mechanism of action of arsenicals is combination with, and inactivation of, sulfhydryl groups* resulting in general depression of metabolic activity. The organs most susceptible to metabolic decline are the brain, lungs, liver, kidney, and alimentary mucosa. In poisoning by inorganic arsenic, the pattern of signs and lesions is the same regardless of the route of absorption, thus indicating that, although alimentary tract signs may dominate the clinical disturbance, they are part of the systemic intoxications. In poisoning by organic arsenic, which is observed in pigs, the signs are referable entirely to the nervous system.

The ingestion of very large amounts of a soluble **inorganic arsenical** may result in death in less than 24 hours. There is profound depression and peripheral circulatory collapse; at postmortem in such cases, there are usually no lesions, or at most, slight edema of the abomasum.

With poisoning of lesser severity, 1–2 days lapse between the ingestion of arsenic and the onset of clinical signs. The onset is sudden with acute abdominal distress, nervous depression, circulatory weakness, and, after some hours, terminal diarrhea and convulsions. Some cases may survive for several days and show additional neuromuscular signs of tremor and incoordination. In chronic poisoning, the signs are nonspecific, being those of unthriftiness, capricious appetite and loss of vigor. Pregnant cows may abort. Visible mucous membranes and the muzzle may be hyperemic and inflamed.

Lesions produced by *acute poisoning by inorganic arsenicals* can be largely explained on the basis of *vascular injury*. There is splanchnic congestion with petechial hemorrhages of serous membranes. The mucosa or submucosa of the stomach or abomasum is intensely congested, and the abomasal plicae are usually thickened by edema fluid. There are intramucosal and submucosal hemorrhages of patchy distribution, and these lead quickly to more or less extensive ulceration of the stomach and intestine. The intestinal content is very fluid and may contain shreds of mucus and detritus. There is mild, usually fatty, degeneration of the parenchymatous organs, sometimes with hepatocellular necrosis and edema of the kidney. Lesions in the brain develop in the course of 3–4 days and consist of moderate diffuse cerebral edema and petechiation. The hemorrhages, which are of capillary type and apparently due to necrosis of the walls of these vessels, are distributed throughout the white matter.

The anatomical changes in *chronic arsenical poisoning* have the same distribution as in the acute poisoning. The stomach and gut remain mildly congested, edematous, and ulcerated, and there are prominent fatty changes in the heart, liver and kidneys. Neural lesions may not be found in the CNS except for those changes that are secondary to peripheral neuropathy. In both sensory and motor components of peripheral nerves, there is degeneration of myelin and axons.

The application of arsenic to the skin may cause acute and chronic dermatitis if cutaneous circulation is poor, but if the circulation is good the arsenic tends to be absorbed and to cause systemic rather than local toxicity. Dermatitis, when it develops, is characterized by intense erythema, necrosis, and sloughing; the residual ulcerative lesions are indolent.

Organoarsenical phenylarsonic acid derivatives are commonly used as feed additives for swine, for growth promotion and the control of enteric disease. Poisoning is thus largely confined to this species, and is caused by accident or careless management; however, the margin of safety can be quite low when arsanilic acid is used to control swine dysentery. Two syndromes are recognized, caused by p-aminophenylarsonic acid (**arsanilic acid**), and 3-nitro-4-hydroxyphenylarsonic acid (**3-nitro**).

In *arsanilic acid poisoning*, there is usually acute onset of cutaneous erythema, hyperesthesia, ataxia, blindness, vestibular disturbances and, terminally, muscular weakness. There are no gross neural lesions but, microscopically, mild edema of the white matter may be present in the brain and cord, and a few shrunken and degenerate neurons in the medulla. Extensive Wallerian degeneration frequently develops in the optic and peripheral nerves, but may not be present in spite of severe clinical signs.

In *3-nitro poisoning*, there is a syndrome of repeated clonic convulsive seizures following exercise, with progression to paraplegia, but no blindness. Pathologically there is Wallerian degeneration consistent with distal axonopathy in the spinal cord. The lesion is intense in the dorsal proprioceptive and spinocerebellar tracts of the cervical cord, and lateral and ventral funiculi of the caudal cord. Optic and peripheral neuropathy are mild.

Neonatal copper deficiency (swayback, enzootic ataxia)

It is generally accepted that maternal/fetal copper deficiency is a major factor in a characteristic neurologic disease of lambs, goat kids, and piglets. The syndrome has been most studied in the lamb, and the terms "*swayback*" and "*enzootic ataxia*," used to describe the signs shown by affected animals, are entrenched as names for the disease. The provision of adequate copper supplementation of pregnant animals at risk can effectively eliminate the disease in their offspring, and treatment of affected animals with copper may produce some remission of signs. Supplementation of unaffected lambs at risk has also been claimed to be effective in prevention. Other manifestations of copper deficiency, such as "steely wool," osteoporosis, and hypopigmentation of black wool, could be expected in affected sheep flocks.

The bioavailability of and physiologic requirement for copper are influenced by many factors, and a functional deficiency state is often determined by overall availability rather than actual copper intake. Thus there may be *absolute primary deficiency*, or *conditioned secondary deficiency*, brought about by reduced absorption from the gut, reduced availability in tissues, or enhanced excretion. The interactive roles in copper metabolism of soil and dietary molybdenum, sulfate, iron, and zinc are important. *Molybdenum* is a prime antagonist for copper and, in the presence of adequate sulfate, limits the capacity to absorb copper from the gut and the capacity to store absorbed copper in the liver. This antagonism is unique to ruminants and is provided by the formation in the rumen of *thiomolybdates*, a series of anions in which sulfur progressively substitutes for oxygen in the molybdate ion. Copper complexed to thiomolybdate forms insoluble complexes that are poorly absorbed; this is primarily an effect of maximally substituted tetrathiomolybdate; lesser substituted thiomolybdates may be absorbed and be responsible for reducing copper availability at the local tissue level.

Iron is an antagonist to copper, although the mechanism is not known. Experimental exposure of ruminants to high intakes of iron induces severe hypocupremia, but a role for iron in naturally occurring copper deficiency syndromes is not of known importance.

Copper is required for the catalytic activity of enzymes that are essential for neural function and include tyrosinase for melanin synthesis, cytochrome oxidase for electron transport in mitochondrial respiration, copper/zinc superoxide dismutase for antioxidant activity, dopamine hydroxylase for catecholamine synthesis, and ceruloplasmin for iron homeostasis. Other copper-containing enzymes, such as lysl oxidase, are important in animal disease but anomalous relationships between copper analyses and actions and the occurrence of prenatal and neonatal disease suggest that there are as yet unidentified enzymes or functions required for developing lambs and kids.

Species and breed differences, pregnancy, plant/soil relationships, fiber content of the diet, and seasonal conditions will govern nutritional requirements. Aspects of copper metabolism differ significantly between sheep and goats. It is also possible that undefined factors may bear significantly on metabolic availability. In spite of this, the copper content of CNS tissue in affected neonates tends to be consistently below normal values, and represents the most reliable tissue assay. It is also true that some individuals with similarly low copper values can be clinically normal, although this holds more for goat kids and piglets than lambs. As the ability to metabolize copper is not impaired, tissue concentrations in affected animals may return to normal fairly rapidly after dietary correction, with concentration in the liver recovering more rapidly than in the CNS.

The effects of copper deficiency on the CNS occur in utero and during early neonatal life. Despite intensive investigation, the biological role of copper in the developing nervous system remains unclarified and contentious. Copper is a component of the enzymes cytochrome oxidase and superoxide dismutase, and of the protein ceruloplasmin. Interference with the functions of these has variously been proposed as the molecular basis of the disease via suppression of mitochondrial respiration and phospholipid synthesis or via damage inflicted by superoxide radicals. It should be added that lambs with no clinical signs have been found to have neuronal degenerative lesions, and lambs with clinical signs have minimal lesions.

Clinical swayback in lambs occurs in a congenital form and a delayed form, also called "enzootic ataxia" in which, after being normal at birth, lambs suddenly develop signs at any time between 1 week and several months of age. The clinical signs are dominated by motor

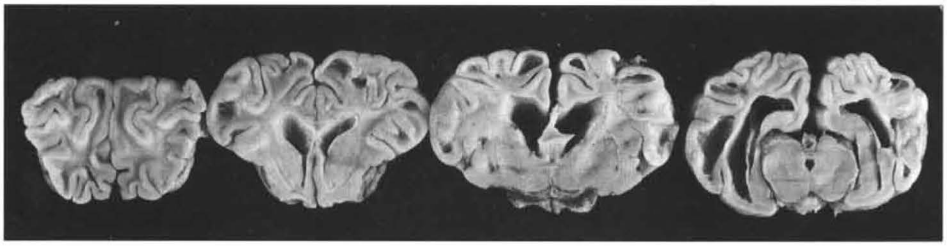

Figure 3.86 Bilaterally symmetrical cavitation of cerebral white matter in **swayback** in a lamb. (Reprinted with permission from Innes JRM, Saunders LZ. *Comparative Neuropathology*. Academic Press, New York, 1962.)

disturbances, with staggering and ataxia. Congenital cases may be blind and unable to stand.

Some lambs with *congenital swayback* have an extensive structural lesion grossly evident in the *cerebral white matter*, but all have some degree of the neuronal degenerative changes described below for the delayed disease. The former lesion is bilateral and symmetrical gelatinous softening or cavitation (Figs 3.27A, 3.86), which may be restricted to the occipital pole or may involve the entire corpus medullare, sparing only a thin rim of white matter adjacent to gray. Histologic and ultrastructural descriptions of the gelatinous lesion are meager, but marked edema with mild fibrillary astrogliosis and a paucity of myelin can be expected. Some myelin degradation products are usually present, but never in great quantity, and gitter cells are sparse. It seems likely that many axons are initially spared, but that rapid dissolution of all elements leads to cavitation. The pathogenesis of this lesion remains obscure; it seems that both hypomyelination and demyelination may be involved but the basis of the tissue lysis is unexplained.

Although lambs with *delayed swayback* do not have lytic lesions in the cerebral white matter, they consistently have changes in both gray and white matter in other parts of the neuraxis. Most investigators consider that these changes largely develop and progress after birth, but this is not absolute, as pointed out above. Extensive Wallerian degeneration is concentrated in dorsolateral and ventromedial tracts throughout the spinal cord. *The pattern of tract degeneration is suggestive of a distal axonopathy*. In addition, conspicuous degenerative changes are present in neurons in the red, lateral vestibular, medullary reticular, and dorsal spinocerebellar nuclei in Clarke's column, and in the spinal motor neurons, particularly in the intumescences (see Fig. 3.1). Many such neurons are undergoing central chromatolysis, and some have nuclear rhexis and lysis. A few may be undergoing neuronophagia. Swollen neurons have been shown by immunocytochemistry to contain masses of phosphorylated neurofilament epitopes. Sites of neuronal loss are marked by fibrous astrogliosis.

Wallerian degeneration may be apparent in ventral spinal nerve exit zones and rootlets, and in peripheral nerves (see Fig. 3.6), although this finding has not been highlighted as much as in goat kids. The pattern of axonal changes is consistent with the degenerating axons being those arising from the nuclei where neurons are also degenerate. Opinion favors the hypothesis that the lesions represent primary neuroaxonal degeneration with secondary myelin loss, although the myelin has been shown to be qualitatively abnormal and therefore theoretically unstable.

A very small number of lambs may have a *cerebellar lesion*, or *cerebrocortical necrosis*, as described below for goat kids. A further variant reported in lambs with delayed swayback is the occurrence of *acute cerebral edema* that is sometimes unilateral and involves both gray and white matter. Small gelatinous or cystic foci may be present at the corticomedullary junction. The pathogenesis is unexplained.

There is no unifying explanation for the spectrum of changes found in swayback, nor for the molecular mechanisms relating to the role of copper. It has been proposed that the spectrum reflects a critical level of copper deficiency, cytotoxic at particular times when different regions of the developing brain/spinal cord are undergoing growth spurts. It has also been suggested that the lesions reflect oxidative damage concentrated in particular vascular fields.

In **goat kids**, the clinicopathologic spectrum is similar, but has different emphasis. The great majority of reports describes delayed swayback, with a high incidence of cerebellar degeneration/dysplasia, and of peripheral motor axon degeneration. The cerebellar changes include necrosis and dystopia of Purkinje cells, depletion of internal granule cells, and Wallerian degeneration in folial white matter. The lesions tend to be multifocal and may involve vermis and hemispheres or be restricted to the vermis. In a very few cases, congenital swayback is reported in kids, and in only two individuals were cerebral gelatinous and cavitating changes found. An additional variant reported in both lambs and kids is the occurrence of diffuse cerebrocortical necrosis.

Lesions in **piglets** have the same general character in regard to Wallerian changes as described above for delayed swayback, but chromatolytic neurons are not evident. A swayback-like disease has also been documented in adult captive *red deer*, but the role of copper is uncertain.

Progressive axonopathy of Boxer dogs

This progressive disorder is inherited as an autosomal recessive trait, and begins in early life. Defects in slow axonal transport are involved in the pathogenesis of this condition; myelin lesions may then occur in response to primary axonal changes, and represent adaptive remodeling to alterations in axonal caliber and metabolism.

Clinical signs first become apparent at about 2 months of age and progress fairly rapidly until 12 or 18 months, when they may either become static or advance very slowly. The dominant clinical sign is *hindlimb ataxia*, with proprioceptive deficits, hypotonia, and areflexia often being evident.

Degenerative lesions have been described in the spinal cord, caudal brain stem, optic nerves, spinal and cranial nerves, and major autonomic nerve trunks. *Morphologic changes are most obvious in the spinal cord and caudal brain stem*, and their intensity seems to parallel the clinical progression. Axonal spheroids develop in the spinal cord and are concentrated in the ventral and ventrolateral funiculi in the cervical and thoracic segments. A few axons undergoing Wallerian degeneration are also evident, but are always in a minority. Myelin sheaths are thinned around the spheroids, as would be expected, but attenuated sheaths may also occur around axonal segments not obviously swollen. Vacuolation of myelin segments is also a feature. These white matter changes have no obvious tract distribution. In the gray matter, spheroids are found in many nuclei of the caudal brain stem, and to a small extent in the spinal cord. However, from the diencephalon forward, there are virtually no gray matter lesions. Axonal swellings and myelin vacuolation are prominent in the optic nerves in the area of the chiasm.

In spinal nerve roots, there are, early in the disease, focal axonal swellings and a range of myelin abnormalities, including vacuolation, thinning, and segmental loss. With time, the involvement of ventral roots is appreciably more severe than dorsal roots. As the disease advances, such changes progress distally down the nerves, but axonal degeneration is accompanied by regeneration, and denervation of muscle is not significant. Changes of a similar character have been described in cranial nerves and large autonomic trunks.

Degenerative radiculomyelopathy of German Shepherds and other dogs

This idiopathic condition is a slowly progressive, irreversible, adult-onset disease, characterized by paraparesis and truncal ataxia. The condition is not completely defined, but may be hereditary, and the neurodegeneration appears to have an immune-mediated component. Vitamin E deficiency seems unlikely to be involved.

Some studies describe lesions in spinal nerve roots and cord, whereas others restrict changes to the cord; secondary degenerative changes have been noted in brain nuclei. In about 10–15% of cases, there is loss of patellar reflexes and degeneration in femoral nerves. Arguments have been advanced for and against a distal dying-back type of pathogenesis, and the affliction of dogs of large breeds other than the German Shepherd.

Axonal degeneration and evidence of demyelination are present in the spinal cord and probably, on occasion, in the spinal nerves. While there have been descriptions of symmetrical degenerative changes at the distal extremities of long tracts in the cord, a separate study documented myelin vacuolation, myelin deficiency, a few spheroids and some Wallerian degeneration, distributed randomly and asymmetrically, and most intense in the thoracic segments.

Giant axonal neuropathy of the German Shepherd Dog

This uncommon disease is a *distal axonopathy* in which disorderly clumps of neurofilaments accumulate towards the extremities of long axons, and their most distal regions eventually degenerate completely. The *neurofilamentous accumulations create the very large argentophilic axonal swellings* that give the disease its name.

The clinical onset is at about 15 months of age and there is progression to paraparesis, ataxia, and megaesophagus within a few months. The disease is apparently inherited in an autosomal recessive manner.

In the CNS, the giant swellings are found in the rostral regions of the ascending fasciculus gracilis and the dorsal spinocerebellar tracts, and in the caudal regions of the descending lateral corticospinal tracts. In the peripheral nervous system, they are found in both myelinated and unmyelinated large fibers in the more distal regions of the major nerves of the limbs and the recurrent laryngeal nerves. Small focal axonal swellings are also scattered through various regions of the brain from the cerebral cortex back to the caudal brain stem, and on to the dorsal and intermediate gray columns of the cord. Some Wallerian changes accompany the small swellings in these areas.

Progressive motor neuron diseases

There is a group of neurodegenerative diseases, described in several species, which have a common clinical and pathological theme, and which can therefore be dealt with together. They appear to have as a counterpart *amyotrophic lateral sclerosis in humans*. Diseases with this basic theme have been described in Brittany Spaniels, Swedish Lapland Dogs, Rottweiler dogs, domestic shorthaired cats, various breeds of horses, Yorkshire and Hampshire pigs, and in Brown Swiss, Danish Red, Piedmont, and Holstein-Friesian calves.

The clinical presentation in **horses** is dominated by progressive lower motor neuron paralysis which usually ends in tetraplegia and muscle atrophy. There is preferential damage to type 1, high-oxidative fibers, reflected in wastage especially of postural muscles. The pathological findings are dominated by denervation atrophy of pelvic and pectoral muscle groups, and by regressive changes in spinal motor neurons. Other neurons in the motor hierarchy may be afflicted, including the pyramidal cells of the motor cortex. In some instances, neurons in the brain stem and peripheral ganglia are also involved. In the earlier stages of neuronal degeneration, there may be chromatolytic swelling of the soma, with reduced basophilia, and fading of the nucleus, which tends to remain centrally located. In many of the diseases, the swollen cell bodies are often crowded with neurofilaments. Eosinophilic inclusions may be present in the cytoplasm, usually representing clustered remnants of normal organelles trapped amongst arrays of neurofilaments (see Fig. 3.4). In some cases, these inclusions may be found to have the characteristics of Hirano, Lewy, or Bunina bodies described in human neuropathology. The neuronopathy progresses eventually to neuronal death on a cell-by-cell basis, with individual neurons in different stages of the process at any one time. Ultimately there may be considerable neuronal loss, with residual gliosis, and Wallerian change in motor nerves and spinal white matter.

These diseases are considered to be primary metabolic dysfunctions of the nerve cell body; most have an apparently *genetic basis* and an early-age onset. Hereditary spinal muscular atrophy in calves may result from a defect in the survival motor neuron gene. A series of horses is reported from the northeast United States in which the epidemiology strongly suggests an environmental cause. Horses particularly at risk are those that for long periods do not have access to green pasture. Vitamin E status is deficient, which suggests that the lesion is a result of *free radical injury*. The presence of lipofuscin pigments in vascular endothelium and in the retinal pigment epithelium in some affected horses supports the concept of *vitamin E deficiency*. It should be noted also that the neuronal lesions in congenital copper deficiency have many of these features (see Fig. 3.1). Variations on the basic theme are provided in terms of the age of onset and speed of progression of signs, the extent and pattern of frank neuronal degeneration, involvement of nuclei in the mid- and hindbrain, and the presence of Wallerian degeneration in the spinal white matter and peripheral nerves.

Probably the most comprehensively described condition is **hereditary spinal muscular atrophy of Brittany Spaniels**, and it will serve as a generic example. In the Spaniels, there is *autosomal dominant* inheritance and three phenotypic variants: chronic, intermediate, and accelerated. The latter leads to quadriplegia at about 3 months of age, the others over several years, if at all. At the end-stage, there is pronounced denervation atrophy of pectoral and pelvic muscle groups, as well as of the tongue and masseter muscles.

The neuropathology is marked by degenerative change in spinal motor neurons, focused in the intumescences, with similar involvement of the hypoglossal and trigeminal motor nuclei. Particularly in the accelerated, homozygous variant, there are numerous pale, swollen, and chromatolytic motor neurons, with occasional cells undergoing fragmentation and necrosis. Swollen neurons are depleted of ribosomes and a few are packed with neurofilaments (Fig. 3.87). Most characteristically, large argentophilic swellings are present in the proximal segments of many axons close to the affected cell bodies. These have been shown by electron microscopy to be *tangles of disorganized neurofilaments* (Fig. 3.88A). All these changes are much less evident in the more chronic, heterozygous, forms of the disease and clinical weakness is only mild in many cases. Although it is established that there is a defect in the metabolism of neurofilaments as they move from the cell body into the proximal axon of individual neurons, it is not yet clear that this is the primary molecular lesion. Recent studies have shown that there is growth arrest of spinal motor neurons and, initially, affected pups have a greater than normal number of these cells, with a shift to a smaller cell size. Ventral root axons undergo atrophy, which may be followed by loss of entire neurons.

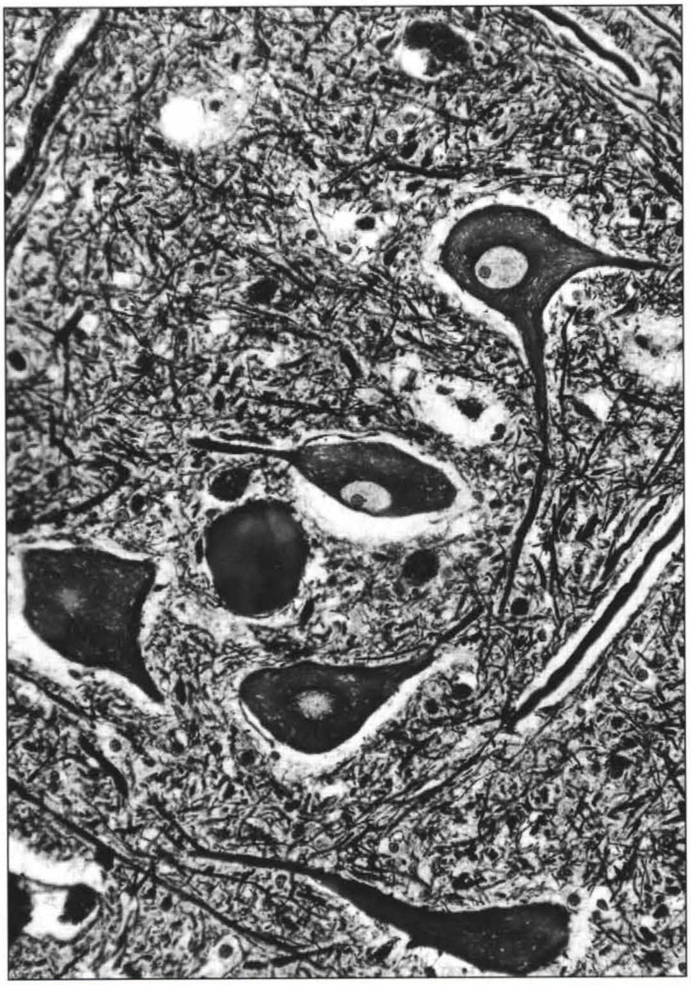

Figure 3.87 Proximal axonal swelling packed with neurofilaments in a spinal motor neuron of a Brittany Spaniel with **motor neuron disease**; silver impregnation. (Courtesy of LC Cork.)

In the **Swedish Lapland Dog**, the pattern of lesions is different, there being degeneration of spinal motor neurons only in the lateral aspects of the intumescences; neuronal degeneration also occurs in spinal ganglia and cerebellar Purkinje cells, but not in brain stem nuclei. The disease has been termed *neuronal abiotrophy*, and is included here because of the dominance of denervation atrophy of muscle in the clinical presentation. The atrophy is concentrated in the more distal muscle groups of the limbs, in keeping with the topography of degenerate spinal motor neurons. Any cerebellar deficits are probably over-ridden by the lower motor neuron impairment.

In the **English Pointer** dog, a strikingly different motor neuron disease has been described in which weakness and muscle atrophy become obvious at about 5 months of age and severe by about 9 months. There is correspondingly severe distal degeneration of peripheral motor nerves and denervation of muscle. However, rather than the changes described above, spinal motor neurons are

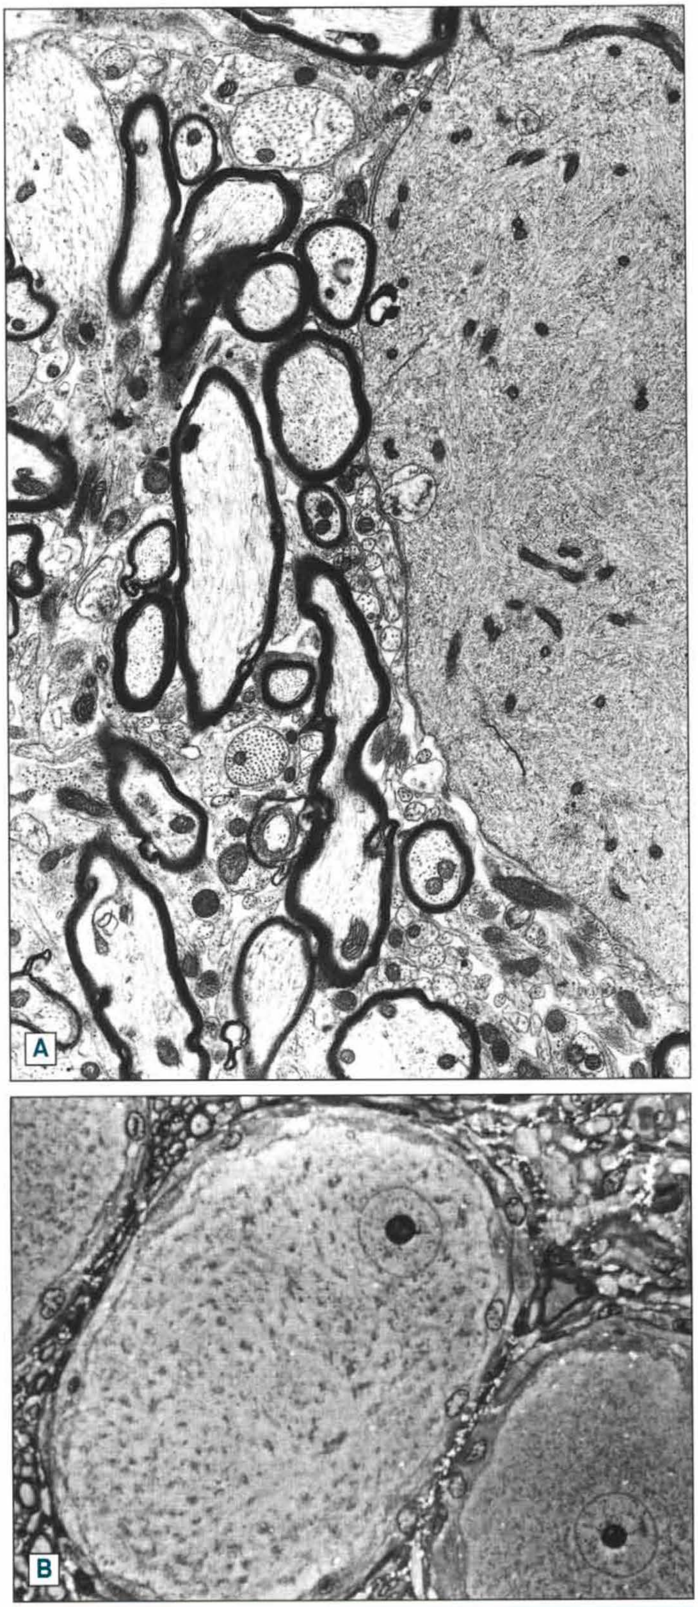

Figure 3.88 A. Proximal axonal swelling packed with neurofilaments in a spinal motor neuron of a Brittany Spaniel with **motor neuron disease**. (Courtesy of LC Cork.) **B.** Swollen neuron in a spinal ganglion of a "**shaker calf**": Nissl substance is dispersed by neurofilamentous masses. (Courtesy of CG Rousseaux.)

filled with *cytoplasmic lipid inclusions* reminiscent of those seen in the gangliosidoses and mucopolysaccharidoses, and in some drug-induced conditions. No significant loss of motor neurons is apparent, and similar inclusions are present in the hypoglossal and spinal accessory nuclei, but not elsewhere.

Focal, asymmetrical spinal motor neuron degeneration with acute onset and a rapid course is described in **German Shepherd** pups. The affected neurons are within the cervical spinal cord intumescence, and exhibit peripheral chromatolysis or vacuolation. There is secondary denervation and wasting of forearm muscles. Progressive lower motor neuron disease has also been reported in **Saluki** and **Griffon Briquet Vendeen** pups.

Neurodegeneration of horned Hereford calves

The term "**shaker calf**" refers to a disease in which newborn horned Hereford calves are unable to stand without assistance and develop generalized fine tremors and profound muscular weakness. While they often die in the neonatal period because of secondary complications, some, after a short period of apparent remission, show relentlessly progressive spastic paraparesis, but remain alert and may survive for some months. The disease is presumed to be inherited on the basis of pedigree analysis. The fundamental metabolic defect remains to be characterized.

The pathology is characterized by dramatic swelling of the cell bodies and processes of neurons throughout the spinal cord. Swelling is due to the *accumulation of masses of neurofilaments* that impart a faintly fibrillar, amphophilic appearance in routine sections. This lesion involves ventral horn motor neurons, sensory neurons of the substantia gelatinosa, Clarke's column, and the intermediolateral (sympathetic) nuclei. Neuronal necrosis is minimal, although the site of occasional cell loss can be found as nodules of reactive glia. Some

Wallerian degeneration is evident in ventral spinal nerve roots and the ventromedial spinal white matter.

The neuronal lesion is also present in the major motor nuclei of the brain stem, the reticular formation and the cerebellar Purkinje cells, and to a slight degree in the lateral geniculate nucleus and layer 5 of the frontal cortex. Some affected cells are evident in peripheral ganglia (Fig. 3.88B), including the myenteric plexus, and in the retinal ganglion cells.

Neuropathy in Gelbvieh calves

A familial, and likely hereditary, condition has been reported in Gelbvieh calves that had developed hindlimb ataxia and paresis, and were found histologically to have peripheral neuropathy and proliferative glomerulopathy; skeletal muscle degeneration was prominent in some cases. Degeneration was severe in peripheral nerves, dorsal and ventral spinal nerve roots, and less marked in dorsal fasciculi of the spinal cord.

Progressive neuronopathy of the Cairn Terrier

Progressive neuronopathy occurs only in Cairn Terriers and is suspected to be inherited. This multisystem chromatolytic degeneration clinically resembles globoid cell leukodystrophy, from which it can be differentiated clinically by the exercise-induced deterioration of neurological signs in progressive neuronopathy. Animals of both sexes develop hindlimb weakness, tetraparesis, ataxia, head tremor, and loss of reflexes between 5 and 7 months of age.

Both central and peripheral chromatolysis of neurons are evident, and occur in Clarke's column and dorsal and ventral horn cells in the spinal cord, in sensory ganglia, and in the cuneate, lateral cuneate, glossopharyngeal, vagus, reticular, lateral vestibular, mesencephalic trigeminal, red and cerebellar roof nuclei. Wallerian degeneration is present in lateral and ventral funiculi of the cord, to various degrees, and also in dorsal and ventral spinal nerve roots.

Ultrastructural studies on one case suggested that the chromatolytic change was associated with depletion of ribosomes and increased numbers of mitochondria in perikarya, and that Wallerian degeneration was probably secondary to the metabolic disturbance in the cell body. This case was also marked by onset of signs at 11 weeks of age, bouts of cataplectic collapse, and thoracolumbar myelomalacia.

Primary hyperoxaluria in the cat

In this inherited metabolic disorder in cats, profound deficiency in the activity of D-glycerate dehydrogenase is associated with L-glyceric aciduria, hyperoxaluria and the heavy deposition of oxalate crystals in the renal tubules. This leads to *oxalate nephrosis* and renal failure before a year of age.

An accompanying neuronal lesion occurs in the form of large swellings in the proximal axons of spinal motor neurons, ventral roots, intramuscular nerves, and the dorsal root ganglia. These swellings are caused by *neurofilamentous accumulations*, and are accompanied by some Wallerian degeneration in peripheral nerves. There is no obvious metabolic link between the neuronal lesions and the other biochemical disturbances, and the syndrome may represent a dual genetic defect.

Bibliography

The dysautonomias

The term dysautonomia denotes a profound failure of both sympathetic and parasympathetic functions across several organ systems. Domestic animals affected include horses (**equine grass sickness**), cats (**Key–Gaskell syndrome**), and dogs. *Clostridium botulinum* is thought to play a role in equine dysautonomia and perhaps in the feline syndrome, which may hence be toxico-infectious forms of botulism.

Particularly in the cat, it is considered that there is a single episode of injury to neurons, with acute degeneration and subsequent reparative reactions if the animal survives for a number of weeks. There is a good correlation between the clinical signs and the extensive destruction in autonomic ganglia, and *autonomic denervation would account for the major functional disturbances.* The occasional expression of mild proprioceptive and lower motor neuron deficits may be explained by the lesions in dorsal root ganglia and spinal motor neurons respectively.

In the equine disease, the clinical picture is primarily the result of neurogenic obstruction of the alimentary tract with various parts of the tract involved to differing degrees, with distinct acute, subacute, and chronic forms. Clinical differential diagnosis can be exceedingly difficult. The outcome is usually fatal; some chronic cases may recover with intensive care.

In the cat, there is acute onset of clinical disease that in a few cases may resolve after many months, but many animals die or require euthanasia early in the course. Onset is marked by dilated pupils, prolapsed nictitating membrane, dry mucous membranes, megaesophagus, constipation, vomiting, and dehydration. In the dog, the most severe and consistent loss of autonomic neurons occurs in the pelvic, mesenteric, and ciliary ganglia. Minimal changes are reported in the CNS. Differential diagnoses in dogs include ganglioradiculitis (sensory neuronopathy).

In the acute phase, *extensive chromatolysis and death of ganglion cells* is present throughout the peripheral autonomic ganglia (Fig. 3.89), with axonal degeneration in autonomic nerve fibers. There is also neuronal

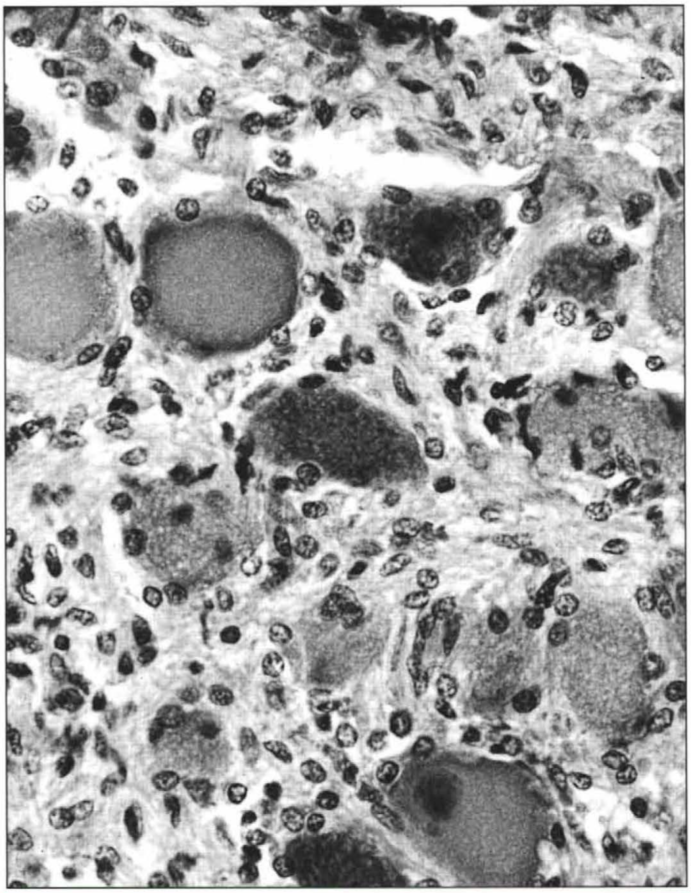

Figure 3.89 Central chromatolysis in ganglionic neurons of a horse with grass sickness.

degeneration in the nuclei of cranial nerves III, V, VII and XII, the dorsal motor nucleus of the vagus, and the nucleus ambiguus. Some neuronal degeneration may be found in dorsal root ganglia, and in the ventral horn and intermediolateral areas of the spinal gray matter. In later phases of the disease, depletion of neurons at the above sites is evident, with reactive and proliferative changes on the part of non-neuronal elements.

Sensory neuropathies in the dog

Sensory neuropathies are reported in an increasingly long list of various dog breeds. A small number of **English Pointer** pups from a particular mating developed a syndrome of acral mutilation and analgesia. The size of spinal ganglia was reduced, with reduced numbers of neurons, and reduced fiber density in the dorsolateral fasciculus of the spinal cord (Lissauer's tract). These clinical and morphologic findings are consistent with a *specific deficit in nociceptive pathways*. It is suggested that the presumably genetically based disorder involves both hypoplasia of the system and continued degeneration postnatally.

In **longhaired Dachshunds**, proprioceptive, nociceptive, and urinary deficits are associated with a *distal degenerative axonopathy*. Distal cutaneous nerves have marked loss of large myelinated fibers, and degenerative changes in both myelinated and unmyelinated fibers. In the spinal cord there is axonal degeneration in the fasciculus gracilis, of greatest intensity at its distal extremity in the cervical region.

Progressive myelopathy and neuropathy causing progressive ataxia in littermate **New Zealand Huntaway** dogs is described as a *central–peripheral distal axonopathy*, in which there is degeneration of axon and myelin in sensory, proprioceptive, and motor tracts of the spinal cord and to a mild degree in some peripheral nerves.

In dogs of **various breeds**, there are reports of diffuse ganglioneuritis, with destruction of primary sensory neurons and subsequent Wallerian degeneration and axonal loss in peripheral nerves in the spinal dorsal funiculi, spinal tract of the trigeminal nerve, and solitary tract. These cases are mentioned here as the *extensive axonal degeneration* is the more likely lesion to be routinely noted, and its pattern should immediately draw attention to the primary involvement of dorsal root ganglia. The pathogenesis of this ganglioneuritis is not known but may be similar to that of Guillain–Barré syndrome, a post-infectious syndrome in people.

Peripheral axonopathies

Lesions involving single peripheral nerves are termed **mononeuropathies.** They are usually the result of focal compression or contusion by trauma, tumor masses, or similar lesions, and involve centrifugal Wallerian degeneration about the lesion. If several nerves are randomly involved in such a way, the term **mononeuropathy multiplex** may be applied. **Polyneuropathy** describes bilaterally symmetrical involvement of several nerves, and carries the implication of a systemic disturbance.

From the clinical point of view, most peripheral polyneuropathies occur in association with polyneuritis or demyelination, but in this section our focus is on **noninflammatory axonopathies**, and the other types of disease are discussed elsewhere. Intense Wallerian degeneration of peripheral motor axons will of course accompany degeneration of the ventral spinal motor nerve cell bodies, as occurs in the motor neuron diseases previously discussed. Similarly, in the very rare primary sensory polyneuropathies, peripheral sensory fibers will degenerate, but the degeneration will also extend, with the central projections of these cells, into the dorsal funiculi of the spinal cord. In some intoxications, delayed organophosphate for example, peripheral neuropathy will be accompanied by central axonopathy, as has been illustrated above. All the foregoing emphasizes the unity of the nervous system and the inconsistencies involved in deciding where neurons begin and end, but nonetheless certain diseases have a clear central or peripheral focus.

With the exception of equine recurrent laryngeal neuropathy, *noninflammatory peripheral polyneuropathies are uncommon and are generally to be regarded as distal axonopathies of the spinal neurons*. Motor axon involvement means that *denervation muscle atrophy* is a frequent concurrent lesion. It should be remembered too that with advancing age, subclinical degenerative changes are to be expected in peripheral nerves and spinal roots.

Equine laryngeal hemiplegia

The clinical manifestations of this common and well-recognized disease are the consequence of *denervation atrophy of the intrinsic muscles of the left side of the larynx*. The resultant inability to adduct the arytenoid cartilage and the vocal fold leads to partial obstruction of the airway on inspiration, and inspiratory stridor on exertion, referred to as "*roaring*."

The underlying lesion is *idiopathic degeneration of the left recurrent laryngeal nerve*, suggested to result from progressive degeneration of large myelinated axons, which increases in intensity towards the distal extremities of the nerve. During active degeneration, localized axonal swellings result from paranodal and internodal accumulations of granular dense bodies and degenerate mitochondria, although numerous atrophied axonal segments have also been described. Loss of axons is indicated by the presence of Bungner's bands, which may contain fragments of axonal and myelin debris, and permanent axonal loss is reflected in considerable endoneurial fibrosis. Some axonal regenerative activity may be apparent. There is also evidence of recurrent demyelination and remyelination, considered to be secondary to axonal degeneration.

The cause of this axonopathy remains unknown. Young, tall male horses with long necks seem predisposed and there is a high incidence in Thoroughbred and draft breeds. *Mechanical factors* operating on the left recurrent laryngeal nerve have been proposed, such as stretching of the anchored nerve, or pressure exerted where it reflects around the aorta. However, subclinical involvement of the right recurrent nerve seems to be the rule. Studies of clinically normal horses have revealed bilateral neuropathy with more severe denervation of the laryngeal adductor muscles as compared to the abductors, and this pattern also holds true for horses with laryngeal hemiplegia. The factors determining progression of the subclinical disease, the mechanism for the preferential adductor involvement, and the reason for the greater severity on the left side are unexplained.

One study suggested that similar distal degenerative changes also occur in the long axons of the hindlimbs, but only a few horses were sampled. Such a finding implies a *systemic metabolic or toxic disorder*, producing a polyneuropathy with maximal expression in the left recurrent laryngeal nerve. In New Zealand, laryngeal hemiplegia in association with stringhalt has occurred in seasonal outbreak form in horses grazing the plant *Hypochaeris radicata*. Laryngeal paralysis has occasionally been reported in cases of intoxication with *lead*, or *organophosphates*, as part of widespread axonopathy.

No convincing evidence of lesions in the CNS is available at present, although they have been sought in the nucleus ambiguus from which the recurrent laryngeal axons arise. It has been claimed that axonal spheroids in the lateral cuneate nucleus are more numerous in horses with laryngeal paralysis, but the significance of this is unclear. Such lesions are common and generally nonspecific, and it is difficult to see how they could be related pathogenetically to the rather different lesions in the motor axons supplying the larynx.

Equine stringhalt

Stringhalt is the name given to a clinical condition of horses characterized by *extreme exaggerated flexion of the hindlimbs*. It has been recognized for many years to occur in *sporadic* and *epizootic* forms, the latter associated with the grazing of certain plants, notably *Hypochaeris radicata* (false dandelion, flatweed). Stringhalt may develop subsequent to trauma to the dorsum of the metatarsus. Various degenerative changes have been reported in the spinal cord and peripheral nerves in stringhalt. Selective loss of large-diameter myelinated fibers in peripheral nerves in horses with Australian stringhalt is consistent with distal axonopathy leading to neurogenic muscle atrophy.

Equine suprascapular neuropathy

Mononeuropathy of the suprascapular nerve in the horse has been designated for many years by the old clinical term "*sweeney*." The nerve is prone to injury at its site of reflection around the wing of the scapula, and in many cases *trauma* at this site is probably the initiating cause. Evidence has been advanced to suggest, however, that *entrapment of the nerve* by a tendinous band may lead to degeneration in the absence of additional trauma. In cases of sufficient severity, axonal degeneration, demyelination, and endoneurial fibrosis will be associated with denervation of the spinatus muscle and chronic lameness.

Canine laryngeal neuropathies

Cases are described of neurogenic laryngeal muscle atrophy in old dogs of several breeds but, in the **Bouvier** breed, autosomal dominant inheritance has been proposed for a unilateral or bilateral condition with onset at an early age. Clinical laryngeal paresis/paralysis is evident and is accompanied by denervation atrophy of laryngeal muscles, and Wallerian degeneration of the distal recurrent laryngeal nerves. In this breed, laryngeal paralysis is attributed to an abiotrophic process in nucleus ambiguus in the medulla. Gliosis and neuronal atrophy have been recorded in vagal nuclei in **Siberian Huskies**. In **Dalmatian** dogs, the laryngeal paralysis–polyneuropathy complex is a generalized axonopathy with dying back of laryngeal and peripheral nerves. Neurogenic atrophy of muscles, including those of the larynx, is reported in related **Leonberger** dogs with a spontaneous distal, symmetrical polyneuropathy.

Endocrine neuropathies

Clinical polyneuropathy has been associated with *diabetes mellitus in the dog and cat* and is well recognized in people. In the cat, hindlimb weakness, poor postural reactions, depressed patellar reflexes and plantigrade stance are described. Axonal conduction velocity is reduced in the sciatic and ulnar nerves. Clinical remission often follows therapeutic management of the diabetic state.

The pathogenesis of diabetic neuropathy remains uncertain, but it is generally accepted that there is *distal axonopathy* with cycles of degeneration/regeneration and accompanying demyelination/remyelination. The distal degeneration may be due to impairment of axonal transport mechanisms secondary to reduced availability of glucose for the neuron. Lesions include axonal atrophy of myelinated and unmyelinated fibers, demyelination and, in some animals, intra-axonal accumulation of glycogen.

A peripheral neuropathy has also been associated with *canine hypothyroidism*.

Feline hyperlipoproteinemia

A series of cats has been described with a *genetically based deficiency of lipoprotein lipase activity* and a resulting severe hyperchylomicronemia. Amongst other manifestations, there is a high incidence of *mononeuropathy multiplex*, with clinical palsies related to various peripheral and cranial nerves, including instances of Horner's syndrome. Neurological deficits are related to multiple focal red/brown nodules in the perineurium of nerve trunks, which are organizing hematomas associated with a xanthomatous/granulomatous component. Xanthomatous masses extend between nerve fascicles and appear to compress and distort them, inducing Wallerian degeneration to various degrees of severity. The xanthomas arise from phagocytosis of cholesterol esters by macrophages. These lesions are generally located in loci where trauma is likely and also occur commonly at the emergence of spinal nerve roots.

"Kangaroo gait" of lactating ewes

This condition was first reported from New Zealand, and subsequently from the United Kingdom. There is a low flock incidence and only ewes in lactation or up to 1 month post-weaning are affected. The clinical syndrome is consistent with *bilateral radial nerve palsy*, and there is a characteristic bounding gait during attempted rapid movement. In most cases, there is gradual clinical improvement and eventual recovery. The cause is not known. There have been limited studies of pathology. Extensive Wallerian degeneration with regeneration has been described in the radial nerve trunks of chronically affected ewes, but in some acutely affected animals no radial nerve lesions could be demonstrated. In one study, there were additionally reported spongy change in the neuropil, dorsal root ganglionopathy, and neuronal degeneration in the hippocampus and cervical spinal cord, although these findings were variable.

Myelinopathies

Myelin sheaths in the central or peripheral nervous system may be the focus of various disease processes, but simultaneous central and peripheral involvement is rare. This is not surprising when one considers the fundamental differences between the two. As previously noted, myelin breakdown and removal in Wallerian degeneration will follow as a **secondary** consequence of axonal degeneration. On the other hand, in some inflammatory diseases, macrophages acting within the orchestration of the immune system will strip myelin from axons, leaving the latter intact for a time at least. In this context, antibodies or inflammatory mediators may bind to and destabilize the structure of the myelin lamellae, causing disruption of the sheath and provoking its phagocytosis. Such **primary demyelination** occurs for example in the CNS in canine distemper, and in the peripheral nerves in "coonhound paralysis." The demyelinating aspects of these entities are discussed elsewhere.

Attention in this section is on *noninflammatory diseases in which some disorder of myelin formation, maintenance, or stability is the primary event*. It should be remembered that the myelin sheath is a specialized extended process of oligodendrocyte or Schwann cell plasma membrane, and myelinopathies are therefore part of the cytopathology of these cells. Within the complex category of myelinopathies, we will discuss *leukodystrophies*, or disorders of myelin synthesis or maintenance; *hypomyelinogenesis,* which may be at one end of the spectrum of leukodystrophy; and *spongy degeneration* or spongiform myelinopathies.

Hypomyelinogenesis

The great majority of the hypomyelinogeneses are restricted to the CNS, and they have been described in most domestic species with the notable exception of the horse. Although in many cases a genetic basis has been demonstrated or strongly implied in hypomyelinogenesis, several viruses have been implicated, and the possibility of toxic or nutritional factors should be kept in mind. A common theme is sex-linked inheritance and affected males.

Myelinogenesis begins sometime after the middle of gestation and continues in the postnatal period for various times depending on the species. It is more advanced at birth in those species in which the young are able to stand and walk soon after, for it correlates with the overall maturity of the nervous system.

The process requires a complex unfolding of events in order to be successful. In the first place, there must be differentiation of competent myelinating cells in sufficient number, and they must migrate to, recognize, and contact the target axons appropriately. Second, the axon itself must send a specific signal to the myelinating cell to initiate its investment. The diameter of the axon dictates whether or not it is myelinated and how thick the sheath will be. The threshold size is about 1 μm in the CNS and 2 μm in the peripheral nerves. Finally, the molecular components of the myelin must be produced and delivered to their correct sites in the membrane. One or several of these processes may be perturbed to give rise to diseases characterized by hypomyelinogenesis.

Myelination does not occur synchronously throughout the nervous system, but in a distinctly regional sequence. Thus lesions of this type may involve some tracts more than others, or completely spare some tracts. There may be complete absence of myelin, or an inadequate amount of myelin that may be either chemically normal or abnormal. For the latter case, the term *dysmyelination* has been coined but, as these conditions are characterized by a reduced quantity of myelin, **hypomyelination** is a suitable generic term. As would be expected, such diseases are manifested early in life, and a very common and dominant clinical feature is the onset of a severe generalized tremor syndrome. This has led to the use of names such as *congenital "tremor," "shaker," or "trembler"* to describe the clinical state. The severity of the clinical signs can vary from life threatening to mild.

The deficiency of myelin may in some instances be permanent, while in others it seems that myelination may be delayed, but eventually proceeds to the extent that clinical deficits resolve. In general, the pathologic picture is dominated by a paucity of myelin with little or no evidence of the breakdown and removal of previously formed sheaths. There may be other accompanying structural defects, notably cerebellar hypoplasia, particularly when a teratogenic virus is the cause.

When routine morphologic evaluations are being made on very young animals, reference should be made to age-matched controls. In the dog for instance, very little myelin is normally present prior to 2 weeks of postnatal age, whereas in the sheep myelination begins at about day 50 of gestation. The investigation of such conditions makes use of traditional stains for myelin and axons, plastic-embedded sections for light and electron microscopy, and immunostaining techniques for marker antigens, such as myelin basic protein. There needs to be some familiarity with the normal morphologic features of early myelination. Some of these are mentioned in the disease descriptions that follow.

Canine hypomyelinogenesis

A number of canine hypomyelinogeneses have been documented and several provisional conclusions can be made. All but one of the diseases involve the central myelin only, and it appears that they are not pathogenetically identical and can be divided into two broad groups according to severity. The most severe are those described in the Samoyed, Springer Spaniel, and Dalmatian breeds.

In the **Samoyed**, severe generalized tremors become apparent at about 3 weeks of age, with a predominance of males being affected. Inability to stand leads to severe incapacitation and a high mortality rate. A genetic basis is suspected. It has been suggested that a central pathogenetic event is *retardation of gliogenesis*, with oligodendrocytes failing to differentiate fully. Profound hypomyelination is suggested on gross inspection of the brain by a lack of contrast between gray and white matter throughout the CNS. The sparing of the peripheral nervous system is well appreciated macroscopically by comparing the myelin-deficient optic nerves to the other cranial nerves, in particular the adjacent oculomotor nerve.

By routine light microscopy, there is normal peripheral myelin but *almost total absence of central myelin, and diffuse microgliosis*. Silver stains suggest axons to be present in normal number. Electron microscopy reveals a few axons to have thin and poorly compacted myelin sheaths, the presence of numerous astroglial processes, and a large number of microglia. Oligodendrocytes are greatly reduced in number and appear immature. Axons, by contrast, are normal in number and morphology but the great majority are devoid of a myelin sheath.

In the **Springer Spaniel**, severe generalized tremor in male pups is evident at 10–12 days of age ("*shaking pups*"). The condition is inherited as an *X-linked recessive*, and severe myelin deficiency is caused by the shaker pup (*shp*) mutation of the myelin proteolipid protein (*Plp*) gene. Central hypomyelination is profound but less severe in the spinal cord than in the brain and optic nerves. In contrast to the Samoyed, microgliosis is not prominent, but in other respects the gross and histologic features are similar. The electron microscope, however, resolves some further differences. For example, some thin myelin sheaths are present that have lamellae of normal configuration. Some axons have a few internodes sheathed, many of which are shorter than would be expected for the axonal caliber, and many of which are single units terminating as "heminodes." Although some immature oligodendrocytes are evident, so too are normally mature ones. In animals 2 months old or more, there are also hallmarks of the early stages of normal myelination that persist well beyond their usual period of the first month of life. These include such features as large amounts of oligodendrocyte cytoplasm in lateral loops, and outwardly terminating lateral loops. In addition, many oligodendrocytes have lysosomal digestive vacuoles thought to relate to the degradation of abnormal myelin components.

The disease in the **Dalmatian** is reported in a male pup that developed severe tremors in the neonatal period and was destroyed at 8 weeks of age. Profound deficiency of central myelin was accompanied by reduced numbers of oligodendroglia, with a few axons having extremely thin and poorly compacted sheaths.

Disorders of lesser severity are described in the Chow Chow, Weimaraner, Bernese Mountain Dog, and in two crossbred ("Lurcher") dogs.

Affected **Chow Chow** dogs have marked impairment from 2 weeks of age, but progressive improvement leads to a virtual absence of clinical deficits by the end of the first year of life. At all stages, the animals remain ambulatory, bright, and responsive, in spite of a pronounced hypermetric gait with a distinctive "rocking horse" motion when trying to initiate movement. Tremors and head bobbing are exacerbated by excitement and disappear at rest. It has not been possible to establish a definite heritable basis for this disease, but it is suggested to be the result of a genetically determined delay in oligodendrocyte maturation.

In pups examined at about 3 months of age, no gross lesions are reported, but profound hypomyelination is evident histologically in the CNS. This is particularly so in the cerebral subcortical white matter, cerebellar folia, ventral half of the cerebral peduncles, optic tracts, and the peripheral zones of the ventral and lateral funiculi of the spinal cord. By contrast, the cerebellar peduncles and fasciculus proprius of the spinal cord are relatively well myelinated. Electron microscopy reveals mostly thin myelin sheaths in the least-affected areas, and mostly naked axons in the worst-affected areas. Oligodendrocytes are present in normal numbers and generally appear morphologically normal, although stellate cells containing intermediate filaments may be found.

In older dogs in clinical remission, the brain is well myelinated apart from some mildly deficient foci in subcortical white matter and corpus callosum. However, myelin deficiency is still marked in the lateral and ventral funiculi of the cord, which also has a few degenerate axons. Ultrastructurally, these areas contain a few well-myelinated or thinly myelinated axons separated by masses of astrocytic processes. Indications of immaturity are provided by poorly compacted sheaths and some massively oversized sheaths that fold away from the axon in redundant loops.

The **Weimaraner** syndrome is closely similar to the above but has only been studied pathologically in the early phase. The tremor syndrome, in evidence at 3 weeks of age, seems to resolve by a year. A heritable basis has been proposed but not confirmed, and delayed oligodendrocyte differentiation suggested as the underlying defect. Pups necropsied at 4–5 weeks of age have no gross abnormalities, but histologic staining reactions suggest myelin deficiency, and this is particularly obvious at the periphery of the lateral and ventral funiculi of the spinal cord. This contrasts with the relatively well-myelinated dorsal columns. Oligodendrocytes are reduced in number. Ultrastructurally, there is considerable evidence of myelin immaturity as described above. Astrocytic fibers are prominent and oligodendrocyte morphology seems normal.

The **Bernese Mountain Dog** "trembler pup" has a fine head and limb tremor that subsides with sleep and improves substantially by 9–12 weeks of age. An autosomal recessive mode of inheritance has been proposed. There are no gross lesions and hypomyelination is concentrated in the spinal cord, where axons are thinly sheathed by morphologically normal myelin. Oligodendrocytes in this case appear to be increased in numbers and morphologically normal. **Lurcher** pups were reported to have unmyelinated and thinly myelinated axons in the peripheral sections of the lateral funiculi of the spinal cord. The changes are subtle and not readily apparent unless plastic-embedded sections are employed. These animals are of interest as they are crossbred, making a genetic cause a more remote possibility.

Hypomyelination has been reported only rarely in **cats**.

The sole reported occurrence of **peripheral hypomyelination** in domestic animals involves the **Golden Retriever** breed. Two littermates, one male and one female, had ataxia, weakness, a crouched stance, and pelvic-limb muscle atrophy at about 2 months of age. Peripheral nerve samples revealed axons of all calibers to be thinly myelinated and Schwann cells to be increased in number and hypertrophied (see Fig. 3.11). There were no indications of demyelination.

Porcine hypomyelinogenesis

Syndromes of **congenital tremor** (CT, myoclonia congenita, dancing pig) are well recognized in pigs. CT has been classified on the basis of the presence (type A) or absence (type B) of myelin deficiency in the central or peripheral nervous system; CT type A has been subdivided into five subtypes, AI–AV. The various forms of CT are similar clinically; affected piglets may bounce on their digits, and have rhythmic whole-body tremors that worsen with excitement and cease with sleep.

CT type AI is caused by transplacental infection in the middle trimester with *Classical swine fever virus*, which causes significant hypomyelinogenesis in addition to other neural lesions in the fetus, most notably cerebellar hypoplasia. The cerebellar changes may be focal and are most likely to be detected in sagittal sections of the vermis and hemispheres. The myelin lesion is generally similar to that seen in lambs with Border disease.

CT type AII may be the result of *Porcine circovirus* type 2 infection, but the role, if any, of this virus remains controversial.

CT type AIII occurs in Landrace or Landrace-crossbreds, and is inherited as an X-*linked recessive* trait, afflicting male neonates, and due to a mutation in the proteolipid protein gene *Plp*. There is myelin deficiency throughout the CNS, but most obvious in the spinal cord, cerebellum, and cerebral gyri. Oligodendrocyte numbers are reduced; many small and medium-sized axons are unmyelinated or only thinly so. Large-diameter axons appear normally myelinated.

CT type AIV occurs in the British Saddleback breed; there is an *autosomal recessive* inheritance mode. Hypomyelination is present throughout the neuraxis with axons of all sizes affected. Many sheaths are poorly compacted and vacuolated. Oligodendrocytes are numerous, and many appear immature ultrastructurally, and sometimes contain cytoplasmic intermediate filaments. Still others contain autophagosomes and dense bodies. The neuropil also contains excessive astrocytic fibers and lipid-laden macrophages. These findings, together with biochemical evidence of myelin degradation, suggest that newly formed myelin is unstable and is rapidly broken down.

CT type AV occurs in piglets of sows exposed to the organophosphate *trichlorfon* between days 45 and 63 of pregnancy.

CT type B is idiopathic, and lacks structural or neurochemical defects.

Ovine and caprine hypomyelinogenesis

Border disease in lambs has become the model for the several pestivirus-induced myelin disorders of animals. *Border disease virus* can cause transplacental infection, which, if on or after day 50, has the potential to produce a range of terata. In the classical syndrome, newborn lambs are often referred to as "*hairy shakers*," due to the combination of generalized tremor and hairy birth coat. There is *diffuse hypomyelination in the CNS,* which is especially prominent in the spinal cord, particularly the more caudal regions. Some myelination is present, but has ultrastructural features of immaturity, in that lamellae remain uncompacted and axons retain the angulated profiles they normally acquire just before myelination and lose soon after. There are also compact sheaths abnormally thin for axonal diameter, and intramyelinic and periaxonal vacuoles.

While glial cell numbers may appear normal by light microscopy, there are in fact reduced numbers of mature oligodendrocytes and increased numbers of microglia. Many microglia are packed with lipid droplets, the origin of which does not appear to be degraded myelin. It is suggested that maturation of oligodendrocytes is delayed, and that although the time of onset of myelination is close to normal, its rate is greatly reduced. The blockade of glial maturation may be the result of virus-induced fetal hypothyroidism; abundant viral antigen can be found in the thyroid, and circulating thyroxin is significantly depressed, but this alternative hypothesis remains unproven.

Severe hypomyelinogenesis is a feature of neonatal goat kids with **β-mannosidosis**. Hypothyroidism has been proposed as the underlying mechanism, as a consequence of the lysosomal storage disease.

Bovine hypomyelinogenesis

Myelination in calves proceeds between gestational week 20 and postnatal week 8. A spectrum of terata and spinal hypomyelinogenesis similar to that in piglets and lambs may develop in calves infected with *Bovine viral diarrhea virus* in utero after day 100 of gestation.

Leukodystrophic and myelinolytic diseases

This section will address those diseases characterized by degeneration and loss of myelin, not as a result of, or in association with, inflammation but due to some failure of myelinating cells to sustain and maintain their sheaths in an intact and ordered condition. The implication is that sheaths are initially formed, but then deteriorate, leaving their axons intact for a time at least. The use of terminology in this area is of course somewhat arbitrary. For our purposes, **primary demyelination** is taken to imply the removal from around intact axons of structurally and chemically normal myelin, usually by macrophages and often in an inflammatory setting. The term **leukodystrophy** is applied to diseases with a heritable basis, early onset in life, lack of inflammation, symmetry of lesions, and in which some inherent qualitative defect in myelin (*dysmyelinogenesis*) leads to its dissolution and removal. **Myelinolysis** refers to the initial disruption of myelin structure by extensive decompaction of lamellae as a prelude to its breakdown and removal, and as such could be involved in many processes. There is scope for considerable overlap and liberal interpretation of definitions. The diseases discussed in this section will not include any which could easily be classified as demyelinating, in the sense indicated above, or as malacic in the sense indicated elsewhere in this chapter, in spite of the propensity for focal softening and even cavitation in some of the leukodystrophies.

Globoid cell leukodystrophy

This disease, also known as *galactocerebrosidosis*, *galactosylceramide lipidosis*, and *Krabbe disease*, has been documented in the Cairn and West Highland White Terrier, miniature Poodle, Bluetick Hound, Bassett Hound, Beagle, domestic cat, and polled Dorset sheep. It is due to a genetically determined deficiency, usually autosomal recessive, in the activity of lysosomal *galactocerebrosidase*, and as such falls within the *sphingolipidosis group of lysosomal storage diseases*. However, it has special characteristics that make it more appropriate to be discussed as a leukodystrophy, and it was so named before the lysosomal defect was recognized. Neurologic impairment begins at an early age and progresses rapidly to a fatal conclusion. The enzymic deficit blocks the catabolism of the galactocerebrosides (galactosylceramides). These compounds are major components of myelin, and the disorder thus principally affects the metabolic well-being of oligodendrocytes and Schwann cells.

Early in the disease, during active myelination, the myelinating cells store galactocerebroside within lysosomes. However, the enzyme is also involved in the breakdown of other metabolites, most notably galactosylsphingosine (psychosine), which is also normally synthesized by oligodendrocytes. This substance is highly cytotoxic to oligodendrocytes when it accumulates, and causes their extensive degeneration and death. Myelination ceases and formed myelin degenerates. During this process, macrophages accumulate to ingest the degenerate myelin but are also unable to degrade galactocerebroside. They give rise to the distinctive, swollen, PAS-positive "*globoid cells*," which form large cuffs around blood vessels in the central white matter, and are also found in the leptomeninges and in the endoneurium of peripheral nerves (Fig. 3.90). Their presence at the latter site is useful for premortem diagnosis by nerve biopsy. At end-stage, the pathology of the disease is marked by the presence of these cells, together with diffuse demyelination, axonal loss, and dense astrogliosis in the brain and spinal cord.

Dalmatian leukodystrophy

Reported only from Norway, this cavitating leukodystrophy has a probable autosomal recessive inheritance and a clinical onset at around 3–6 months of age. The signs are progressive and variable, and

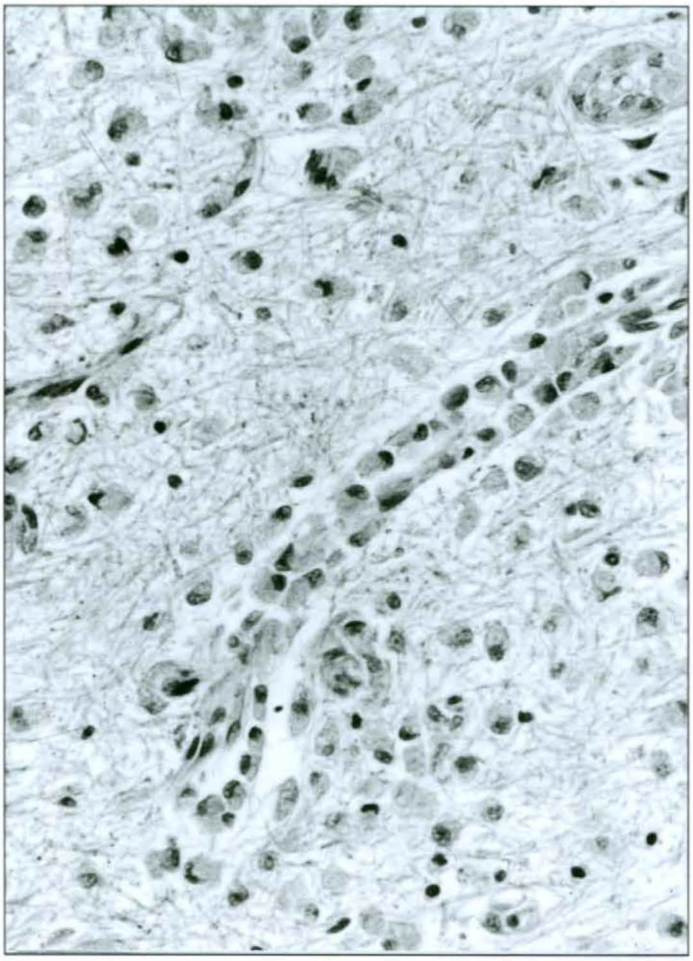

Figure 3.90 Macrophages, filled with degenerate myelin products, aggregating around vessels in **globoid cell leukodystrophy** in a Cairn Terrier.

include either gait deficit or visual impairment or both. The former begins as pelvic and then thoracic limb ataxia and dysmetria, with eventual paraparesis. Mental status remains unimpaired throughout.

The neuropathology is characterized by *bilateral, symmetrical, focal areas of intense loss of myelin* in the centrum semiovale, corpus callosum, internal capsule, caudate nucleus, optic nerves, and thoracic cord white matter adjacent to the ventral horns. Initially axons remain intact. The myelin destruction appears to begin with lamellar vesiculation followed by phagocytosis, and gitter cells are abundant. Fibrous astrogliosis becomes prominent around advanced plaques. The intensity of the process is variable, but lesions are usually visible macroscopically in the central cerebral white matter, appearing as gray depressed areas or, in advanced cases, as cavitations. In some animals, the brain is small and the lateral ventricles enlarged.

Afghan Hound hereditary myelopathy

The initial reports of this disease described acute necrotizing myelomalacia, but subsequent studies indicated a mechanism involving *florid myelinolysis and cavitation*, but essentially sparing axons. It has an apparent recessive inheritance, pre-adult onset, symmetry of lesions, and is noninflammatory, all of which allow for classification as a leukodystrophy. The fundamental pathomechanisms remain undefined. The age of clinical onset is between 3 and 12 months, and caudal ataxia and weakness progress rapidly to paraplegia in a few days. Within 2 weeks there is thoracic limb weakness and phrenic paralysis. A similar syndrome is reported in Kooiker dogs.

The lesions (Fig. 3.91A, B) are focused in the *thoracic spinal cord* where cribriform and spongiotic changes are present in all funiculi (Fig. 3.91B) and are grossly discernible as discoloration and softening or cavitation. Caudally the lesions extend into the lumbar segments, but only in the ventral funiculi; they extend cranially to the midcervical level in the dorsal and/or ventral funiculi (Fig. 3.91A). In some cases there may be lesions in the superior olivary nuclei.

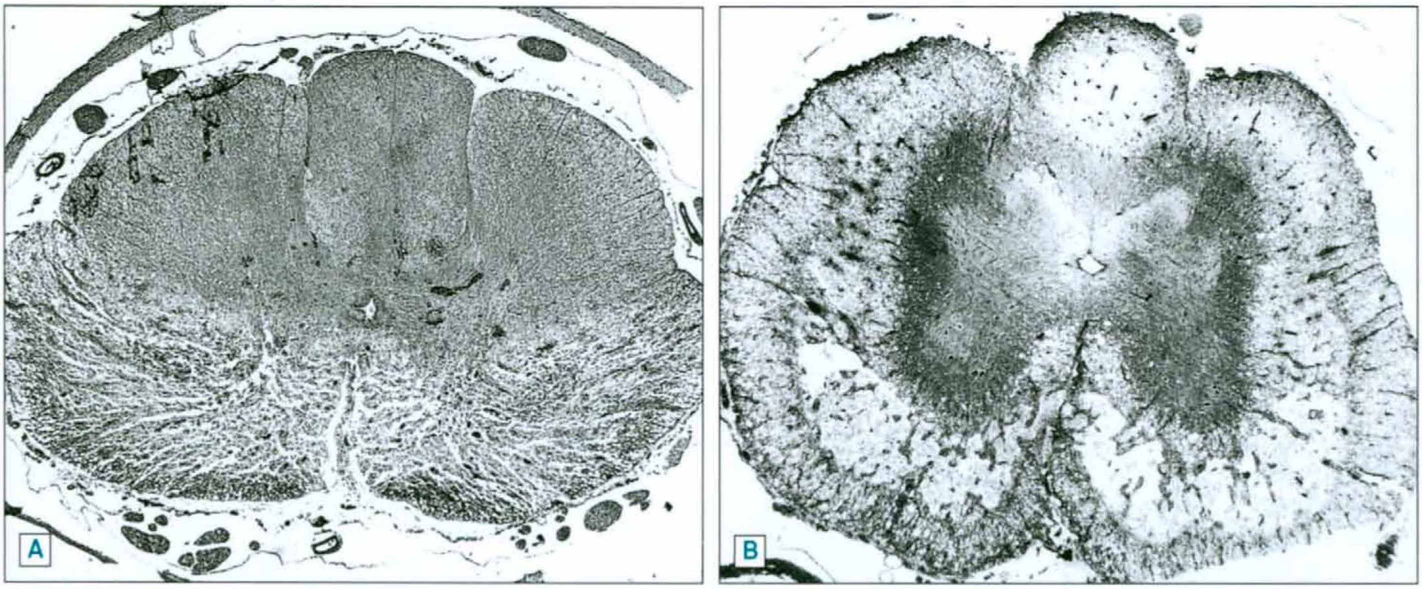

Figure 3.91 Afghan myelopathy. A. Caudal cervical spinal cord. **B.** Thoracic spinal cord.

The sparing of axons is reflected in the paucity of distal Wallerian degeneration in tracts ascending or descending through the lesions.

Light and electron microscopic examination has revealed initial vacuolation of myelin by splitting of lamellae at the intraperiod line and expansion of the extracellular space. Fragmented and degenerate myelin is phagocytosed by gitter cells, leaving surviving axons and reactive astrocytes within microcavities. The cavities are traversed by blood vessels associated with delicate glial strands. Some focal axonal swelling and disintegration are evident, but myelinolysis following vacuolation is the dominant change.

Rottweiler leukoencephalomyelopathy

Some difficulties arise in classifying this disease as a true leukodystrophy, as the onset is delayed until after 12 months of age. However, there is the probability of autosomal recessive inheritance, and the lesions involve progressive noninflammatory symmetrical myelin degeneration and removal. Clinically there are slow, but relentlessly progressive, ataxia, hypermetria, and paresis of all limbs, especially the forelimbs, and ultimately severe proprioceptive loss.

The principal locus of the disorder is the *cervical spinal cord*, which on gross inspection may have extensive dull white discoloration of the dorsal and lateral funiculi. Histologic examination reveals lesions to be present in these funiculi, and also in the deep cerebellar white matter and in other regions of the cord. Lesions are marked by significant loss of myelin (Fig. 3.92), with preservation of most axons, either naked or thinly myelinated, and fibrous astrogliosis. There is some evidence that vesicular degeneration of myelin is an early change. In the cervical cord, there may additionally be focal microcavitation deep within the affected areas, edema, numerous gitter cells, and vascular prominence. A narrow rim of intact white matter usually survives immediately deep to the glia limitans. These severe changes may on occasion extend into the thoracic cord and pyramidal tracts.

Fibrinoid leukodystrophy (Alexander disease)

This rare and unusual *myeloencephalopathy*, analogous to Alexander disease in humans, has been reported in the Scottish Terrier, Labrador Retriever, Miniature Poodle, and sheep. The clinical signs of progressive tetraparesis and ataxia are associated with spongy white matter lesions, astrocytic gliosis, and accumulation of eosinophilic refractile bodies (*Rosenthal fibers*) within the processes of astrocytes disposed around blood vessels in the CNS.

Progressive spinal myelinopathy of Murray Grey cattle

Reported in calves of the Murray Grey breed in Australia, this disease may afflict animals at birth, or not become expressed until about 12 months of age. The clinical syndrome is one of spinal ataxia, manifested as incoordination of the pelvic limbs and lateral swaying of the hindquarters at rest. A consistent sign is collapse of one hindlimb, with a tendency to fall to one side. These pelvic limb deficits are progressive and lead to increasing impairment. A similar condition is reported in Simmental calves.

The characteristic lesions are microscopic only, symmetrical, and consistently occur in the *lateral and ventral funiculi throughout the spinal cord*. There is a *distinct deficit of myelin* in the lateral funiculi beneath the dorsal root entry zone, and in ventral funiculi adjacent to the ventral median fissure. In some cases, the fasciculi gracilis and cuneatus are also involved. The process appears to involve ballooning degeneration of myelin sheaths, which may impart a distinctly spongy appearance to the lesion. The progressive loss of myelin is not accompanied by large numbers of myelinophages, and Wallerian degeneration is minimal. There is substantial astrogliosis and thickening of the glia limitans.

In the brain, similar white matter lesions may be found in the spinocerebellar tracts, tectospinal tracts, and medial longitudinal fasciculus. Some neurons undergoing central chromatolysis are present in ventral spinal gray matter, Clarke's column, the red nuclei, lateral vestibular nuclei, reticular formation, and cerebellar roof nuclei.

Progressive ataxia of Charolais cattle

This disease is pathologically unique amongst the domestic species, and appears to represent a progressive inability on the part of some oligodendrocytes to maintain the paranodal extremities of their myelin domains; it may represent oligodendroglial dysplasia. The disease is presumably genetically determined, but has been reported in three-quarter crossbred animals. Both sexes may be affected and clinical signs become evident between 8–24 months of age.

The clinical spectrum involves increasing ataxia and dysmetria, head tremor and some tendency to aggressive behavior. The mental status remains bright and alert. Affected females often urinate in a series of short spurts. The clinical signs progress slowly but steadily, and the animals can be expected to become recumbent by 3 years of age at the latest.

There are no specific gross lesions, but the microscopic findings are distinctive and unprecedented, and are located mainly in the cerebellar white matter and peduncles, the internal capsule, corpus callosum, optic tract, lateral lemniscus, median longitudinal fasciculus, pontine decussation, and ventral and lateral funiculi of the spinal cord. In these white matter tracts, there are *multifocal, granular eosinophilic plaques* about 30 μm in diameter (Fig. 3.93). The plaques are traversed by axons and stain with many, but not all, of the features of normal myelin. There is no sign of myelin degradation or

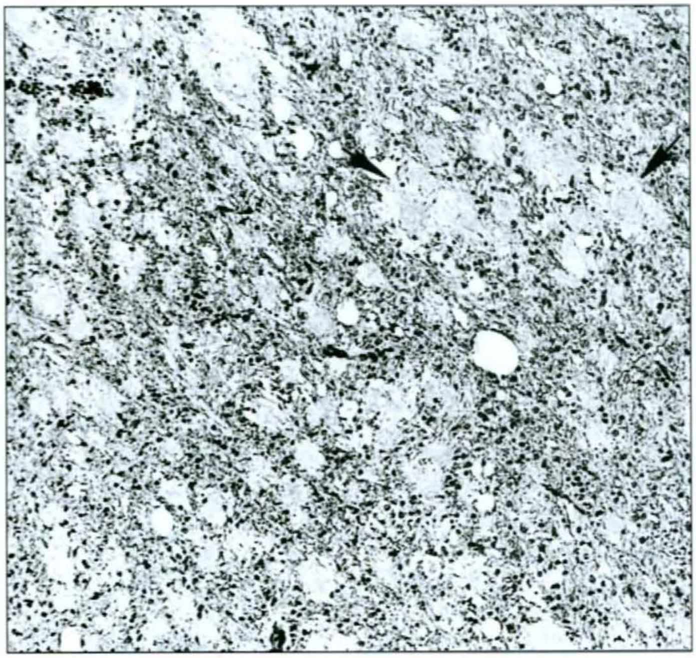

Figure 3.93 Plaques in white matter (arrows) in **progressive ataxia** of Charolais cattle.

phagocytosis. Immediately around the plaques there appears to be an increased number of astrocytes and oligodendrocytes. Some very minor axonal degeneration may be found in some plaques and in normal white matter. It has been concluded that early plaques can be distinguished from old ones. Electron microscopy reveals them to be complex. The ultrastructure suggests great disorder at the myelin paranodes, with relatively normal internodal regions. New plaques reveal axons encompassed, near abnormally long nodes of Ranvier, by hypertrophied oligodendrocyte tongues and processes within a thin myelin sheath. Old plaques contain demyelinated axons (some of which are swollen), surrounded by disorganized myelin lamellae and masses of oligodendrocyte processes. It is suggested that each plaque represents the territory of one oligodendrocyte, and reflects its failure to maintain normal paranodal myelin loops, in the course of which a massive hypertrophy of its processes occurs.

Multifocal symmetrical myelinolytic encephalopathy of Simmental, Limousin, and Aberdeen Angus calves

Reports from Australia, New Zealand, the USA, and Britain describe similar diseases in calves of these breeds, in which *spongy vacuolation of white matter progresses focally to lysis and cavitation*, but with the initial sparing of many axons and nerve cell bodies. In Limousin calves, such foci are present in the cerebellar peduncles and optic chiasm; in Simmental calves, in the internal capsule, caudate nucleus, putamen, periaqueductal white matter, lateral cuneate nucleus, and inferior olive. The distribution extends more widely in Aberdeen Angus and in some cases will include the spinal gray matter. In Limousins and Aberdeen Angus, blindness and dysmetria appear at about 1 month of age, and some animals develop seizures and opisthotonos, while others remain stable. In Simmentals, the clinical onset is between 5 and 8 months of age. There is progressive ataxia, weight loss and eventual dullness and emaciation, with death usual by 12 months of age. The pathogenesis of these diseases is uncertain; similarities exist with Leigh disease of humans, and familial syndromes in Australian Cattle Dogs and Alaskan Huskies.

Feline spinal myelinopathy

An adult-onset condition involving progressive noninflammatory myelin loss in the spinal cord has been reported in cats in California. The pathomechanism is undefined. Myelin deficiency develops in the absence of significant axonal degeneration, and is accompanied by astrogliosis. The lesions occur in all funiculi, and are most intense in the thoracic and lumbar segments.

Tibetan Mastiff hypertrophic neuropathy

This recessively inherited condition affects *peripheral nerves* and is considered to reflect a primary metabolic defect of Schwann cells, with failure to maintain myelin during axonal elongation in postnatal growth. The CNS is not involved. The clinical onset is consistently between 7 and 10 weeks of age. There is rapid progression of generalized weakness with hyporeflexia, slowed nerve conduction velocity, and ultimately tetraplegia in many cases.

In peripheral nerves and their spinal roots, there are changes consistent with *demyelination, remyelination, and endoneurial fibrosis*. Thus many axons are denuded, while some have a thin sheath; proliferating Schwann cells form onion bulbs, and endoneurial collagen is prominent. Axonal degeneration is not a feature. The most characteristic features are revealed ultrastructurally. Schwann cell cytoplasm contains *dense accumulations of 6–7-nm filaments*, occurring at sites where the myelin sheath has separated along the major dense lines, and in the adaxonal cytoplasm. There are also anomalous incisure patterns within the sheaths, with many incisural openings staggered through the entire thickness of the sheath.

Spongiform myelinopathies

There is a group of diseases in which the dominant pathological feature is *dramatic vacuolation of myelin* that often occurs without any overt indication of large-scale myelin breakdown or phagocytosis. There is still the familiar problem, however, of deciding how to categorize some diseases that have overlapping features of myelin vacuolation and myelin degeneration and it is acknowledged that some of the conditions described below could be placed elsewhere.

Myelin vacuolation is one of several different morphological changes encompassed by the term "**status spongiosus**" of nervous tissue (Fig. 3.94). Although producing a striking light microscopic picture when well developed, electron microscopy is required for its fine definition (Fig. 3.95A, B, C). Histologic changes suggestive of this lesion are a fairly common postmortem artifact.

Vacuolation of myelin may come about in several ways, the most frequent of which involves *separation of lamellae along the intraperiod*

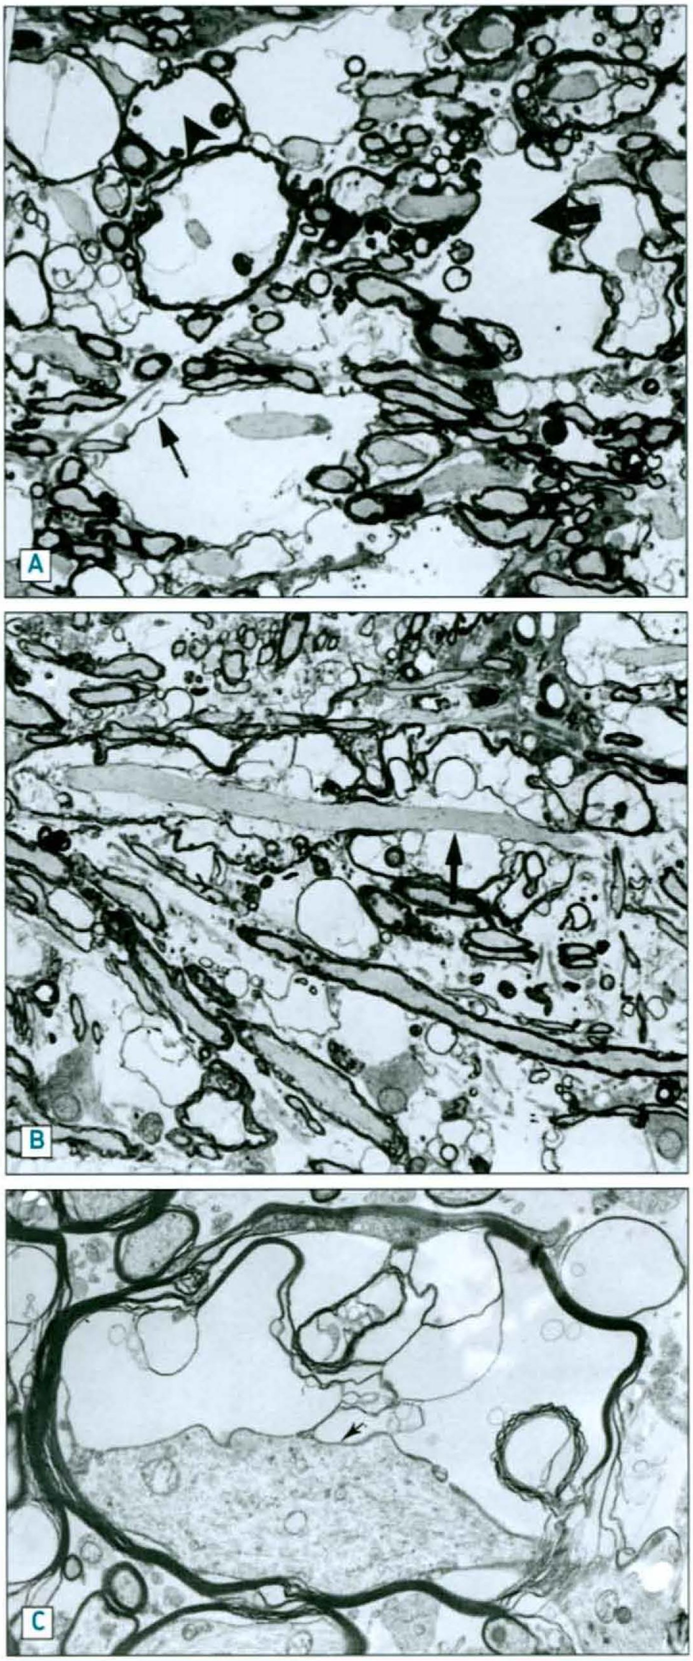

Figure 3.95 Spongiform myelinopathy in a silver fox. **A.** Note thin and dilated myelin sheath around normal axon (small arrow), empty myelin-bound vacuole (arrowhead), and expanded extracellular space (large arrow). **B.** Disrupted myelin around normal axon (arrow). **C.** Electron micrograph demonstrating periaxonal vacuolation and split myelin lamellae around normal axon (arrow). (Reprinted with permission from Hagen G. Bjerkas I. Vet Pathol 1990:27:187.)

line, thereby reopening the extracellular space originally obliterated within the spiraling processes of the myelinating cell. This mechanism can produce vacuoles within the sheath at multiple levels and multiple loci along an internode. In experimental situations, this type of vacuolation has been associated with an increase in tissue water and electrolytes, consistent with simple edema, and accounts for the brain swelling which may occur in severe cases. The vacuoles therefore contain no stainable material. A variety of associated functional disturbances has been described but, remarkably, the lesion may have little functional impact, even when quite intense and prolonged. It seems likely that the myelin lesion is one facet of a complex metabolic disturbance, whose ramifications vary according to basic causes. In humans, the classical disease of this type is *Canavan's disease*, with congenital and infantile forms due to an autosomal recessive trait, and a rare juvenile form with no demonstrable familial association.

Vacuolation may also arise by separation of lamellae at the major dense line, reopening the intracellular compartment of the myelinating cell, or by ballooning of the periaxonal space. Depending on the particular disease, the vacuolation of the myelin may or may not be accompanied by structural changes in other elements of the tissue, including the myelinating cell bodies, and, in general, these are more likely to occur if vacuolation has been prolonged. In some instances too, prolongation of the process is associated with a reduced quantity of myelin. In those cases where there is no indication of myelin degradation, its steady withdrawal by the normal catabolic pathways with concurrent suppression of synthesis is implied.

The spongiform myelinopathies of animals fall into two broad groups: those that are **idiopathic**, and those that have a defined **metabolic** or **toxic** basis.

Idiopathic spongiform myelinopathies

This group is documented in a small number of case reports involving calves, pups, and kittens, and most are suspected to have a heredofamilial basis. Several conditions involving newborn **Hereford** calves have been described over the years, with some conflicting and confusing aspects. Earlier reports proposed a condition, dubbed "hereditary neuraxial edema," to be a single entity with a variable clinical and pathological expression – the pathogenesis of several of these conditions has been unraveled, including *inherited congenital myoclonus* and *branched chain ketoacid dehydrogenase deficiency* (BCKD). The former is recognized in several countries in newborn polled Herefords that have violent myoclonic muscle spasms that prevent them from standing. There are no structural lesions, but biochemical studies have revealed an absence of glycinergic receptors on spinal inhibitory neurons. The functional disturbance is thus analogous to strychnine poisoning and is equally fatal. BCKD is discussed below.

From New Zealand, a disease of **horned Hereford** calves has been named *congenital brain edema*. Newborn calves are unable to stand after birth and have coarse tonic muscle contractions. Vacuolation of myelin is diffuse, extends into the gray matter, and is accompanied by elevated brain water content. Hydropic degeneration of astrocytes and expansion of the extracellular space are detectable ultrastructurally. There is also considered to be a deficiency of myelin.

In Britain, a very similar picture is recorded in **polled Hereford** calves. There may remain an entity in Hereford calves, severely neurologically impaired at birth, in which myelin vacuolation is extensive in the CNS, is confined to the white matter, and is not associated with hypomyelinogenesis. For the time being, such cases could be classified as hereditary neuraxial edema in the absence of any demonstrable metabolic disturbance suggestive of BCKD or other aminoacidopathy.

In **Samoyed** pups, a generalized tremor syndrome occurs in the first few weeks of life, with a severe and ultimately fatal outcome. Myelin vacuolation is diffuse throughout the CNS and there is no change in any other tissue element.

Labrador pups are described to have initial episodes of extensor rigidity, tremor, and dorsal flexion of the neck at 4–6 weeks of age, and then progressive dysmetria. Intense vacuolation of myelin is confined to the white matter in the CNS, but occurs to a mild degree in peripheral nerves as well. Throughout the CNS, the myelin lesion is accompanied by fibrous astrogliosis and prominence of capillary blood vessels. A similar condition with a familial pattern (familial spongiform leukodystrophy) is recognized in **Shetland Sheepdogs**. Clinical signs usually start at 3 weeks of age and include progressive seizures and dysphagia. Spongiform degeneration is most prominent in the cerebellum and corona radiata.

In a **Silky Terrier** pup, a myoclonic syndrome is described, with vacuolation of myelin occurring in the brain but not the spinal cord, together with the presence of Alzheimer type II astrocytes. In **Egyptian Mau** kittens, there is progressive ataxia and hypermetria; vacuolar change extends from white into gray matter throughout the CNS. Spongiform CNS myelinopathy has been reported in a group of related **African dwarf goats**.

Spongiform myelinopathy of silver foxes

A hereditary nervous disease occurs in farmed silver foxes in Norway. The presenting sign is hindlimb ataxia appearing between 2–4 months of age, and progressing over the next 4–8 weeks, after which time clinical improvement seems to occur.

No gross lesions are present, and histologically there is *symmetrical myelin vacuolation* affecting white matter of the cerebrum, cerebellum, brain stem, and spinal cord (Fig. 3.94). The extent and severity of vacuolation vary from case to case. In long-standing cases, vacuolation seems to resolve to a large extent, with residual intense astrogliosis.

Ultrastructurally, early features of the disease include intramyelinic vacuolation due to lamellar separation at the intraperiod line, large cytoplasmic vacuoles in oligodendrocyte cytoplasm, demyelination, expansion of extracellular space, and astrocytic hypertrophy (Fig. 3.95A, B, C). Late in the disease, there is evidence of remyelination in gliotic areas.

Toxic/metabolic spongiform myelinopathies

Hepatic and renal encephalopathy

Endogenous intoxications associated with hepatic and, to a lesser extent, renal failure, are recognized to induce brain lesions of this type, the former quite frequently, the latter less so.

The familiar clinicopathologic term, *hepatic encephalopathy*, designates a complex autointoxication, in which accumulations of ammonia and other metabolites reflect the inability of the liver to carry out its normal detoxifying role. This may in turn reflect reduced liver mass, portosystemic shunting, or both. *The neural lesions of hepatic encephalopathy are several and variable.*

Clinical evidence of nervous dysfunction may be accompanied by extensive and well-developed *spongy vacuolation of myelin* (Fig. 3.96), which tends to be most intense at the junction of the cerebral cortex and adjacent white matter, and often around the deep cerebellar nuclei. The lesion is to be expected in ruminants with subacute or chronic phyto- or mycotoxic liver injury, and in small animals with developmental portosystemic shunts or acquired liver disease. In sheep, copper toxicosis may lead to massive myelin vacuolation. There may also be *Alzheimer type II astroglial cells* (see Fig. 3.16) although, with the notable exception of the horse, this is generally less a feature in animals than in humans. In the horse, hepatic encephalopathy is characterized by the presence of Alzheimer type II cells, with no significant myelin vacuolation.

Although myelin vacuolation may be induced experimentally with ammonia alone, the syndrome is *not simple ammonia intoxication*, but may also involve perturbed monoamine neurotransmission, imbalance between excitatory and inhibitory amino acid neurotransmission, and accumulation of an endogenous benzodiazepine-like substance.

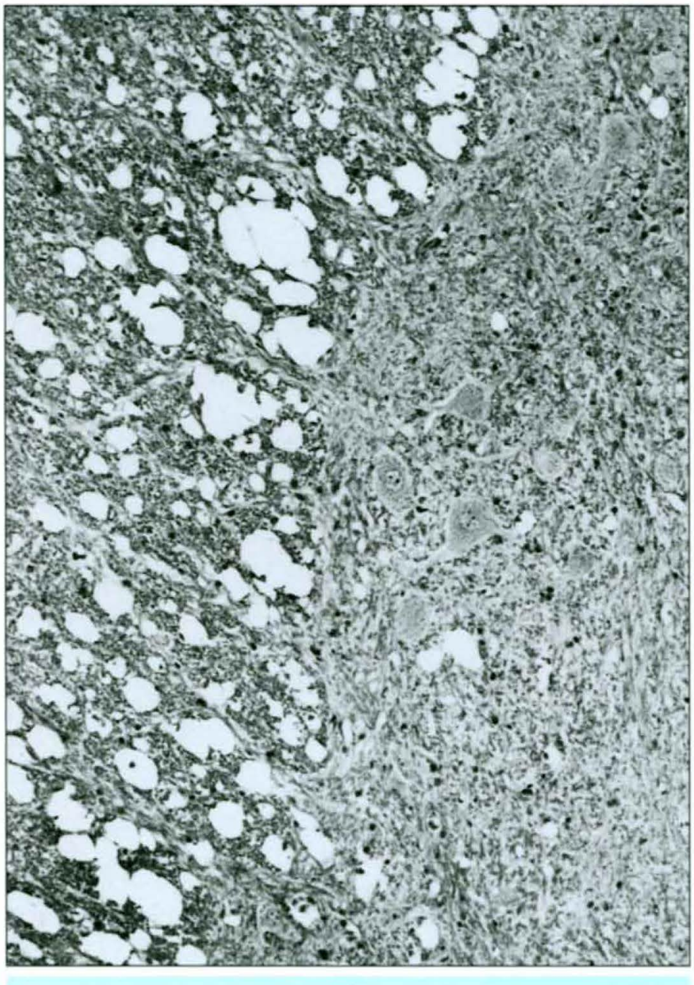

Figure 3.96 Intramyelinic edema and spongiform change surrounding spinal gray matter in **hepatic encephalopathy** in a sheep.

Branched chain α-ketoacid decarboxylase deficiency

This disease, also known as **maple syrup urine disease**, has been described in Hereford, polled Hereford, and polled Shorthorn calves, and is inherited as an *autosomal recessive* character. This mutation causes deficiency of the mitochondrial branched-chain α-ketoacid dehydrogenase (BCKD) complex. Deficiency of BCKD leads to the accumulation of the branched-chain amino acids leucine, isoleucine, and valine and their respective ketoacids, ketoisocaproic, keto-β-methylvaleric, and ketoisovaleric acids. The molecular mechanism of the intoxication remains to be precisely defined, but probably involves toxic metabolites.

The disease may be expressed in utero, and calves become dull and recumbent by 2–4 days of age, and finally develop opisthotonos. The urine in many cases has the smell of maple syrup, the characteristic which gave the disease its common name in affected children. Branched chain amino acids are found to be in abnormally high concentrations in plasma, cerebrospinal fluid, and tissues.

Pathologically, there may be gross evidence of brain swelling expressed as flattened cerebral gyri and, histologically, *severe spongy vacuolation of myelin in the CNS.* The spongiotic change is pronounced in the large myelinated tracts of the cerebral hemispheres and cerebellum (Fig. 3.97), and in myelinated tracts abutting brain-stem nuclei and spinal gray matter. Most of the spinal white matter is not affected. In cases that survive for a week or more, a modest number of axonal spheroids may be found in affected white matter. The

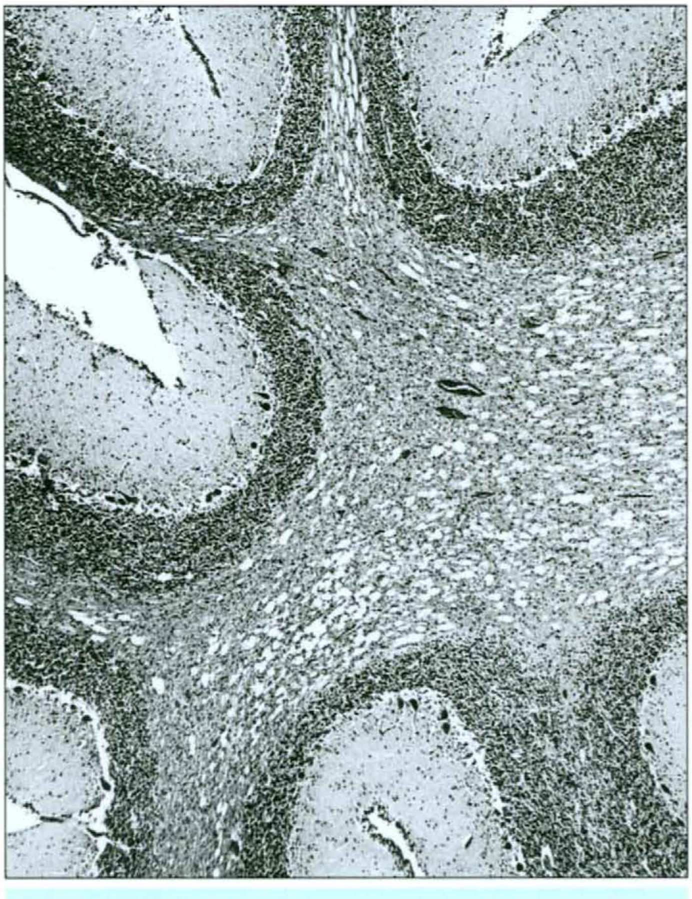

Figure 3.97 Status spongiosus in the central cerebellar white matter of a calf with **maple syrup urine disease**.

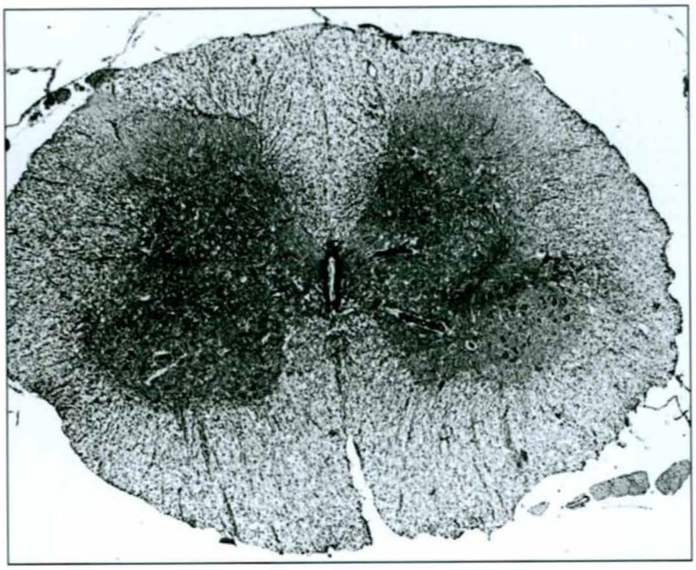

Figure 3.98 Intramyelin edema and diffuse spongiform change in the spinal cord white matter of a dog with **hexachlorophene poisoning**.

brain water content is elevated, and the electron microscope reveals splitting of myelin lamellae at the intraperiod line.

Hexachlorophene toxicosis

Hexachlorophene is a polychlorinated phenolic compound with useful topical antiseptic properties, and is sometimes given orally against *Fasciola hepatica*. Intoxication has usually been associated with repeated application to the skin of very young animals, whence absorption is rapid, and systemic accumulation may cause effects within several days. The clinical features of severe intoxication are shaking, shivering, excitement, tonic-clonic convulsions, and terminal coma.

The major lesion is *spongy vacuolation of central and peripheral myelin* (Fig. 3.98), with lamellar splitting at the intraperiod line, and no associated degenerative or reactive changes. This lesion may persist for many weeks, even after clinical signs have abated. Under experimental conditions, vacuolation of the retinal photoreceptor outer segments is also evident, but this has not been a reported feature of accidental intoxication.

Halogenated salicylanilide toxicosis

The halogenated salicylanilides are long-acting anthelmintics used in sheep and goats, and include closantel and rafoxanide. Accidental overdosing has led to intoxication expressed as ataxia, depression, and blindness, which may be permanent. The response appears to be inconsistent, and unknown predisposing factors are possibly involved.

Microscopically, there is *spongy vacuolation of myelin in both the CNS and peripheral nerves*, without any accompanying reaction or degeneration. The lesion in the brain is most intense in the brain stem. This change may persist for several weeks. Acute degenerative changes may be found in the optic nerves and in the retinal ganglion cell layer, where hemorrhage has also been described. The syndrome has some similarities to stypandrol poisoning, described below.

Stypandra toxicosis

The binaphthalene tetrol, **stypandrol**, is the toxic principle of the Australian liliaceous *Stypandra* sp. ("blindgrass") and also of the Asiatic *Hemerocallis* sp., hence the alternative name **hemerocallin**. Ingestion of toxic strains of such plants by grazing mammals or birds has an acute effect, usually manifested as moderate depression and blindness, although a high dose may produce prostration and death.

In acutely affected animals, *myelin vacuolation* caused by lamellar splitting at the intraperiod line is extensive throughout the CNS, and may persist for many weeks or even months, without apparent functional effect. Blindness, however, tends to be permanent and is associated with Wallerian degeneration of the optic nerves and tracts, and degeneration of retinal photoreceptors. Degeneration of the optic nerves may be the result of compression within the optic canals secondary to swelling caused by the myelin edema, and there may be a separate direct toxic effect on the photoreceptors.

Tylecodon toxicosis

Tylecodon wallichii is the cause of **krimpsiekte, a** neurotoxicosis of small ruminants in South Africa. The toxic principle is **cotyledoside**, a neurotoxic bufadienolide that can produce either acute or chronic poisoning, the latter probably as a cumulative effect of the toxicosis. Affected animals assume a posture with back arched, display torticollis, and then prolonged paralysis. Edema and formation of large vacuoles are particularly prominent in the optic radiations and thalamic white matter. A similar syndrome has been reported in small ruminants poisoned by *Ornithogalum toxicarium* in Namibia.

Helichrysum toxicosis

The many plant species of this genus are widely distributed, and distinct syndromes of toxicity in ruminants occur in Australia and South Africa: *Helichrysum blandoskianum* in Australia produces acute hepatic necrosis, presumptive hepatic encephalopathy, and spongiform change in the white matter of the brain stem, with a high mortality rate; *H. argyrosphaerum* in South Africa is associated with paresis, paralysis, and permanent blindness.

Intense spongy vacuolation of myelin in the brain is sufficient to cause grossly visible swelling of the optic nerves and chiasm, and gelatinous swelling of the periventricular white matter and corpus callosum. Focal hemorrhages may occur in the optic nerves and chiasm. Microscopically, the spongiform myelin lesion in the optic nerves is accompanied by Wallerian degeneration, suggesting compression within the optic canals. Myelin vacuolation is less severe in the spinal cord and peripheral nerves. The syndrome has similarities to stypandrol toxicosis.

Diplodia toxicity (diplodiosis)

Diplodiosis is a mycotoxicosis of cattle and sheep grazing on maize lands towards the end of the growing season in various countries in southern Africa and in Argentina. The causative fungus is *Diplodia maydis*. The fungus is extremely fetotoxic and causes neonatal mortality in lambs of ewes ingesting the toxin during late pregnancy. The spongy change is due to separation of myelin along the intraperiod line and may progress to lysis of myelin.

Bromethalin toxicity

Diffuse white matter spongiosus is described in dogs and cats given a single oral dose of this highly neurotoxic rodenticide.

Spongiform encephalomyelopathies

The term "**status spongiosus**" applies to a variety of lesions in which the microscopic appearance of the neural tissue is transformed by numerous vacuoles or microcavities. As discussed above, one form of this state results from the vacuolation of myelin, and is the most common. In this section will be discussed diseases in which the change results from either the *swelling of astrocytes* or the *vacuolation of neurons and neurites*. Astrocytic swelling may occur nonspecifically in, or adjacent to, any area of neural tissue acutely injured by trauma, or ischemia, or in which vascular permeability is disturbed. In the absence of such circumstances, its occurrence suggests some direct toxic or metabolic influence upon the astrocytes themselves. It can thus be a feature in hepatic encephalopathy. Spongiform vacuolation of neurons and their processes may occur to a limited degree as an incidental change in the red nucleus and nuclei of the caudal brain stem, and also as an artifact of fixation. It needs to be interpreted against this background, and is usually considered in the context of the diagnosis of scrapie and related conditions. It is distinctly different from the foamy vacuolation seen in the lysosomal storage diseases.

Prion diseases

Prions (the word "prion" is a combined form of "proteinaceous" and "infectious") are believed to be the cause of fatal neurologic diseases in humans and several other mammalian species. Prion diseases (*prionoses*) are characterized by chronic progressive fatal neurologic manifestations, with both sensory and motor deficits and spongiform encephalopathy, and result from accumulation of an abnormal isoform (PrP^{Sc}, Sc refers to scrapie) of the host prion protein (PrP). The gene (*PRNP*) encoding the prion protein is highly conserved in animals and humans. Transmissible prion diseases result from infection with an external PrP^{Sc} and accumulation of host-produced PrP^{Sc}, and are called **transmissible spongiform encephalopathies** (TSEs) to differentiate them from prion diseases originating from genetic mutation, e.g., familial Creutzfeldt–Jacob disease in humans. The prion protein is widely distributed in tissues but concentrated in nervous tissue where normal prion protein (PrP^{c}, c is for cellular) is a glycolipid-anchored glycoprotein located on the surface of neuronal plasma membranes; its exact function in mammals is unknown. PrP^{Sc} is not only membrane anchored, but it can also be demonstrated in lysosomes using immunohistochemistry and electron microscopy. PrP^{Sc} almost never triggers an immune response.
